The eagerness with which the Secretary of State for Education and Science has embarked on the development of the polytechnics is one immediate consequence. It seems easier and cheaper to obtain more higher education by building up a second tier of would-be universities than to put more money into the existing institutions. In this atmosphere, however, it is bound to be hard for the universities to lay hands on the funds they need simply to keep ticking over. At the same time there will be created a gulf between the universities proper and the other institutions of higher education. Everything would be simpler if only the universities themselves were to recognize two important sets of problems—the need of something corresponding to a cost-benefit analysis for higher education, and the need of a greater diversity within the system. Unintentionally, the Robbins Report has worked in the other direction, by making existing university practices seem the ideal, and by making it seem that all universities are entitled to the same uniform standards of staffing, accommodation and equipment. It is a step in the right direction that the Committee of Vice-Chancellors plans to support a study of the efficient use of university capital equipment (see page 1113).

The universities as a whole have also been uncommonly slow to give attention to their own curricula and methods of teaching. In half a century, the output of students has multiplied more than ten times, but what is taught and how has not changed anything like as much. Yet it is hard to be sure that the old courses are still the best in circumstances in which the universities must and should be increasingly concerned that graduates go into industry and business. It does not follow that universities should be more concerned with vocational training than they are at present, but there is at least a case to answer in the arguments of those who say that the standard academic diet should be more stimulating of those interests which are most in demand in the modern world. Some universities, not all of them new, are trying out new kinds of courses, but these are only the beginnings of the experiments which circumstances demand. In the same way, though at a more humdrum level, the recent attempt by the universities themselves, under the aegis of the University Grants Committee, to show how better use might be made of audio-visual and other aids to teaching, served principally to show how much remains to be done before the universities will be able to do efficiently whatever job it is that they and the community decide is necessary.

Research comes into this directly and not as icing on the cake. In the past the universities have too often conspired in the belief that the research which their staffs undertake is somehow distinct from the teaching process, and something which must be supported for its own sake. It follows that university research is even more vulnerable than university teaching when public funds are scarce. But in reality, the justification of university research is that it is an essential part of the process of producing competent graduates. In their

own interests, universities should now insist on this connexion, and take some trouble to show outsiders how research fertilizes teaching. For one thing, doing this would help to solve some of the pedagogical problems facing the universities. For another, it would help to bring some sense of realism to those who think the second-tier polytechnics will solve all the problems of higher education at a fraction of the cost of the universities. Most of all, however, a convincing demonstration by the universities that they value the link between teaching and research would help to fend off the attacks, which there are certain to be in the months ahead, on all those activities that are not somehow relevant to the process of keeping Britain solvent.

This is where technology comes in. Just as there is a danger that the pendulum will swing too far against research, so it may swing too far against what is sometimes called pure science. With the Ministry of Technology growing bigger and stronger with the passage of time, and the Department of Education and Science (which is responsible for financing university research) anxious to know where to get money for teachers' colleges, kindergartens and comprehensive schools, it is inevitable that things that smack of being technological should command attention and public support. The fallacy is that technology is not some kind of antithesis of science, but an application of science. To pretend, as some now seem to do, that a country can become prosperous by technology alone is a little like saying that a man can hoist himself off the ground by pulling hard enough on his bootstraps. If the universities were more sure of what they are for in the modern world, they would be able to exert an invaluable influence in this misconceived tug-of-war between science and technology.

But who are the universities? And who speaks for them? This is the root of the trouble. The University Grants Committee has become a kind of government department. The Committee of Vice-Chancellors is still feeling its way, and only time will tell whether it can be an effective initiator of the kinds of self-critical studies of the working of the university system which circumstances demand. (The chance that the Association of University Teachers, torn as always between the roles of trade union and professional organization, will be able to undertake such tasks is small but not to be dismissed outright.) Even within single universities, there is often no means of subordinating the autonomy of individual departments to the need for common policies on matters as innocuous as entrance requirements. If there were time for leisurely solutions, it would be tempting to think of radical innovations in the machinery of university self-government—elected vice-chancellors, for example. But the threats to the character and status of British universities are urgent, and, in the nature of things, the universities will have to make their own defence. It would be ironical if their freedom were to suffer in the months ahead simply because they have exercised their freedom in such a way that there is nobody to defend it.

A POUND FOR A POUND?

THE Consumers' Council is fighting a lonely but entirely just war with the Chancellor of the Exchequer over the decision that Britain should have a decimal currency in 1971. Decimalization as such is not at issue, of course—even the visionaries of the Duodecimal Society, dedicated to what they think of as a reform of the whole of arithmetic, would probably agree that Britain should enjoy the advantages of a decimal currency of some sort in the near future. The only dispute is whether the new coinage should be based, like the present, on the pound sterling as a unit, or whether the new coinage should be based on a unit equal to half the present £. The advantages of keeping the present unit are largely those of familiarity and continuity, although the Halsbury Committee held that overseas confidence in the British economy might be undermined by the disappearance of the pound sterling. The chief disadvantage is that decimalization based on the £1 unit will make it necessary to legislate for half-cent coins, each of them equal in value to 1·2 pence in the present system. By adopting £0·5 as the unit for the new coinage, a cent would have the manageable value of 1·2 pence, but it would also be possible to relate a great many existing coins to sensible decimal fractions of the new unit. In particular, the shilling and sixpenny pieces now in use would become, without change of value, the dime and the nickel of the new currency.

Obviously it is impossible ever to be sure which set of arguments deserves to win the day. It is also somewhat irrelevant of the Consumers' Council to make as much as it does, in its protest to the Chancellor, of the fear that decimalization with the pound sterling as a unit will give shopkeepers a chance to put up their prices; at the worst, that would be only a transitory effect. But it is entirely proper that the council should protest at the irrationality of the Chancellor's reasons for sticking to the £. It is not good enough for him to say that the government "chose to retain the £ only after a full consideration of the many arguments for and against", and then to fall back on the argument that the half-cent coin would be likely to disappear in the course of time. Even if the Chancellor is right in saying that he is counting on prosperity and not inflation to work this vanishing trick, half-cents are likely to survive for long enough to be a galling reminder of the durability of vulgar fractions in British society.

Those who worry about how the pence and halfpennies would vanish should take note of a C.S.I.R.O. training document on *Dollar Currency* prepared for "*C*" day when Australia went decimal and accepted the 1·2*d*. conversion: "It is imperative that on and after '*C*' day cashiers, etc., should accept halfpennies, pennies and threepences only in some combination which is a multiple of sixpence. Halfpennies, pennies and threepences should not be given out in change".

NEWS AND VIEWS

More and Longer Education

CONTROVERSIES may rage over examination systems, school systems and the importance of Oxford to the nation, but two important facts should be kept in mind—Britain is spending a larger amount and a greater percentage on education and more pupils are staying at school longer. These and other interesting facts emerge from the *Statistics of Education* published last week by the Department of Education and Science (H.M.S.O., 19*s*.).

Expenditure by public authorities rose to £1,485 million in 1964–65, nearly three times the figure ten years ago of £513 million, and representing an increase from 3·2 to 5·1 per cent of the gross national product. Of this total, £1,248 million came from the local education authorities and £147 million from the University Grants Committee. More than 60 per cent, or £785 million, of the total went to the primary and secondary education of 8,980,000 children, a 50 per cent increase on the £523 million spent in 1959–60 (during this period the enrolment increased by about 1 per cent). The expenditure and emphasis on new universities are reflected in the 126 per cent increase over the five year period, with £157 million spent last year. Teacher training represented the greatest surge forward with a growth rate of 180 per cent, but this is somewhat misleading for the increase is from £19 million to a slightly improved £53 million; the decrease in the pupil/teacher ratio from 24·8 in 1960 to 23·3 in 1965 is an improvement but does not yet really ease the pressing teacher shortage in Britain.

While there has only been a 53 per cent increase in expenditure on secondary education during the past five years, 22·9 per cent of the 13 year olds in school three years ago were still in school at 16 in 1965, compared with a percentage of 13·3 in 1956 and 17·2 in 1960. The number of sixth-formers in maintained schools rose to 169,000 from 76,000 in 1958—partly because the age-group was larger but also reflecting the tendency to stay in school longer. While the percentage remaining in school drops off rapidly as pupils grow older, 11·4 per cent were still in school at 17 and 4·1 per cent at 18, nearly double the figures for ten years ago. Even the public, non-maintained, schools show a similar, though not as spectacular, increase, with percentages of 69·5, 42·8, and 12·9 for pupils aged 16, 17 and 18, a steady increase from the figures ten years ago of 59·5, 33·1 and 11·4 per cent.

In spite of the increasing emphasis on comprehensive schools, both the number of schools and the total enrolment of grammar and modern secondary schools has increased from 1955. During the same period, it is true, the number of comprehensive schools increased from 16 to 262 with an increase of 224,000 pupils. With more than three million secondary pupils last year, a much more radical increase in comprehensive enrolment must be effected over the next ten years if all schools are ultimately to be made comprehensive.

University Efficiency

AN attempt to study the effectiveness of the use of university buildings and other capital equipment is being sponsored by the Committee of Vice-Chancellors and Principals of Universities of the United Kingdom. The intention is to recruit a person with experience in work study, operational research and the like to carry out a study, lasting two years in the first instance.

C. F. Carter, vice-chancellor of the University of Lancaster and chairman of the sub-committee in charge of the study, called the project "down-to-earth". "We have no large expectations to begin with," he said, "but British universities have been conscious for some time that such a study is needed and there is no doubt that there will be many areas to investigate." The Committee of Vice-Chancellors decided that it would be more economic to make a joint study and agreed to sponsor such a programme.

The programme will start with an efficiency study of lecture rooms in a medium-sized university—how both hours and weeks can be used most effectively. Another area of immediate study will be the use of undergraduate science laboratories. The common practice in British universities of keeping separate laboratories equipped for each year of a degree course invariably leads to much wasted time and space. The sub-committee hopes to determine whether a more intensive use of laboratory space, which would require more technical staff and the moving of equipment, would actually be more economical than the present system. On a wider scale, the study will be concerned with the actual cost per hour of expensive equipment, such as buildings—is centralization an economic and practical solution? No matter what conclusions are reached during the next two years, Mr. Carter feels that there is a permanent need for an advisory staff in this area.

While the study can hardly fail to yield improvements in the use of capital equipment at British universities, it will also have the immediate merit of enabling the universities to refute more easily the criticism that they are unconcerned about the way in which their expensive facilities are used.

Medical Tapes

DR. A. J. HARLEY of the National Lending Library for Science and Technology and director of MEDLARS, the medical information retrieval service, is treating the three year trial period of the service as an experiment. "The most important thing is to determine just how useful the service is—something that has never been studied before for any retrieval system," he said.

MEDLARS—or Medical Literature Analysis and Retrieval System—is an American import from the National Library of Medicine; started in Britain in the spring of 1965, it consists of both a computerized index to medical literature, the *Index Medicus*, and a search service based on the *Index*.

The study in Britain is operated jointly by the Computing Laboratory of the University of Newcastle-upon-Tyne and the National Lending Library for Science and Technology. Copies of the search tapes are flown over from Washington every month and are available at about the same time as the monthly *Index* reaches the libraries; this is the third service to use these tapes—similar services are being studied at the University of Colorado and the University of California. The Computing Laboratory has been given a £27,000 grant for 3 years until the spring of 1968 by the Office for Scientific and Technical Informa-

tion of the Department of Education and Science; they are primarily interested in the computer problems involved and for the past year have been programming the University's English Electric *KDF*9 to carry out searches on the CCF tapes from the National Library of Medicine's Honeywell computer. The National Lending Library is more concerned with training in computer searches and the collecting and editing of requests.

In response to a researcher's request, a list of citations on a specific topic is compiled using the *Index Medicus*. Once a week, searches are processed on the computer; the aim is to provide a comprehensive subject search rather than a rapid answer service. Because the commercial computer time rate for a single search is in the order of £15, MEDLARS can only be economic where a detailed, extensive search involving either a large number of pertinent references or a large number of terms is involved. Since the service came into use 3 months ago, about 220 searches have been carried out and the weekly number has been growing as word has spread. The Library ran a series of four-day courses on the system for librarians and researchers last spring and is starting a new series of two-day courses this autumn. It is hoped that by properly explaining the system it will be possible to eliminate requests that could easily be done by a research worker using the *Index* for half an hour.

"While it is still too early for any analytical results," Dr. Harley said, "it seems that most references could have been found in the *Index* but would almost always have meant more work—say, 2,000 references instead of the 200 searched by the computer." Besides comparing each computer search with a search using traditional methods, Dr. Harley hopes to get feed-back from all research workers using the service; they are requested to grade, on the basis of its usefulness, each reference which they receive. The thirty responses received so far have varied widely; however, some at least have discovered pertinent references that they would either have missed or have spent hours finding. Whether such cases occur sufficiently frequently to justify the cost of the service remains to be seen—Dr. Harley is waiting until next spring to reach any conclusion.

Over the Rainbow

MORE and more young British doctors are avoiding the economic plight of their colleagues by emigration. It is now estimated that about 650 doctors, or the equivalent of more than one-third of the output of British medical schools, emigrated from Great Britain and Ireland in 1965. In a British Medical Association Lecture delivered in Birmingham last spring and published this week in the *British Medical Journal* (ii, 576; 1966), Dr. John Seale of the Middlesex and St. Thomas's Hospitals said that while there was a decline in the rate of medical emigration in 1961 and 1962, from 1963 to 1965 the rate has been higher than ever before.

Based on figures from the medical councils and immigration departments of the Commonwealth countries and the United States, Dr. Seale estimated that emigration from the British Isles has increased from 470 in 1960 to 553 in 1965. "These are estimates," he said, "of the number of doctors leaving each year who will not return to the British Isles for many years—if at all." He added that an earlier study by Professor Brian Abel-Smith and Miss Kathleen Gales (*British Medical Journal*, ii, 53; 1964) showed that Commonwealth and United States estimates should be increased by 17 per cent to give a more accurate estimate of emigration to all countries, thus bringing the 1965 total to 650.

Reflecting this trend over the past few years has been the stagnation of the medical practice in Britain; in the early fifties the number of general practitioners was increasing at the rate of 300–400 each year but in 1965 there were 750 fewer than in 1960. Again, although the number of consultants in England and Wales increased by 1,034 between 1962 and 1965, Dr. Seale noted that this was nearly offset by a fall of 933 in the number of senior hospital medical officers in the same period. Junior hospital staff has been increasing steadily but this is almost entirely due to the large influx of foreign doctors (*Nature*, **211**, 448; 1966).

Halothane Safety

HALOTHANE is a very popular general anaesthetic; it is not inflammable, does not irritate the respiratory tract, and produces little nausea and vomiting and few metabolic side effects. It is therefore not surprising that 5 years after it was introduced in the United States it had become the chosen agent in more than 40 per cent of operations requiring general anaesthesia.

A number of unexplained deaths resulting from liver injury after halothane anaesthesia led to concern about its effects on the liver, and the National Academy of Sciences—National Research Council initiated in 1963 a large-scale investigation of anaesthetics and liver damage. The report of the committee responsible for the survey, under the chairmanship of Dr. J. P. Bunker, has now been published (*J. Amer. Med. Assoc.*; September 5, 1966).

Thirty-four medical centres took part in the survey and contributed histories of 859,515 instances in which general anaesthesia of all types was used. The committee found eighty-two cases of death due to massive hepatic necrosis in the sample. On examination only nine of these were found to be due to "unknown" causes. Seven of the nine dead had been given halothane. The course of the disease and the appearance of the liver in these cases were similar to those in viral hepatitis or to the appearance in chloroform poisoning. This incidence is very small and the committee states that if the drug does cause liver necrosis, it occurs rarely. It failed to establish any causal relation between halothane and hepatic necrosis, and in fact, the survey shows that halothane is, if anything, slightly safer than other common anaesthetics. The report comments that halothane has probably been examined as exhaustively as any drug in the history of medicine, but it is still impossible to give definite answers to a number of outstanding questions about halothane. The committee therefore recommends that this type of survey be applied to drugs as they come into use, through the setting up of a permanent panel of hospitals and institutes. It also calls for statistical surveys of deaths associated with anaesthesia and for a watch to be kept on cases of hepatic necrosis.

An interesting and somewhat disturbing by-product of the survey is the finding of very considerable variations in the death rate after operation between

different institutions in the survey. The highest crude death rate was twenty-three times the lowest, and this cannot be entirely due to differences in the type of patient at the hospitals involved. A study of the reasons for these variations might also produce some interesting results.

Organisms for Biology Teaching

THE boom in biology teaching in British schools, together with the spate of interest in new curricula, has created curious and somewhat unexpected shortages of organisms for students to dissect or otherwise to use. Professor J. W. S. Pringle pointed out, at the British Association last week, that the demands of biology teaching had themselves helped to reduce the size of populations of frogs in Britain, though it is likely that the increasing urbanization of the countryside and the difficulty of persuading men to collect wild frogs have contributed to the difficulties of the biological suppliers in meeting—at an economic price—the demands of the schools. Fortunately there is the promise of a substitute for the frog; the South African clawed toad, *Xenopus laevis*, is as suitable for dissection by juveniles, and has the added virtue that it can be bred in the laboratory, and that the tadpoles—which are almost transparent—are valuable object lessons in development. Precisely these advantages account for the popularity in recent years of the locust as an experimental creature. In the long run, however, the supply of traditional organisms for teaching is likely to be less of a problem than the need to supply unfamiliar organisms. Biological suppliers, and some schools, have been hard pressed in recent years to know how best to handle distinctive mutants of a species of yeast used in a genetical study as part of the biology programme of the Nuffield Science Teaching Project, because one of the mutants tends to revert to the other. Problems like these are bound to become more common in the years ahead.

Fortunately, some of the difficulties seem to have been fully anticipated. The Institute of Biology, independently and through the joint committee on biological education with the Royal Society, is but one of the organizations to have directed attention to the problem. The ideal outcome is a greater awareness among the biological suppliers of the needs of the schools, and a willingness to spend money on development, not merely of methods of culture but techniques of distribution as well. Another prerequisite of good management is that schools and school authorities should be prepared to pay the real cost of the more sophisticated service which the new curricula will require, and not just what it used to cost to supply each half a dozen pupils with a dogfish and a dozen frogs. In the long run, of course, it would be splendid if the universities—which have similar problems on a more exalted level—could keep an avuncular eye on what is happening in the schools.

European Biochemistry

THE Federation of European Biochemical Societies (FEBS) was founded three years ago with the aim of promoting closer contact and co-operation among European biochemists. The federation is governed by a Council of delegates from the constituent societies which meets under the chairmanship of the delegate of the society responsible for organizing the next general meeting. So far, these meetings have been held annually, in London (1964), Vienna (1965) and Warsaw (1966).

The third annual meeting was organized for the federation by the Polish Biochemical Society and was held during April 4–7, 1966, in Warsaw, under the chairmanship of Professor K. Zakrzewski. The meeting was the largest held in Warsaw in recent years and was attended by 1,571 biochemists, of whom 545 came from Poland, 993 from other European countries and thirty-three from overseas, including three from China. The scientific programme consisted of an inaugural lecture by Professor P. Grabar (Paris) entitled "L'immunochimie des protéines", thirty-eight invited lectures given in a symposium on "Properties and Functions of Genetic Elements" and two colloquia, one on "The Biochemistry of Blood Platelets", the other on "The Biochemistry of Mitochondria", and 525 free papers. The contributions to the symposium and colloquia are to be published jointly in November of this year by Academic Press, Ltd., London, and Polish Scientific Publishers, Warsaw. It would be invidious to select for special mention any particular contributions from the large number of papers presented at this meeting. There is little doubt, however, that, provided the present high standard is maintained in future years, the annual FEBS meeting will quickly achieve recognition as one of the most important scientific events for European biochemists.

The federation is also active in directions other than the annual meetings. A programme of summer schools began in 1965 with Professor H. R. V. Arnstein as chairman of the organizing sub-committee. The 1966 programme involved schools at University College, London, on "Mechanisms of Enzyme Action", organized by Dr. B. R. Rabin, and at the University of Uppsala on "Separation and Fractionation of Macromolecules and Particles", organized by Professor A. Tiselius and Professor J. Porath. Financial support for these schools has been given by the European Molecular Biology Organization, the Council of Europe, the Royal Society of London and the British Council. In 1967 there will be two schools, one on "Steroid Biochemistry", organized by Dr. J. K. Grant, which will be held in Glasgow during April 3–14, and the other on "Nucleic Acids", which will be held in Marseilles during September 11–16 under the direction of Dr. M. Grunberg-Manago and Professor R. Monier. Details of the schools are advertised in the bi-annual *FEBS Bulletin*, distributed to all societies in the federation.

The council of the federation, meeting in Warsaw, has taken a major decision to enter the publishing field with a general journal of biochemistry. This is planned to appear early in 1967 and has Sir Hans Krebs as honorary chairman, with Professor C. Liébecq as editor-in-chief, and the support of senior European biochemists as editors and advisers. The appearance of the journal will not however, add to the number of such publications, since an agreement has been reached whereby the new publication will succeed an existing biochemical journal.

Information about the activities of the federation can be obtained from the Secretary-General, Professor W. J. Whelan, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

Changeover at Mt. Stromlo

PROFESSOR OLIN J. EGGEN has now taken up his new post as Director of the Mt. Stromlo Observatory, Canberra. He succeeds Professor Bart Bok, who has been at Mt. Stromlo since 1957 and who has now become Professor of Astronomy at the University of Arizona. Eggen, who is an American by origin, started his distinguished career at Lick Observatory. From there he moved to Canberra when Sir (then Dr.) Richard Woolley was director and when the 74-in. telescope was being built. Since the mid-fifties Eggen has moved between the Royal Greenwich Observatory (which is not at Greenwich but at Herstmonceux) and Pasadena in California. For a time he was assistant to the Astronomer Royal at Greenwich.

Eggen is an astrophysicist who has spent much of his time making photometric observations and has studied motions of stars within our galaxy. He has said in Australia that he intends to concentrate the work of the observatory at Mt. Stromlo on observation and should in this be helped by the care with which Mt. Stromlo is being equipped.

At this stage there is no knowing whether the arrival at Mt. Stromlo of an American astronomer with close connexions in Britain will affect the issue of the Southern Hemisphere telescope. It remains to be decided whether the British Government or the American Government will eventually help with the building of a large telescope (with an aperture of 150 in. or more) in Australia. Astronomers of all nationalities regret the delay there has been.

Railway Relics

NOT only Mr. John Betjeman will be up in arms about the proposal by British Rail to dismantle St. Pancras and Kings Cross Stations, and it is bound to be some time before it is known whether one modern terminal will be built to replace both monuments to the Railway Age. To replace St. Pancras and Kings Cross by a modern terminal would in any case be an unenviable task for the architect chosen, for he could scarcely contrive to improve on their combined merits; the flamboyant self-confidence of St. Pancras, offset by the sterner stuff of Kings Cross. The two buildings epitomize the ambivalence of the Victorian age.

By guile or by accident, however, the railways board has made sure that there will be few technologists among those who will, no doubt, be lying in the road to impede the demolition men. It has been promised that when the soaring Gothic of the station eventually disappears, the arch of the station itself will be exposed for all to see. The arch was built by William Henry Barlow in the continental style in 1868. The vault is vast, and makes great use of cast iron arches and glass, although less elegantly than John Dobson's Newcastle Central Station of many years earlier. The icing sugar hotel façade was added in 1874 to the designs of that high-priest of Victorian Gothic, Sir George Gilbert Scott.

It seems churlish to carp at British Rail when their intention is to cut costs and increase efficiency; a more modern approach to the running of the railways is a right and proper end to pursue, but if St. Pancras and Kings Cross follow the steam engine into oblivion, for many the romantic flavour of the railways will be gone for ever.

University News: The City University

MR. K. J. SHONE has been appointed professor and head of the Department of Management Studies. Mr. M. L. Meyer has been appointed to the second chair of mechanical engineering. Dr. R. N. Cox has been appointed to the second chair of aeronautics. Dr. R. C. Pitkethly has been appointed associate professor in the Department of Chemistry for three years.

Appointments

DR. F. S. DAINTON, vice-chancellor of the University of Nottingham, has been appointed chairman of the advisory committee for Scientific and Technical Information, in succession to Sir James Cook, at present vice-chancellor of the University of Exeter and vice-chancellor designate of the University of East Africa.

DR. C. A. SPOHN has been appointed director of operations of the National Environmental Satellite Center, Environmental Science Services Administration, in succession to A. W. Johnson who has been appointed deputy director of the Department of Commerce facility.

DR. K. O. WRIGHT has been appointed director of the Dominion Astrophysical Observatory at Victoria, B.C., in succession to the late Dr. R. M. Petrie.

Announcements

THE London office of the National Institutes of Health, U.S. Public Health Service, is being closed as from September 12. The functions of this office will be transferred to the N.I.H. European office in Paris. The research grant, fellowship, and other programmes of N.I.H. in the United Kingdom and other areas will continue as before with administrative responsibility consolidated in Paris. Further information can be obtained from Dr. P. G. Condliffe, Chief European Office, National Institutes of Health, 2 Avenue Gabriel, Paris 8e.

THE British Society of Rheology has instituted a gold medal which will be awarded every three years for "the best contribution to the solution of an industrial problem by the application of fundamental rheological knowledge". The first medal will be awarded next year, and the closing date for entries is May 1, 1967. Further information can be obtained from Mr. A. T. J. Hayward, National Engineering Laboratory, East Kilbride, Glasgow.

CORRESPONDENCE

Preprints Galore

SIR,—Your editorial of August 27 will be read with great interest and many biologists will agree with your statement that "The defects of IEG and PIE are no excuse for hiding from the problems which stimulated their emergence". These problems are to be discussed at a conference on "Communication in the Biological Sciences", to be held during December 14–15, 1966, under the auspices of the Biology Group of Aslib and the Institute of Biology. The organizers hope that this conference will agree on the steps needed to deal with the problems of information exchange facing biologists working in laboratory and library. If so, it should guide the various bodies concerned with the publication, dissemination and retrieval of information.

Yours faithfully,

D. J. B. COPP,
General Secretary.

Institute of Biology,
41 Queen's Gate, London, S.W.7.

AGRICULTURE AND CLIMATE

At the end of July an interdisciplinary meeting was held at the University of Reading, to discuss the relationships between climate and agriculture. This symposium was attended by scientists from thirty-six countries, sponsored by Unesco, and organized by Professor A. H. Bunting, professor of agricultural botany at Reading, and Mr. L. P. Smith, president of the Commission for Agricultural Meteorology of the World Meteorological Organization. The conclusions reached at the symposium are summarized here by Mr. L. P. Smith.

THE demand for the correct assessment of climatic factors when planning for the increased food production which is so urgently needed by an expanding world population has become a matter of prime importance to both United Nations technical agencies and individual countries. Time is short, and if the fundamental scientific knowledge is as yet so incomplete that it cannot point immediately to the best solution to any specific problem, at the very least it should be adequate to avoid errors. The cost of the mis-use of land is no longer measured in terms of money, but in human lives.

It is not surprising that agroclimatology is in an imperfect form. Both biology and meteorology are partly understood sciences of infinite complexity, so that the links between the two and the responses of a plant or animal to its physical environment are bound for the most to be tenuous and empirical, or, at the very best, semi-empirical. Empiricism, when applied by skilled brains, is an excellent tool with which to attack practical problems, but its limitations have always to be borne in mind, otherwise considerable dangers can arise.

The validity of any agroclimatological analysis depends basically on the depth of agrometeorological knowledge or, in other words, the way in which any of the manifold agronomic factors, growth, pest and disease incidence, depend on the weather. Considerable progress has been made in the past decade in several such problems. This progress has been made both on the micro-meteorological scale and in field research on a meso- or macro-scale. As a result, much more confident deductions can now be made regarding agricultural potential by the use of weather parameters than was hitherto possible.

The increasing accuracy, on a practical scale, of such bio-climatic "models" leads to a greater demand for data. In the past, meteorological data, albeit of a fairly simple character, have been more plentiful than biological data, but in the future it is clear that progress must be made on both sides. For the meteorologist more radiation data are required, and problems of the routine measurements of evaporation or transpiration, and of soil moisture, with the attendant instrumental errors, exposure errors and sampling errors are nowhere near a satisfactory solution. In many areas, almost any biological or agricultural data would be an advance, provided that a degree of accuracy and representativeness is attained. An increase in plot-trial data is attractive but recent micro-meteorological research casts doubts on the ways in which such trials can be interpreted meteorologically. The climate in which a plant grows depends greatly on the nature of the ground surface up-wind; this takes a considerable distance to become established so that small plots are not all experiencing the same weather on a micro-scale, especially when they have been randomized in conformity with the statistician's designs. The science with the all-embracing brief, ecology, would appear to be suitable to play a leading part in satisfying this need for more biological data, and yet it has provided its exponents with so many fascinating by-ways that so far it seems to have made little progress along the main road to agronomic assessment. Perhaps the old practice of phenology needs reviving in terms of functional agriculture.

In the absence of measurement of the precise meteorological parameters required, principally radiation and evaporation or transpiration, many ways are now available to estimate such parameters, using data of a simpler nature which are more readily measured. Radiation estimates can be made from sunshine or cloud amount observations which, on average, are not much greater in error than direct measurements often made by inaccurate or poorly maintained instruments, but with transpiration the position is more difficult. So far as potential transpiration is concerned, as was pointed out at the Reading symposium, there now exist almost as many meteorological formulae as there are religions. This comparison is not so ridiculous as it sounds, for each of these formulae have their extreme supporters who will hear no ill of their chosen idol and lose no opportunity to heap scientific scorn on the beliefs of others. Fortunately this frustrating combination of blind trust and illogical intolerance is not common to all scientists and with careful choice of formula appropriate to the conditions under review it is possible to obtain a close approximation to the potential transpiration factor.

Further troubles arise, however, in the search for an estimate of actual transpiration, which is extremely difficult to measure accurately in natural conditions. Here again "models" proliferate, and the results of small-scale experiments, both in the laboratory or in the field, tend to confuse rather than clarify. Progress can nevertheless be expected in this difficult aspect of the subject, for there are quite a few distinguished micro-meteorologists and research plant physiologists carrying out research in

several countries. Many of them are associated with the production processes section of the International Biological Programme, and the World Meteorological Organization has recently formed a small working group to facilitate collaboration and the cross-fertilization of ideas and techniques.

The correct interpretation of climate in terms of agriculture has always been one of the most important aspects of the problems of land-use in semi-arid zones. Three United Nations technical agencies, Unesco, F.A.O. and W.M.O., have recently joined together in sponsoring agroclimatological surveys of the semi-arid zones in the Levant and in the area of Africa lying to the south of the Sahara; one is an area of limited winter rainfall, the other of limited summer rainfall. These surveys, each carried out by a team of a meteorologist and an agronomist, were discussed in detail at Reading. The methods used received general commendation from the meeting, especially when the limitations of time and data were considered. Sound precedents for such work were lacking, so that the degree of scientific caution which had been exercised met with general praise, in that no conclusion was reached or method of argument used without corroboration from the limited evidence available. In particular the treatment of the water balance was approved; this involved the choice of Penman's formulae for calculation of potential transpiration, in that it was the least likely to introduce major errors in this fundamental factor.

It was not suggested that these studies were either perfect or complete and more elaborate analysis was needed on a more local scale. Such analysis should include the theoretical investigation of the water balance for alternative systems of cropping. This follow-up action demanded increased co-operation with the existing research stations in the area and increased scientific activity by the countries concerned both in meteorology and agronomy, and, most important of all, greater collaboration between the two sciences.

This collaboration is possibly the key to more rapid progress in agrometeorology but it is easier to specify than to bring about. It is always evident at international meetings, and Reading was no exception, that there is rarely a balance between the two sciences in terms of the numbers of participants. In only a small minority of countries does there exist a tradition of active co-operative research or investigation. The reason for this might with justice be traced back to the schools, where biology is often taken as an alternative to physics or mathematics, and few universities include adequate teaching of meteorology in any course of agriculture or horticulture.

The result is that, at postgraduate stage, there is no convenient common scientific language in which ideas can be exchanged. Beyond the universities, it is not common to find active collaboration between research stations dealing with agricultural problems and professional meteorologists, although Britain is one of the conspicuous exceptions, and the closing of this gap is not made easier by the preoccupation of weather bureaux with the treadmill of forecasting and the fulfilling of insistent aviation demands for meteorological aid.

It is clear that a radical review of scientific education is needed in almost every country, but in the meantime there is an increasing tendency for agricultural meteorologists to work within the biological field. This process is resulting in more knowledge being gained in the basic problems and more reliable practices being advocated in agricultural advisory and extension services. A similar evolution is taking place in hydrology where the scientist is coming more and more to the aid of the water engineer. Indeed, as one of the clues to greater food production lies in the increased use of skilled irrigation, it may be said that agrometeorology and hydrometeorology must advance together, quite apart from the fact that both applied sciences are fundamentally concerned with the water use of crops and ground cover.

The Reading symposium did not overlook the secondary effects of weather and the part which climate plays in determining the incidence and epidemiology of pests and diseases, both during growth and in storage. It also touched on the modifications of climate which are within the scope of the farmer. Irrigation and shelter have been used since time immemorial to ameliorate a difficult climate; in modern times, science is replacing art as the prime mover in such management.

Climate assessment is also a factor in determining correctly the economics involved in seasonal decision-making in practical agriculture. The risks, climatically speaking, of early or late planting of a crop can be interpreted in terms of economic risk, if the crop–weather relationships are known. The difficulty arises, however, in determining the variability of the climate. It is often thought, without much justification, that while weather is variable, climate is constant, but nothing could be more misleading.

The climate of most areas of the world is constantly changing, and it is a matter of mortification that such changes, or climate trends, are rarely identified in meteorology until they have almost ceased to be effective in terms of agriculture—or, on the other hand, agriculture may have adjusted itself, by force of circumstances such as three successive crop failures, before any scientific guidance can be given.

This points to the need for a relatively new line in meteorological research, backed by modern data and machine analysis, with the aim of attempting seasonal forecasting or even forecasts of climatic change. There is no immediate hope of such aids to agronomical planning becoming available in the near future, but, as more is learnt of world circulation patterns and the forces behind them, then the more distant future may see a new scale of weather forecasting.

In the past, agroclimatology has been a creature of a world more academic than practical, more of the lecture-room than the field, and bedevilled by the enthusiasm of the scientifically ill-equipped. Climatic classifications have been proposed, with criteria which owe more to the ingenuity of the originator than to any basic scientific truth, and have been applied on a world scale with a degree of labour and devotion that seems largely misapplied. The gibe of "little lines on little maps, drawn by little men with little brains" is not entirely devoid of truth. Simplicity has often demanded, and been granted, the sacrifice of validity. While the world, and world science, owes much to its enthusiasts and non-conformists, the energetic worker with the second-class mind can cause infinitely more trouble than the gifted idler.

The originator of any new technique, designed to make a practical approach to resolving an area of ignorance, is often aware of its limitations. His disciples, fired by the new possibilities, sometimes disregard these zones of uncertainty and apply new ideas rigidly and with limited imagination. The result can be chaos, and we would be well advised to remember the dictum of Descartes: "Nothing must be accepted as true till it has been clearly recognized as being so; which means that every care must be taken to avoid haste and prejudice."

Haste, however, is inevitable in modern times, and the future of agroclimatology must take this into account. It must help to provide reliable answers to land-use problems, and provide them quickly. It must not only improve its own methods and techniques, but also must ask agrometeorologists to provide more reliable aids. Thus on one hand it must look to the furtherance of fundamental research on the micro-scale; on the other it must make the most use of macro-data.

The data themselves must be improved and greater care must be devoted to establishing the radii of error involved. Short-term field experiments must be better

planned and the results interpreted with care. In far too many cases experimenters tend to find the answers which they have (perhaps subconsciously) determined before starting the practical proving test.

Interchange of ideas between biologists, physicists and mathematicians is essential; one of the major advantages of meetings such as the symposium at Reading lies not in the papers presented or the proceedings published, but the endless open-ended discussions which take part between scientific workers in different fields and from different parts of the world.

The international technical agencies provide, at little enough cost, an immense service to humanity in organizing these meetings. An idea, picked up at Reading, may lead to a completed research in Tokyo which could resolve a practical problem in Argentina. The future, however, demands more than these interim aids to the improved application of science. Education, balanced in nature and pruned of its archaic inaccuracies, has to be advanced at all levels. Not only must the scientist of tomorrow be better armed at all points for his attack on ignorance, but the farmer of tomorrow must be better equipped mentally to make use of new discoveries.

It is probably true to say that a very small proportion of existing knowledge is properly applied to practical agriculture on a world scale. Errors are still being made in land-use that were made by the Romans two thousand years ago. Peasant wisdom tends to be forgotten, sound technical advice does not advance rapidly enough to replace it.

Unsound pseudo-scientific advice, unhappily, sometimes appears to advance very rapidly indeed and for this reason agroclimatology must maintain a very high degree of scientific honesty Even though the demands are urgent, facile approaches cannot be tolerated unless every precaution has been taken to eliminate error.

The participants at Reading clearly realized these principles and, while it would be untrue to say that every view advanced could be accepted without reservation, there was a conspicuous absence of anything resembling charlatanry. If we are to survive on this planet, every advantage must be taken of the natural resources to produce more food, and we can no longer rely on the old-time, hit and miss, trial and error methods of a more leisurely age. It is vital that agrometeorology and agroclimatology should advance.

PREDICTION OF ECLIPSES

By D. H. SADLER

Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, Sussex

THE main object of this article is to review the most recent contribution to the prediction of solar eclipses, namely the *Canon of Solar Eclipses*[1] prepared by J. Meeus and colleagues. Before doing so it may be of interest to give some background and historical information about the prediction of eclipses in general.

There are two essentially different methods of predicting eclipses: they can be predicted, without any real knowledge of the theories of the motions of the Sun and Moon, on the basis of mean periods derived from investigations of past records; and they can be calculated in advance, to almost any desired degree of precision, from theories of these motions. Gravitational theories of the motions of the Sun and Moon only became available in the past three hundred years, but they rapidly improved to the point at which predictions adequate for all practical purposes could be made without any difficulty of principle; the computational difficulties continued to be considerable, and it is only in recent years that electronic computers have made it possible to calculate the detailed circumstances of all eclipses over several thousand years.

At the instants of new moon (for solar eclipses) and full moon (for lunar eclipses) the Sun, Moon and Earth are aligned in longitude (that is, lie in the same plane perpendicular to the ecliptic). Eclipses occur at such times when the Moon is sufficiently close to the ecliptic in latitude. The Moon moves in an orbit which is inclined at an angle of about 5°·15 to the ecliptic, and its latitude is sufficiently small for eclipses to occur only when it is close to the "nodes" in which its orbit intersects the ecliptic. "Ecliptic limits" (of latitude, angular distance from the nodes, or more crudely of time from the nodal passage) can be specified within which eclipses must or may occur and outside which they cannot occur. These limits vary slightly, mainly on account of the varying distances of the Sun and Moon, but may be treated as fixed for general descriptive purposes. The important periodicities are therefore the synodic month or lunation (the interval between successive new or full moons) and the nodical or draconic month (the interval between successive passages of the Moon through the nodes of its orbit).

The main features of the occurrences of eclipses (as contrasted with the detail of times, magnitudes and visibility) can be derived from a consideration of the mean values of these periods which are, at the present time

lunation, $L = 29{\cdot}53059$ days
draconic month, $D = 27{\cdot}21222$ days

Starting from a full or new moon, at which the Moon is a fraction f_0 of a revolution past a node, it will be $f_n = f_0 + 2{\cdot}170392\,n$ revolutions past a node after n lunations; eclipses must, may, or cannot occur according to whether the decimal part of f_n is within prescribed limits. Thus, provided an initial value of f_0 is known, the main features of the occurrences of eclipses can be obtained in a simple calculable sequence. With the introduction of refinements arising from the consideration of the relationship to the year and to the anomalistic month (the interval between successive passages of the Moon through perigee—or its closest point to the Earth), more detailed circumstances of eclipses (such as the nature of the eclipse, durations and areas of visibility) can be given. Such methods have been extensively developed and analysed by G. van den Bergh[2].

Most interest, however, attaches to the rational approximations to the decimal fraction 0·170392; a converging sequence (1/5, 1/6, 7/41, 8/47, 15/88, 23/135, 38/223, ...) is immediately obtainable from its representation as a continued fraction. The ratio 38/223, corresponding to the Saros of 223 lunations and 242 draconic months, is in error by only 0·000012, the equivalent of 0·04 days after a cycle of 6585·32 days. Eclipses therefore are repeated, but not at the same times of day, at intervals of 223 lunations. Such regular cycles, and even the more complicated patterns that occur over shorter intervals, can

be derived from an investigation of the occurrences of eclipses, without any knowledge of the underlying reasons; the Saros was so derived by the Chaldeans in about 750 B.C., and was probably used for the famous prediction of the eclipse of Thales which is now considered to be that of May 28, 585 B.C.

In view of the recent suggestions that Stonehenge was designed and built to serve as an aid for the prediction of eclipses, it is of interest to examine how these "simple" cycles are related to the more complicated procedures put forward. Neglecting complicated refinements, there are six periodicities involved, only three of which are independent; these are the periods of revolution of the Earth about the Sun, of the Moon about the Earth, and of the nodes of the Moon's orbit

the year,	Y	=	365·24220 days
the month,	M	=	27·32158 days
the nodal period,	N	=	6798·37 days

The derived periods are the lunation (L = 29·53059 days), the draconic month (D = 27·21222 days) and the eclipse year (the interval between successive passages of the Sun through the nodes of the Moon's orbit, E = 346·62005 days). Using lower-case letters for the daily motions in revolutions (for example, $l = L^{-1}$, $d = D^{-1}$), the following exact relationships hold

$$l = m - y;\ d = m + n;\ e\ (= d - l) = y + n$$

For the prediction of eclipses, the only periods required are the lunation L and the draconic month D, or its equivalent; the nodal period N enters only in so far as it is necessary to derive D from other periods.

G. S. Hawkins[3–5] has suggested that Stonehenge was designed to mark the extreme and mean azimuths of the rising and setting of the Sun and Moon, corresponding to declinations of 0°, ±5°·2, ±18°·3, ±23°·5, ±28°·6; although the evidence is far from conclusive, this suggestion is astronomically acceptable. He goes on to suggest that the purpose of this construction was to facilitate the prediction of eclipses, using a combination of observations over the markers with a simple computer based on the fact that the number (fifty-six) of Aubrey holes is about three times the nodal period N measured in terms of years Y (N = 18·613Y). F. Hoyle[6] elaborates the method of use, and his method may be briefly summarized as being equivalent to predicting the relative longitudes of the Sun, Moon and node by using

$$13\ y = 2/56;\ m = 2/56;\ n = 3/56\ y$$

The approximations to the periods are poor but they are only required to serve for short intervals, being monitored by deductions made from the observation of the azimuths of the rising and setting of the Sun and Moon.

Both Hawkins and Hoyle base their suggestions on the number fifty-six and its relationship to the ratio N/Y, presumably on the grounds that the independent periods Y, M and N can be derived from the observations of azimuths; this is certainly true for Y and M, but some care is required to derive N (though not to the accuracy required) because of the possible error of 0·5 days in the time, and a corresponding error in the declination, of moonrise or moonset. As has been seen, however, the only relationship required for the prediction of eclipses is that between L (which is the first and most obvious periodicity to be observed) and D. A simple calculation, or even better a reference to a list of eclipses, since there is no change of principle over the centuries, provides the sequence of full moons at which lunar eclipses, visible from Stonehenge, occurred. Because of the gaps this sequence is very complicated, but the Saros is readily seen; moreover, there are several recognizable shorter cycles, particularly that of forty-seven lunations, though it is questionable whether such would have been recognized by a primitive people. The sequence of risings or settings of the full moon in directions opposite to those of sunset or sunrise would fill the gaps, and, apart from solar eclipses, there are other, less likely, methods of determining the relationship between L and D from observation. Such information might suggest a single shift, at each lunation, of four stones in a circle of forty-seven; this would predict eclipses more simply and more accurately than Hoyle's method.

One further point should be clarified: with three independent periods, there are two independent ratios; one of these, L/D, gives rise to the Saros in which

	223 lunations	(L)	= 6585·32 days
	242 draconic months	(D)	= 6585·36 days
giving	19 eclipse years	(E)	= 6585·78 days

The other ratio, L/M, provides the Metonic cycle in which

	235 lunations	(L)	= 6939·69 days
	254 months	(M)	= 6939·68 days
giving	19 years	(Y)	= 6939·60 days
but	255 draconic months	(D)	= 6939·12 days

In his book[5] Hawkins refers to the Saros, which is fundamental to the prediction of eclipses, as "the saros of 18 years" and misleadingly refers to the Metonic cycle as an eclipse cycle because it operates as such over a very limited range; it is in fact only as accurate as the 13/12 ratio for L/D. Hoyle[6] uses the relationship 223 L = 19 E with the comment "This is probably the method of the Saros used in the Near East". F. Wheeler[7] refers to the 18·6 year "Metonic cycle" and later to "the nodes circle the Earth once every 19·61 years—the Metonic cycle...". The nodal period N of 6798·37 days (= 18·61 years) is not an eclipse cycle and has no simple ratios with L, M or D.

Clearly no definite answer can be given as to whether Stonehenge was designed and used as suggested; it appears that it could have been so used, but it is strange that so complicated a procedure should have been used when apparently simpler methods were available.

It is nevertheless interesting to note that Hoyle propounds the concept of an all-powerful god at the nodes of the Moon's orbit. Can he not know of the well-known[8] origin of the term "draconic" for the nodical month, or of the dragon that supposedly eats up the Sun or Moon at the nodal points ? god eats dragon ?

A great deal has been written[9] about ancient eclipses and about the methods used by the ancient civilizations for their prediction; the Assyrians, the Babylonians, the Chaldeans, the Chinese, the Egyptians, the Greeks and the Romans were all able, in lesser or greater degree, to make predictions. And, generally, the basis was the Saros or an equivalent cycle. Hipparchus, who flourished in the second century B.C., is credited with the discovery of the nodal period, as a result of investigating the Chaldean and Babylonian records of observed eclipses; he was aware of all the principal periods involved. With this knowledge, the prediction of eclipses, though still an esoteric art commanding the greatest respect, became less specialized.

With the introduction of the theory of gravitation, the prediction of eclipses became the supreme test of the theories and tables of the motions of the Sun and Moon; and it was for long regarded as an intellectual triumph to be able to predict eclipses to within a few minutes, and later seconds, of time. Apart from the technical and computational difficulties, which were considerable, precise times and local circumstances were limited by the

irregular rotation of the Earth; predictions over long periods were also uncertain on account of the unknown secular accelerations of the Sun and Moon, as a result of the dissipation and interchange of energy within the Sun–Earth–Moon system. The astronomer's interest in ancient eclipses lies primarily in their use in determining such accelerations[10], and much research into old records has been done for this purpose.

In 1829 F. W. Bessel introduced the geometrical method of prediction that bears his name; this was used, in conjunction with the best available ephemerides of the Sun and Moon, for the predictions in the national ephemerides and is still so used. Meanwhile in 1887 Th. Ritter von Oppolzer produced his famous *Canon der Finsternisse* which gives the main circumstances of all (there are a few missing!) solar eclipses from 1208 B.C. to A.D. 2161 and all lunar eclipses from 1207 B.C. to A.D. 2163. The basis of this enormous work consists of approximate tables of the motions of the Sun and Moon, in which only the prinicpal terms are included; the Saros was used to indicate the occurrence of the eclipses. Elements of the eclipses are given in an abbreviated form of Hansen's method, and, together with the charts showing the central lines of total and annular solar eclipses, provide the data for its two main objects: to give the occurrence and the circumstances of future eclipses to a precision that is adequate for planning purposes; and to provide material for the identification and investigation of ancient eclipses. For long a carefully guarded scarce treasure, it has recently been made generally available by the publication of a most excellent reprint[11].

The general introduction, in 1960, of the concept of ephemeris time and of the ephemeris meridian made it possible to predict all the circumstances of eclipses without reference to the irregularities in the Earth's rotation; a final reduction to the Greenwich meridian can be made simply at the time of the eclipse. Computer programs for these calculations, requiring only the date and the positions of the Sun and Moon (from other programs) as input data, were written at the U.S. Naval Observatory (which is responsible for the calculation of eclipses under international agreements) and elsewhere.

This then is the background to the publication of the *Canon of Solar Eclipses*[1]. In this magnificent volume, J. Meeus, who is an amateur astronomer, has given essentially all required data for the 1449 solar eclipses occurring between July 1898 and March 2510 with almost the maximum possible precision. Whereas Oppolzer used very crude tables of the motions of the Sun and Moon, Meeus has used modifications (based on his own tables[11]) of the best currently available theories which considerably reduce the amount of calculation while preserving the high precision, of order 1″; also, because positions are required only near the times of new moon, many terms dependent on the elongation of the Moon from the Sun can be greatly simplified. With ephemerides of such high precison, Meeus and his colleagues have calculated, using rigorous formulae, and tabulated: (*a*) the general circumstances (date, time, nature, magnitude) in Part I; (*b*) the Besselian elements for each hour covering the whole eclipse in Part II; (*c*) all data for the central line of the track on the Earth's surface for central eclipses in Part III. These central lines are also plotted, as precisely as the scale will allow, on a series of charts similar in concept and design to those so usefully given by Oppolzer in his *Canon*. All the calculations have been carried out in terms of ephemeris time.

The data given are not sufficiently precise for the rigorous comparison of observation with theory, but they are almost as good as many observations are likely to be and they are certainly far more than adequate for all other purposes. With one important reservation, the volume thus pre-empts the data on solar eclipses to be tabulated in future editions of *The Astronomical Ephemeris* (*A.E.*). Ruefully it has to be admitted that a discrepancy between the figures in the *A.E.* and the *Canon* for the annular eclipse of July 31, 1962, arises from an error in the *A.E.* (in the initial data, not in the eclipse calculation itself). At the request of the International Astronomical Union, detailed predictions of eclipses have been made available ten years in advance for the planning of eclipse expeditions, and so many years in advance of the systematic calculations for the ephemerides; the data available in Meeus's *Canon* now meet this requirement and will make unnecessary the always dangerous practice of special non-systematic computations.

A thorough investigation into the precision of Meeus's ephemerides and eclipse data is unnecessary, as anything less than the rigorous evaluation of the internationally adopted theories is unsuitable as a reference standard; apart from the approximations there are also a few minor differences in the constants used, but the main limitation, over the period of 600 years, is certainly the uncertainty in our knowledge of the secular accelerations. The eclipse data in the *A.E.* must, therefore, be continued and must be used in the reduction of observations.

All the calculations were performed on the *IBM* 1620 computer at the Computing Laboratory of the University of Ghent; this is a relatively small machine and nine separate programs were necessary, involving much handling of cards. The theory, the planning, the programming, the execution and the production reflect the greatest credit on Meeus and his co-workers; as one example, the data in Part I are given for the time of closest approach rather than for the traditional time of conjunction. Meeus also contributes a long introduction containing (in addition to all necessary explanations of the data and methods of their calculation and use) much information of interest regarding eclipse cycles, comparison with Oppolzer's *Canon*, etc.; his enthusiasm and his energy appear inexhaustible.

His enthusiasm has, however, overstepped his understanding of the relationship between ephemeris time (E.T.) and universal time (U.T.). The difference, ΔT = E.T. − U.T., which depends on the departure from regularity of the Earth's rotation, cannot be predicted; in fact estimates based on all available observations in 1957 were 2^s in error by 1960. Anxious to have values of ΔT in order to use Greenwich longitudes for the plots of the central lines, Meeus has used an incomplete formula for extrapolating values of ΔT; his values after 1963 are likely to be increasingly in error. Since his values of ΔT can result in a shift of up to 6½° in longitude at A.D. 2500, the tracks of the central lines as plotted on the charts may be significantly in error as given—though easily corrected when better values of ΔT become available. The tabulated ephemeris longitudes should be used, with E.T. as the time argument; the tabulated values of ΔT and the deduced Greenwich longitudes should be ignored after 1963.

Meeus's *Canon* is none the less a monumental work, extremely well produced; and it certainly is the "last word" in eclipse prediction. Could it possibly be that Stonehenge was the first ?

BOOK REVIEWS

MOONS, MOTORS AND MARS

Advances in Space Science and Technology

Vol. 8. Edited by Frederick I. Ordway, III. Pp. xiv+396. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 128*s*.

PREVIOUS volumes in this series have provided lengthy reviews of known techniques or speculative essays on future developments in space science and technology. The present volume conforms to this pattern and consists of four lengthy contributions.

The first is a persuasive discourse in support of the volcanic theory of lunar craters, by G. J. H. McCall. The author is a geologist, and his arguments depend largely on detailed examination of the pattern of the craters and the way in which the smaller bite into the walls of the larger. He also produces some interesting new comparisons with terrestrial features. His thesis, though it may have little impact on exponents of the meteoric school, really leaves them with a great deal to explain away.

In Chapter 2, which runs to 130 pages, the structure of lunar craters has yielded place to the structure of solid-fuel rockets. The case of a solid-propellant rocket not only houses the propellant but also has to withstand the hot pressurized gases and carry the flight loadings due to aerodynamic forces; furthermore, its weight has a critical effect on the rocket's performance. The authors of this chapter, C. W. Bert and W. S. Hyler, provide a very thorough survey of the subject, covering stresses, structural design, reliability, forms of fracture, fatigue behaviour, environmental effects and other factors, with 317 references to support their case.

The third and longest chapter, by G. W. Morganthaler and G. E. Fosdick, is devoted to the future exploration of the solar system. Readers may quail when faced with a speculative preview extending to 150 pages. And they may also be irritated by the assumption that up to 1 per cent of the gross national product of the U.S.A. will continue to be devoted to space exploration: anyone with the smallest concern for the happiness of mankind could find better uses for $\$10^{10}$ per year, or even $\$10^{9}$; and if that concern is absent, is our way of life worth exporting to the planets? However, any such irritation tends to evaporate as one reads on. Although the authors are prone to quote 'authorities' of doubtful worth, their survey is impressive in its scope and detail. They provide extensive tables giving a complete space programme, with costs yearly for the next three decades, including manned spacecraft for landing on Mars and fly-by of Venus. It is quite a relief to find that the total cost is only about $\$10^{11}$.

In the final contribution, which is almost an appendix to the preceding one, E. A. Steinhoff considers the logistics of exploring Mars and its satellite Phobos. In particular he discusses how far to exploit extra-terrestrial resources instead of bringing all the required materials from earth.

In its printing, production and price, as well as its contents, the book maintains the high standard of its predecessors.

D. G. KING-HELE

GYRO-MECHANICS

Mechanics of Gyroscopic Systems

By A. Yu. Ishlinskii. Translated from the Russian by A. Barouch. Edited by T. Pelz. Pp. iv+313. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 135*s*.

THIS is primarily a textbook on the geometry and kinematics of gyroscopic systems. As such it is excellent, particularly in the development of mathematical expressions where the author applies approximations immediately they become relevant and not, as is commonly done, at a stage long after the less mathematical reader has lost the trend of the argument.

The scope of the book, however, is largely limited to geometry and kinematics. This, to some extent, is explained by the date of the first edition (1952) and that this is the first revision. Before 1950, the use of unmonitored gyros was almost entirely restricted to marine applications with a few exceptions such as the twin gyro guidance system of the German *V*2 rocket. The philosophy of this latter guidance system is clearly explained in the book. The continuous rolling and pitching of a ship makes gimballing errors of major importance, and a proper understanding of these, as is given in this book, is essential to the marine gyro designer. Since 1950 a vast amount of research and development has been done on gyros in connexion with inertia navigation. In this field, where the premium on space limits gyro angular momentum to values two or three orders of magnitude less than those of marine gyros, investigations have of necessity been directed towards ways and means of minimizing random precession of the gyro, arising from such sources as instability of the position of the centre of gravity, frictional torques in the gimbal suspensions and anisoelasticity of the rotor bearings. These topics are touched on in one chapter of the book and the few examples given are well chosen, but the treatment is too limited in view of the vast strides which have been made in the past two decades in the development of new suspension systems and in the development of single axis rate and rate integrating gyros.

I consider this book excellent in its analysis of the geometry and kinematics of gyro mechanics but I hope that in a future edition the appendix on inertial navigation will be brought into the body of the book so that the mechanical design difficulties of small angular momentum gyros and the methods adopted to overcome them could be analysed and thereby add to what is already an excellent textbook.

A. I. STEVENSON

EMIL ARTIN, MATHEMATICIAN

The Collected Papers of Emil Artin

Edited by Serge Lang and John T. Tate. Pp. xvi+560. (Reading, Mass., and London: Addison-Wesley Publishing Company, Inc., 1965.) 102*s*.

EMIL ARTIN was born in Vienna in 1896. His father was an art dealer and his mother an opera singer. Artin himself

was a keen musician, playing the flute and several keyboard instruments.

His interest in mathematics, he tells us, was not awakened until he was 16 years of age. But after that his rise to fame was very rapid. Although his studies were interrupted by military service in the First World War, he was appointed to the Faculty at the University of Hamburg in 1923 and elected to a chair in 1926. Escaping from the tyranny of Nazi Germany, Artin emigrated to the United States in 1937. His stay in America, and especially the twelve years he spent at Princeton, had a profound effect on the development of mathematics. Many mathematicians of many nations were thus given the opportunity of benefiting from Artin's brilliance both as a research worker and as a teacher. Artin returned to Hamburg in 1958 and remained there until his death in 1962.

Artin will rank as one of the great mathematicians of this century. His work is admired for its depth and for its elegance, and it is distinguished by an aesthetic approach to mathematics which is communicated in lucid and eminently readable expositions, however technical their contents, and whether composed in German or in English. It was his basic conviction that "we all believe that mathematics is an art" and that "the author tries to convey the structural beauty of mathematics to his readers".

This volume is edited by Serge Lang and John T. Tate, who have prefaced the work with a short biography and an interesting discussion of some of Artin's conjectures, several of which had not been previously published. They have also added a list of text-books and lecture notes which are not included in this volume. All Artin's papers are reproduced in this collection. They are arranged according to topics, the chronological order being preserved in each section, beginning with the doctoral thesis on quadratic fields. This is followed by the section on class field theory, which includes Artin's celebrated discoveries on L-series and the general reciprocity law. The other headings are algebraic number theory, real fields, algebra and number theory, topology, and miscellaneous, 44 titles in all. Finally, there is a set of five general papers dealing with various aspects of mathematics, historical, educational and critical, which are addressed to a wide audience. Every mathematician, whatever his field of interest, will treasure this volume, which enshrines the work of a genius whose inspiring influence will extend far beyond his own generation.

W. LEDERMANN

WHITEHEAD DEFENDED

Experience and Conceptual Activity

A Philosophical Essay based upon the Writings of A. N. Whitehead. By J. M. Burgers. Pp. vii+277. (Cambridge, Mass.: The M.I.T. Press, 1965.) $7.50; 57*s*.

THE purpose of this essay is to indicate a system of thought in which notions concerning values can find a place along with ideas of causal relationships which are applied in the physical sciences. It stems from Prof. Burgers's admiration of A. N. Whitehead, and from his belief that the views of the great philosopher deserve re-interpretation and extension because of their complexity and because Whitehead was not always the clearest of communicators. The basis of Whitehead's doctrine is that in every act occurring in the universe, experience derived from that which has gone before is integrated with conceptions concerning possibilities. To this, Burgers grafts on the theme that throughout the universe there is an underlying purpose and design and that this can be discerned in the inanimate and animate worlds; in the latter, this is reflected in conceptual activities even in the lowest animal orders. Although Burgers recognizes the difficulty of ascribing values to any but human activity, he is "convinced that values, intentions and anticipation are not features of human life alone. I therefore believe that biological research can not come to terms with life unless it recognizes the effectiveness of such features in the activities of living organisms".

Such is the thread which winds through a book of vast scholarship supported by copious annotation. Its main defects are that argument fails to convince if premises are not acceptable—and Burgers's are founded on assumptions which are not capable of substantiation in much human experience—and that the attempt to elucidate Whitehead might have been more successful with less turgid prose, greater use of orthodox grammatical construction, and the avoidance of words whose coinage seems to have come from an overheated furnace. Inadvertently, however, the book may achieve its aim of drawing renewed attention to Whitehead's philosophy; it should lead many students to re-read his works in the original.

T. H. HAWKINS

DIFFRACTION AND COHERENCE

Diffraction : Coherence in Optics

By M. Françon. Translated from the French by Barbara Jeffery. Translation edited by J. H. Sanders. (The Commonwealth and International Library of Science, Technology, Engineering and Liberal Studies.) Pp. ix+139. (London and New York: Pergamon Press, Ltd., 1966.) 20*s*. net.

THIS is a book for students, based on the courses given by the author in the University of Paris. It contains a fairly detailed discussion of a great number of special cases of diffraction, together with an elementary discussion of coherence. Prof. Françon is known as a masterful lecturer, and it is therefore somewhat surprising that his course-book makes rather dry reading and has the character of a manual rather than a text-book. I suspect that to save space he has left out many of the illuminating remarks with which he illustrates his lectures, leaving only a skeleton of formulae. It is also somewhat surprising that in a book on diffraction phenomena which are all within the scope of Kirchhoff's integral, that general formula cannot be found and even Kirchhoff's name is not mentioned. But, lest one might accuse the author of nationalism, Fresnel zones are not mentioned either.

This makes the treatment rather too mathematical. I suspect that the beginner will have difficulties because of the reluctance of the author to introduce Dirac functions on pages 32–34, for example. Surely, it would help the beginner simply to state that the Fourier transform of an infinite sine wave is a Dirac function. It would also help him if he were to have been told, on page 51, that the Fourier transform of a periodically repeated signal goes over into a Fourier series, especially after such pains have been taken to work it out for one, two, . . . repetitions. It was probably the preoccupation of the author with physiological optics which made him introduce the resolving power of an optical instrument, which after all is an objective phenomenon, as something relating to the perception by an eye with a pupil of 0·6 mm diameter and a contrast threshold of 0·02. This too, I am afraid, can scarcely fail to confuse the beginner.

All this had to be said in the hope that in the next edition the author will make this a much better book, but even as it stands, it is a valuable introduction for second and third year physics students into this very important field. The many excellent illustrations make up for much that appears to be lacking in the text.

D. GABOR

SOVIET QUANTUM RESEARCH

Methods of Quantum Chemistry

By M. G. Veselov. Translated by Scripta Technica, Inc. Translation edited by S. Chomet. Pp. xi+181. (New York: Academic Press Inc.; London: Academic Press Inc. (London), Ltd., 1965.) $7.50.

Advances in Quantum Chemistry

Vol. 2. Edited by Per-Olov Lowdin. Pp. xi+372. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 116s.

THE current research literature of the U.S.S.R. can nowadays be read translated into English; text-books, research monographs, and even review periodicals cannot. A few books recognized as outstanding, like the works of Landau and Lifschitz, have appeared in translation several years after first publication, but most are never seen at all in western countries, and one has little idea of the character and scale of such secondary publishing in comparison with the bewildering abundance in the West. Do scientists in the U.S.S.R., in reflective assessments of recent work, assign importance to the same discoveries? Do they have distinctive scientific attitudes to the role of theory in chemistry? Is there a distinguishable official "line" informing their more critical writings and tending to influence the course of original work? On present-day evidence, supported by the evidence of *Methods of Quantum Chemistry*, there are no such differences. Indeed, there seems no particular reason why this book, which is a collection of reviews, should have been singled out for translation because most of the material, while perfectly soundly presented, is widely available in English language review publications. This is true of "Semi-empirical Methods in the Theory of Small Molecules" (T. K. Rebane), of the chapters on molecular orbital methods (Mestechkin), and theoretical reactivity studies in conjugated systems (Tupitsyn and Adamov). Nikitin's article on "Interelectron and Non-Adiabatic Interaction in Long Molecules", and to a lesser extent Rebane's on finite difference methods in molecular orbital theory, have greater interest on account of their discussions of the application of less familiar theoretical methods. M. G. Veselov's connexion with the book is that of editor, a fact which is not disclosed on the cover and title page. It is regrettable that he is not also one of the authors.

The second *Advances in Quantum Chemistry* is well up to the standard of the first. The articles are by Boys and Rajagopal, Fischer-Hjalmars, Blinder, McWeeny and Steiner, Jansen, Jehle and Löwdin. Good reviews are always to be welcomed; and as the original literature slips out of reach by its sheer quantity, recovery in digests and comprehensive reviews as good as in these *Advances* is the more worth while and essential.

D. P. CRAIG

ONE-DIMENSIONAL FLAMES

Flame Structure

By R. M. Fristrom and A. A. Westenberg. (McGraw-Hill Series in Advanced Chemistry.) Pp. xiii+424. (New York: McGraw-Hill Book Company, Inc.; Maidenhead: McGraw-Hill Publishing Company, Ltd., 1965.) $17.50; 140s.

A FLAME is, at first sight, the obvious medium for the experimental investigation of high temperature processes. It may be time-invariant phenomenon, almost completely free from surface effects and cheap to set up. Flames can be produced with a wide range of temperature and composition. However, the disadvantages of flames—having many components and large temperature and concentration gradients in the reaction zone—have caused many research workers interested in physical and chemical processes at high temperatures to dismiss flames as too complex to be suitable media for research. The authors of *Flame Structure* believe that this view is too pessimistic and their belief is fully substantiated by this book. There is no denying, of course, that flames are more complex than some other experimental media and that the steep gradients which exist in them make the analysis of flame data to obtain chemical kinetic information more difficult. These gradients can, however, be measured accurately and taken into account in many cases and the expenditure of effort involved is amply repaid by the results obtained.

This book is intended for combustion research workers, in particular for those working in the field of gas phase reaction kinetics. It is concerned primarily with measurements of the properties of pre-mixed, laminar flames and with the interpretation of these measurements to obtain information on fundamental physical and chemical processes in flames. This type of flame is chosen because it approximates closely to a one-dimensional flow system and is therefore the most amenable to quantitative analysis. It is also the best type of flame to use to assess the validity and accuracy of some of the experimental techniques commonly used in combustion studies.

The book begins by dealing with the basic equations needed in discussing flame processes, together with an essential amount of relevant information on transport processes, thermodynamics and chemical kinetics. The basic equations for the conservation of energy and the conservation of species are given with emphasis on the forms of the equations applicable to flat and spherically symmetrical flames. The information which can be obtained from these equations is discussed as are the flame variables which have to be measured to do so.

The second, and principal, section deals with the practical measurement of the properties of one-dimensional flames. It begins with a description of different types of burners and of the ancillary flow metering and pumping equipment. This is followed by accounts of experimental techniques used to obtain flame velocities, temperature profiles, the concentration profiles of stable species (by probe sampling), the concentration profiles of free radicals and ions and by accounts of techniques for measuring distances and positions in flames, and obtaining flame photographs.

Throughout this section careful attention is paid to essential practical details and clarity of presentation. Each technique is illustrated by numerous excellent diagrams—somewhat over-elaborate in some cases—and photographs. In addition there are several compact summaries of useful practical data, numerous references and a critical evaluation of the accuracy of the results obtained by different methods of measuring the same physical quantity. Most of these techniques are not, of course, limited in their usefulness to one-dimensional flames but can be used in many combustion systems. Because of this, *Flame Structure* will also appeal to research workers who study flames other than the idealized ones with which the book is mainly concerned. The weakest parts are those dealing with spectroscopic measurements of flames. Descriptions of spectroscopic methods of determining flame temperatures and species concentrations are not given at the same depth and with the same amount of detail as are descriptions of the other techniques.

The chapter summarizing values obtained experimentally for the diffusion coefficients and thermal conductivities of binary mixtures of gases is particularly valuable. Included also are the means for calculating the values of these transport quantities at flame temperatures either from the kinetic theory of gases or from values which have been obtained at lower temperatures. As the authors say, "The magnitude of the diffusion velocities

found in typical cases may seem surprising to anyone inclined to ignore diffusion and look upon a flame as a purely thermal phenomenon". The importance of diffusion in sub-atmospheric flames is brought out very clearly here.

The final two chapters deal with the information which can be deduced by applying the conservation equations to data on laminar flames. The two chapters cover the results on physical properties of flames and chemical reaction rates in flames, respectively; the latter subject is generally the principal reason for studying flames of this type. The chemical reactions considered are only those which are thought to occur in normal flames and the detailed descriptions of low temperature or "cool" flame kinetics which are commonly substituted for a discussion on combustion chemistry are not included. An account of the analysis of a fairly complete set of data on methane–oxygen flames is given as an example of the kind of information which can be obtained. Included also are summaries of the values of rate constants for elementary reactions in flames, given in the form of Arrhenius plots whenever a sufficient range of values is known.

Within its framework this book is first rate and will be found very valuable by research workers interested in high temperature gas phase kinetics and by combustion engineers who need to make measurements of flame properties. Unfortunately, as a good deal of the material which appears here has been published previously, it is likely that many who would like to have their own copy of this book will find the price too high.

D. R. JENKINS

PROGRAMMING AND FLOW

Programming, Games and Transportation Networks

By Claude Berge and A. Ghouila-Houri. Translated by Maxine Merrington and C. Ramanujacharyulu. Pp. x + 260. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1965.) 55*s*. net.

THIS book consists of two parts of nearly equal length. The first part, by Prof. Ghouila-Houri, is entitled "General Theory of Convex Programming", and devotes its first three chapters to an account of the pure mathematics needed later in the book. The topics considered include vector spaces, linear manifolds, convex sets and convex functions, open, closed and compact sets, continuous and semi-continuous functions, convex hull of a set, intersections of convex sets, Von Neumann's minimax theorem and the Farkas–Minkowski theorem. The presentation is clear and is adequate for a reader well grounded in a modern approach to pure mathematics, but those who do not possess such a background and are more interested in applications than in mathematical foundations would find the reading severe. The next two chapters are concerned respectively with programming and with convex programmes with linear constraints, and are still mainly of a theoretical nature. The final chapter of Part 1, the shortest in the book, deals with games of strategy and is at a less abstract level than the preceding chapters.

The second half of the book, by Prof. Berge, is entitled "Problems of Transportation and Potential". The first two chapters give the necessary theoretical background of graph theory and a general theoretical study of flows and potential differences. The central theme is that of duality, first between cycles and co-boundaries of a graph, then between trees and co-trees, continuing with a planar graph and its dual graph, strongly connected graphs and graphs without circuits, flows and potential differences, cyclomatic and co-cyclomatic matrices, and finally between the transportation problem and the problem of potential. The whole treatment has unity and coherence and is extremely elegant.

The remainder of the book is entirely concerned with applications. A large number of algorithms for solving various flow problems are given and there is a chapter devoted to problems related to the transportation problem. The detailed examples illustrate methods due to Dantzig, Ford and Fulkerson, Hoy, Minty, and others.

The book will be read with interest and pleasure by those concerned with theoretical aspects of the subject, and with profit by those interested in the applications. Although a number of errors were noted, the presentation is of a high standard and the translation reads well. There is an excellent index. H. O. FOULKES

A USEFUL TECHNIQUE

Agar Gel Electrophoresis

By R. J. Wieme. Pp. xiii + 425. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 110*s*.

SOME years ago, in my review of Dr. Wieme's thesis *Studies on Agar Gel Electrophoresis*, I expressed the hope that it would form the basis of a more widely presentable work. This hope has now been realized. Agar gel is, of course, widely used for immunoelectrophoresis, but it is also a useful medium for simple zone electrophoresis, having a separating power between paper or powder slabs and starch or acrylamide gel, and it is to this aspect of its use that *Agar Gel Electrophoresis* is mainly devoted.

The first chapter provides an excellent account of the physics underlying electrophoretic processes in non-convective media and compares the properties of agar with those of other gels. (Incidentally it scarcely seems appropriate to give details in this chapter of the preparation of acrylamide gels, which are not complete anyway.) The next chapter surveys the various techniques used for agar gel electrophoresis. This is followed by a chapter which chooses the three techniques which the author considers to be of most general usefulness. These are a macrotechnique using gel on long glass plates, a microtechnique on microscope slides and a special procedure designated "fluid film" which uses dilute agar. The practical details are very adequately described. In the next chapter quantitative aspects are fully discussed, as are the properties of different varieties of agar, its chemistry and purification and the preparation of agarose (the representation of the linear agarose molecule is not correctly given). There is also a good discussion of various other properties of agar gel—endosmosis, interactions with electrophoretic substances and ion exchange and molecular sieve effects. Next comes a survey of the methods for rendering substances visible following electrophoresis, which provides full details of reagents for proteins, lipids, carbohydrates, nucleic acids and so on. Of particular interest is the description of reagents for substances having enzymatic activity. There is a short but useful section on immunoelectrophoresis giving useful details of preparation of immune sera, electrophoretic procedures and interpretations.

The sixth and final chapter is the longest, occupying seventy-one pages. It is a detailed review of the many applications of simple agar electrophoresis and covers a very wide field. Though it contains much useful information, this chapter suffers from being written in the style of a thesis where everything is included, important or not, and where arguments sometimes verging on the polemical are indulged in over matters not always worth arguing about. This does not help to make for easy reading, neither does the occasionally obscure English. Since 1959, when Dr. Wieme's thesis was published, the applications of agar electrophoresis have grown enormously,

but so have those of other types of electrophoresis, not to mention non-electrophoretic methods. Consequently to concentrate on one technique, as this chapter does, carries the danger of giving the erroneous impression that this technique has played a major part in advancing knowledge in some important fields. Some examples are the isolation and properties of human β_2 serum globulins, structural studies of immunoglobulins (it is admitted in this section that "analysis on Sephadex columns also proved fruitful" for this purpose !), human haemoglobin varieties and the study of plasmocytoma. Many of the detailed discussions of these and other subjects are scarcely relevant to a book of this nature and publications about them exist which cover all the analytical methods. This chapter does show that agar-gel electrophoresis is a useful complementary analytical technique, however, and the full coverage of the literature will be of great value to those who may want to use it for their own particular problems.

Agar gel electrophoresis is probably not so widely used in Britain as it is in the author's own country and other Continental countries. It has been used with great success in some important fields, a good example being isoenzyme studies. In general this book, well printed and illustrated, provides excellent guidance on the methodology of agar gel electrophoresis and should encourage its wider use. R. CONSDEN

VANISHING PEOPLE

Documents Anatoliens sur les Langues et les Traditions du Caucase

Par Georges Dumézil. 3: Nouvelles Études Oubykh. (Université de Paris. Travaux et Mémoires de l'Institut d'Ethnologie, 71.) Pp. 269+6 planches. (Paris: Institut d'Ethnologie, 1965.) 60 francs.

THE Ubykh are a small but important branch of the Caucasian family of peoples, closely related to the Circassians and the Kabardians. Since Greek and Roman times, they are reported as inhabiting a stretch of the Black Sea coastline between Abkhazia and the Crimea, not far from the modern Sochi. In 1864, the Russian conquest of the Caucasus resulted in the total dispersion of the Ubykh people, one segment being deported to the province of Kostroma, the other preferring to emigrate *en bloc* to the Ottoman Empire, to join forces with their Muslim co-religionists. In both cases, linguistic and cultural assimilation proceeded apace. To-day, Ubykh is spoken and understood only by a handful of old men, and these are rapidly dying out.

The interest presented by the Ubykh and their language was appreciated by scholars over the past century; the Russian Baron Uslar, the German Dirr and the Hungarian Mészáros all produced valuable pioneer studies. Much remained to be done, however, towards recording the vocabulary and phonology of this unique language before its final disappearance. Prof. Georges Dumézil, of the Collège de France, whose publications in the Caucasian field cover more than 30 years, has for several years been making annual trips to the remaining Ubykh villages in Turkey to preserve and interpret the vestiges of Ubykh folklore and oral tradition. This latest volume in his series of Ubykh publications commemorates the centenary of the annihilation of the Ubykh nation by Tsarist troops. Opening with a historical narrative of the last years of the independent Ubykh people, and biographical notes on Ubykhs whom the author has known, the book continues with nearly 150 pages of fresh Ubykh texts—traditional stories, anecdotes and personal reminiscences, of Caucasian and Turkish provenance—given with French and Kabardian translation. There is also an analysis of Hans Vogt's Ubykh dictionary, published at Oslo in 1963, as well as miscellaneous notes on Ubykh grammar and personalia. With six plates depicting the life of the survivors of this dying warrior nation, the book is a worth while addition to all libraries of ethnography anthropology and linguistics. DAVID M. LANG

The Principal Diseases of Lower Vertebrates

By H. Reichenbach-Klinke and E. Elkan. Pp. xii+600. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 126*s*.

THIS book fills a gap in the literature and brings together a vast amount of information on the pathology, bacteriology, zoology and parasitology of fishes, amphibians and reptiles. It is not a "popular" book but can be recommended to students.

Although the cover citation states that the book "is designed to help owners of such animals to maintain healthy stock, to afford some explanation of the losses they invariably suffer and to suggest the means of avoiding their occurrence", I consider it to be much too advanced for the ordinary owner. It will, however, find a place in laboratories which conduct post-mortem examinations and carry out investigations into losses of animals in these three groups.

The problem of diseases in these animals is immense, and this book emphasizes the difficulties of diagnosis, particularly in fishes. The present outbreak of disease among salmon in the Republic of Ireland is a case in point. Despite weeks of careful investigation, no clear pronouncement on the cause of the trouble has yet been made. To a pathologist this book emphasizes the unity of pathology in all species. The diseases and parasites of domestic animals have their counterparts in the lower animals and the means of investigation are not dissimilar.

Part I deals with fishes. Methods of investigation, infectious diseases, non-infectious diseases, environmental factors, healing of wounds and regeneration are adequately covered. Chapter 6 is devoted to lampreys, and Chapter 7 deals with fish as carriers of human disease. In Chapter 8 is given a useful review of the main symptoms and localization of fish diseases. Chapter 9 deals with treatment but emphasizes the importance of hygiene. Treatment at the moment does not seem too promising and prevention is obviously to be aimed at. Part II deals with amphibia, and Part III with reptilia, on similar lines to those on fishes.

Altogether this book is most interesting and the authors are to be congratulated. H. G. LAMONT

Advances in Chemotherapy

Vol. 2. Edited by Abraham Goldin, F. Hawking and Robert J. Schnitzer. Pp. x+330. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) $13.

LIKE its predecessor, this book devotes nearly half its space to the chemotherapy of cancer, but the emphasis is perhaps more derived from the volume of work than the rate of advance in this field. What advances have been made in the recent past stem not from new drugs but from the more skilful clinical application of those drugs already available. This is described with a fascinating precision by Frei and Freireich in their account of the four-drug attack on leukaemia being conducted in the United States. Wallace Fox's chapter on "Tuberculosis" presents a most interesting comparison. He also describes a pattern of combined therapy with streptomycin, *p*-aminosalicylic acid and isoniazid, and even though the antitubercular drugs available can achieve cures—which are most rare in the leukaemias—the author comments that "100% success has only been

achieved in the best hands". This chapter as a whole, excellently written though it may be, fits oddly into the series. Much of it is devoted to discussion of the relative merits of institutional and domiciliary treatment and this surely is much more a medico-social question than a problem of chemotherapy.

The two chapters, one on "Cephalosporins" and the other on "Olivomycin, Mithramycin, Chromomycin: Three Related Cancerostatic Antibiotics", are perhaps the best models for collections of this sort. They deal most readably with limited topics, authoritatively enough for the expert while still maintaining interest for the general reader. To a slightly lesser extent, the same is true of the very different chapter on "Systemic Control of Plant Nematodes". But of the chapter on "Purine and Pyrimidine Analogs" one can only agree with the authors themselves when they say that "To some extent . . . readability has been sacrificed to logic. . . ." This proves a severe disadvantage in a book that has been produced to be read. WALTER DAVIS

Human Nutrition and Dietetics

By Stanley Davidson and R. Passmore. Third edition. Pp. xii+864. (Edinburgh and London: E. and S. Livingstone, Ltd., 1966.) 95*s*. net.

IN bringing this invaluable text-book on human nutrition up to date the authors have revised all the sections and brought the bibliography up to 1965 to include most recent revisions of recommended allowances of nutrients and other such important material. Chapters on the composition of the body, appetite and satiety, proteins, fats, carbohydrates, poisons, various deficiency diseases and the population problem have been completely rewritten.

In Part IV of the book, which is concerned with diet and physiological stress, the chapter on nutrition and care of the aged is considerably revised and new statistical data are included as well as a brief comment on social aspects of the problems of the increasing numbers of aged members of the population. This is only one example of the way in which the text has been improved since the first edition in 1959. The book continues to be indispensable for all students and teachers in the field of nutrition and dietetics as it brings together in one volume the whole subject of food for man. It is written by medical authors but their language, style and approach are such as to be fully understood by both medical and non-medical readers. In fact, most of the text makes easy reading for the student or the layman. For those who need deeper knowledge of particular problems the references give proper leads into the relevant literature. References to recent reviews are especially useful and are given in many sections where only a brief treatment of a subject is indicated.

A. M. COPPING

Embryology of the Ovary and Testis

Homo sapiens and *Macaca mulatta*. By Gertrude van Wagenen and Miriam E. Simpson. Pp. xvii+256. (New Haven and London: Yale University Press, 1965.) 56*s*.

Dr. Gertrude van Wagenen and Dr. Miriam E. Simpson have provided a valuable illustrated atlas which compares successive stages in the development of the ovary and testis in Man and the Rhesus monkey. Half the volume consists of plates of photo-micrographs, and for this reason alone its price is very moderate. Unfortunately the text is limited, both in scope and in the quality of the interpretation. The descriptions are on simple classical lines, and the study extends neither to an electron microscopic analysis of the kind with which students of gametogenesis are now becoming familiar, nor to a quantitative analysis of the stages of development which are described. Students will, none the less, find the book valuable, since even if it only confirms the classical picture of the development of the gonad, it provides useful background material with which those new to the subject will be able to orientate themselves in their more detailed studies.

Insects in Southern Africa

How to Control Them—a Handbook for Students, Health Officers, Gardeners, Farmers. By Bernard Smit. Pp. xiv+399. (London and Cape Town: Oxford University Press, 1964.) 63*s*. net.

No text-book of economic entomology has been published in southern Africa since C. K. Brain produced his *Insect Pests and their Control in South Africa* in 1929. Since that time many new crops and new pests have been introduced; and the method of control, whether by cultural and biological means or by the use of modern insecticides, have been transformed. During the past forty years Dr. Bernard Smit has been engaged in economic entomology in South Africa and has indeed been responsible for many of the advances that have been made. It is most valuable to have all this accumulated experience, much of which has hitherto been reported only in science bulletins and leaflets, brought together in book form. The book is wholly practical. Introductory matter is reduced to a minimum; no attempt is made to give more than the barest elements of insect anatomy, and insect physiology does not come into consideration. Clear and homely line drawings serve for identification. The insects are given their scientific, English and Africaans names; their life history and habits are clearly described; and measures of control are set out in a simple and effective style. The book is intended "for students, health officers, gardeners, farmers". It will fulfil this purpose admirably and can be warmly recommended. It may even find use outside South Africa. V. B. WIGGLESWORTH

Physical Properties of Martensite and Bainite

(Report of the Proceedings of the joint conference organized by the British Iron and Steel Research Association and the Iron and Steel Institute, held at Scarborough, 10–12 May, 1965. Special Report 93.) Pp. 211. (London: The Iron and Steel Institute, 1965.) 100*s*.

THE physical properties of martensite and bainite are of great technological importance to the steel industry and also provide challenging topics of investigation for research workers in industry, the universities and research associations. This volume reports the proceedings of a conference attended by representatives from these different backgrounds and successfully reflects the diversity of interest in the crystallography, morphology and kinetics of these classes of phase transformations. Eighteen papers, which review the field and describe recent research, are included. These were circulated to participants before the meeting and this has helped to produce an informed discussion which provides a major and valuable section of the book. Although the martensite and bainite reactions in steels are given prominence, work on non-ferrous metals and alloys is also described, emphasizing the close relationship which exists between transformations in a wide range of materials. The most striking feature of the book is the wealth of experimental information on the internal structure of transformation products which has been revealed by thin foil electron microscopy in recent years. This should provide a stimulus to the further development of theories of martensite crystallography which have undergone only minor modifications in the past decade.

The papers and discussion are of a generally high standard and the presentation is attractive. In particular the Iron and Steel Institute are to be congratulated on publishing this report less than five months after the conference was held. A. G. CROCKER

MEETINGS

PLANT TERPENOIDS

A SYMPOSIUM on "Terpenoids in Plants" was held in conjunction with the annual general meeting of the Phytochemical Group at the Department of Agricultural Biochemistry, Aberystwyth, during April 12–14, 1966, under the chairmanship of Professor E. Lederer (Gif-sur-Yvette). The symposium covered aspects of the occurrence, chemical structure, biosynthesis, and biological function of the major groups of terpenoids.

In the opening lecture Professor T. W. Goodwin (University College of Wales, Aberystwyth) reviewed some possible biological functions of terpenoids in plants, in particular the role of abscisin in the control of leaf abscission, the control of carotenogenesis in the (—) strain of *Blakesleea trispora* by trisporic acid and the stimulatory effects of sterols on oospore production by *Phytophthora* spp. and by *Pythium* spp.

The biogenetic isoprene rule was reviewed by Professor D. Arigoni (Federal Technical College, Zurich). In the past few years a variety of sesqui-, di-, and triterpenes have been found which have structures which were not expected from the biogenetic rule. These apparent anomalies, however, can now be explained by several types of intramolecular arrangements which were outlined. Recent work on conformational analysis of terpenoids and steroids was described by Dr. J. S. E. Holker (University of Liverpool). He also showed how the behaviour of terpenoid molecules during chemical reactions was correlated with differences in their molecular geometry.

Methods of synthesis of mevalonic acid labelled with carbon-14 or tritium, or deuterium in specific positions were described by Dr. G. Ryback (Shell Research, Sittingbourne); these compounds can be used in the elucidation of the biochemical mechanisms involved in the biosynthetic conversion of mevalonate to terpenoids. The biosynthesis and metabolism of monoterpenoids was described by Dr. W. D. Loomis (University of Oregon). From the results of experiments in which the incorporation of mevalonic acid and $^{14}CO_2$ into monoterpenes was compared, it was suggested that mevalonic acid was formed near the site of monoterpene synthesis, presumably from sugars. The monoterpenes seem to be metabolically interconverted and these reactions are influenced by illumination and by night temperature.

Dr. A. C. Oehschlager (University of Strasbourg) described *in vitro* transformations, and particularly acid-catalysed stereospecific cyclizations of diterpenes; in many of the transformations the sequence of arrangements follows that of the proposed biogenetic pathways, such as in the acid-catalysed stereospecific cyclization of all-*trans* isoprenoid alcohols to *trans* decalins and the conversion of pimaladiene to abietadiene.

The chemistry of sesquiterpenes was outlined by Dr. M. O. Sutherland (University of Brisbane). Although the sesquiterpenes are derived from farnesyl pyrophosphate, the reactions involved in the further transformations are not clear. For example, the hydrocarbon geijerene which has two asymmetric centres is isolated in racemic form and, therefore, cannot be derived as an artefact of isolation from elemol. The toxic principles of *Myoporum deserti* contain sesquiterpene furanoid ketones, related to myoporone, which seem to arise by extensive allylic oxidation of unsaturated precursors.

The chemistry of triterpenes was reviewed by Dr. T. G. Halsall (University of Oxford). Recent structural determinations on more complex molecules and also on small amounts of compounds have clarified views on triterpene biogenesis. It is now clear that, after the methyl and hydrogen shifts accompanying the initial biosynthetic cyclization of squalene, oxidation occurs which leads not only to ketones and acids, for example, but also to loss of carbon, to bond fission, to further carbon–carbon bond rearrangement and even to new carbon–carbon bond formation. Such reactions were illustrated by reference to a number of triterpenes including platanic acid, nycthanic acid, limonin, swietenine, ceanothic acid and related compounds.

The biosynthesis of phytosterols, reviewed by Dr. L. J. Goad (University College, Aberystwyth), appears to be similar in many respects to that of cholesterol in animals. The extra C_{24}-alkyl groups arise by transmethylation probably shortly after the cyclization of squalene. In plants it seems that lanosterol is not in the biosynthetic sequence but that its place is taken by *cyclo*-artenol which has recently been found always accompanying the plant sterols.

Professor R. Tschesche (University of Bonn) described recent experiments on the biosynthesis of steroid sapogenins and related compounds. 21-^{14}C-Δ5-pregnene-3β-ol-20-one glucoside is converted, in leaves of *Digitalis lanata*, to radioactive digitoxigenin, digoxigenin and gitoxigenin. Similarly, 4-^{14}C-cholesterol glucoside is converted to tigogenin, gitogenin and diosgenin. There must, therefore, be a hydrogenase which saturates the Δ5 double bond to give a *cis* configuration in ring *A/B* and hydroxylases which can introduce hydroxyl groups at C_{11} and C_{16} of digitoxigenin and C_2 of tigogenin.

The introduction of infra-red, nuclear magnetic resonance and precision mass spectrometry into structural studies of carotenoids was described by Professor B. C. L. Weedon (Queen Mary College, University of London). Even if the older degradative methods have to be used they can now be combined with chromatographic analysis of the products so that as little as 5 or 10 mg of carotenoid can be used. The newer methods were used to determine the structures of capsanthin and capsorubin, and also more recently the structures of fucoxanthin and foliaxanthin, both of which are shown to possess allene groupings, have been investigated.

Dr. J. F. Pennock (University of Liverpool) reviewed the chemistry and occurrence of the four major groups of terpenoid quinones, namely the vitamins K, plastoquinones, ubiquinones, and tocopherol quinones. These are all associated with intracellular organelles and their functions are associated with hydrogen transport by conversion to the corresponding hydroquinones although the possibility of biological reactions involved in cyclization to the chromanol forms may also be important.

The biosynthesis of the terpenoid quinones was reviewed by Dr. D. R. Threlfall (Aberystwyth). The three major distal precursors of the quinones appear to be mevalonic acid which gives the terpenoid side-chain, shikimic acid which gives the aromatic nucleus of the *p*-benzoquinones, and methionine giving the ring methyls and methoxyls. Permeability barriers across organelles has hampered many of the biosynthetic studies. It is not yet clear whether prenyl phenols, analogous to 2-decaprenyl phenol, are universal precursors of the terpenoid quinones.

Dr. F. W. Hemming (University of Liverpool) described the recent isolation from green leaves of long chain polyisoprenoid alcohols with chain lengths up to 110 carbon atoms. Each of these so-called prenols has more *cis* than *trans* isoprene residues and some of them resemble the pig liver dolichols because the double bond normally β— to the hydroxyl group is saturated. The *cis–trans* prenols occur as a mixture of isoprenologues, varying with the species, the concentration in green leaves increases with age and the bulk of them is associated with the osmiophilic globules of the chloroplast; the rest occurs outside the chloroplast.

J. FRIEND

HAEMORHEOLOGY

THE First International Conference on Haemorheology was held at the University of Iceland, Reykjavik, during July 10–16, 1966.

Haemorheology—the study of the flow of blood and its components, of its coagulation and lysis and of the mechanical properties of the vessel walls—is of such practical importance that it was felt worth while to organize a series of conferences on the subject and to have a society responsible for such organization and international co-ordination. Before the conference started, an International Society of Haemorheology was founded. The Officers and Council of the Society were elected but it was left to the Council to draw up a constitution. The conference chairman, Professor A. L. Copley (United States), was unanimously elected president. Should an international society of rheology as a whole, or of biorheology, be formed at some future date, it was agreed that the new Society would consider some form of affiliation.

After a formal inaugural session at which the conference was welcomed by Professor A. Snaevarr, Rektor of the University, the Minister of Education and Dr. A. Brekkan of the Icelandic Medical Association, there were three short addresses. The first, by Professor A. L. Copley (United States), was an inaugural address covering the general purposes of the conference. This was followed by short lectures on applications of haemorheology to the practice of medicine by Professor H. Hartert (West Germany) and on the link with physics by Dr. G. W. Scott Blair (United Kingdom). More than sixty papers were read during the conference and in the closing session short appraisals of the achievements in the various fields covered were given by specialists.

Dr. A. Silberberg (Israel), in a summary of the papers on haemorheological theory, pointed out the difficulties involved in applying precise mathematical expressions unless certain biological processes are ignored. He noted with approval the paper by Professor W. G. Frasher *et al.* (United States), who combined a rheologically well defined system with the immediate return of the blood to the living animal. A further complication is the two-phase nature of blood which makes the experimentation depend on the dimensions of the apparatus. Casson's very popular equation, for which the square roots of stress and of shear rate are plotted for capillary flow, may be regarded as sound if it is used to study the process of flow in one direction only. Dr. Silberberg also discussed the theoretical implications of an assumed yield value for blood and closed by emphasizing the considerable progress which has recently been made in the haemodynamics of pulsatile flow.

Work on haemorheological techniques was summarized by Dr. M. Joly (France). Of special interest were Professor Frasher's work (already referred to) and a paper by Professor H. Wayland (United States), who emphasized the importance of the exact determination of three-dimensional geometry in *in vivo* studies. The use of cinemicrophotography was emphasized by Professor H. Bloch (United States), and Professor H. R. Jacobs (United States) described studies on meniscal resistance. Thrombodynamography, a technique developed by Professor H. Hartert (West Germany), was now widely used clinically.

Model theory and phase separation were discussed by Professor G. Bugliarello (United States). The models proposed during the conference covered a very wide range from Dr. A. Silberberg's physico-chemical boundary process to Dr. E. O. Attinger's (United States) model of peripheral circulation. Proposed systems included hydrodynamic, mathematical, electrical and visual models. Model suspensions for blood continue to be improved, and the importance of adsorption of molecules on the vessel wall in regulating the flow in small vessels and also bifurcations as controls for the haematocrit in downstream vessels are increasingly being appreciated.

Professor S. Witte (West Germany) summarized work on cellular and fibrin clotting. The two most important questions concerning clotting were undoubtedly the production of fibrin and the aggregation of platelets. Professor M. E. Leroux (France) discussed the effect of platelets on retraction in terms of Professor H. Hartert's thrombelastograph and retractograph techniques. Retraction starts much earlier than was previously supposed. Professor A. Copley (United States) reported investigations of an intermediate product during fibrin development when only the fibrino-peptide *A* is split off from the molecule. Fibrinolysis was also much discussed. This is inhibited by the presence of platelets. The building of platelet aggregates is important for haemostasis and for thrombosis; however, it seems to bear no relation to vascular changes in the early stages of arteriosclerosis, as was shown by Professor W. E. Stehbens (Australia). Dr. G. W. Scott Blair (United Kingdom) made a preliminary attempt to propose basic equations for flow, coagulation and fibrin softening but such generalizations are still at an early stage.

Dr. R. L. Whitmore (United Kingdom) discussed the findings of the conference on plasma expanders. All dextrans of molecular weight greater than about 20,000 tend to cause some aggregation of red cells. The addition of dextrans with molecular weights of 40,000 to suspensions which have been strongly aggregated by fibrinogen or dextran of high molecular weight gives no better flow behaviour than is obtained with those diluted with albumin or saline. The addition of dextrans of high molecular weight to dogs *in vivo* leads to a fall in haematocrit and a dramatic decline in cardiac output. The improvement in the dispersion of red cells following infusion of dextran of 40,000 molecular weight is probably a result of an increase in the shearing forces to which the blood is exposed. Interaction between dextran and platelets on the vessel walls must also be taken into account.

Professor M. G. Taylor (Australia) summarized papers on *in vivo* work but he first emphasized the importance of Poiseuille's work on water and other simple liquids flowing in wide artificial capillaries, which is the basis of all studies of flow under *in vivo* conditions. Conditions in very small vessels, such as were discussed by Professor C. A. Wiederhielm (United States), are particularly complex. Dr. A. C. Groom (United Kingdom) described a muscle preparation giving transit times of cells and muscles through the vascular bed.

Professor A. C. Burton (Canada) discussed the papers on blood cellular elements. He emphasized the importance of microscopy in such studies. "There is no substitute for observation of the shape and general appearance of the erythrocytes." "Black-box" types of apparatus have their uses but one must look inside "to see the wheels of transformation turning". The electron microscopist may miss irregularities in the living membranes of the cells that may be all-important. Other methods, such as the measurement of birefringence, as described by Dr. H. H. Pfeiffer (West Germany), can also be very helpful.

Finally, Professor L. E. Gelin (Sweden) appraised the clinical value of the conference. He emphasized especially the value of current work in relation to the study of shock. The importance of the viscosity of blood and plasma is increasingly realized but viscosity in non-Newtonian systems is itself complex. In the field of blood clotting, the importance of platelet aggregation is increasingly appreciated and also the effect of split products (peptides) on clotting. The importance of fat in the circulation was also discussed.

OBITUARIES

A. T. Glenny

ALEXANDER THOMAS GLENNY died on October 5, 1965, at the age of eighty-three. He was born in Dulwich on September 18, 1882, and brought up—though he never joined the sect—as a Plymouth Brother. He was educated at Alleyn's School, Dulwich, and when in 1899 Dr. W. Dowson, the director of the Wellcome Physiological Research Laboratories, asked the headmaster of the school to recommend two boys as possible laboratory assistants, Glenny was one of those chosen. His association with the Laboratories lasted for forty-eight years, as laboratory assistant and as head of the Department of Immunology.

Much of Glenny's work was done in collaboration, but the ideas are in general his or follow from his own. Apart from a few miscellaneous papers, his output forms a connected whole which deals with a wide variety of problems concerned with immunization of man and animals—the production, purification and assay of antigens, the increase in their potency, and the basic ideas underlying their use in immunization; the characteristics of passive immunity, and its effect on active immunization; the assay of antisera and the nature of the toxins present in bacterial filtrates. In much of this work he was a pioneer, and to everything he worked on he added fundamental observations and ideas.

Some of his earliest papers deal with the basic and almost universal responses to antigens—the primary and secondary response. These and a consideration of the nature of normal antibodies in animals led him to lay down the ideal conditions for immunization—few injections with long rests between them. To this fundamental work he added the production of new antigens—diphtheria and tetanus toxoids, diphtheria toxin precipitated by alum and toxoid antitoxin floccules—and methods for their assay and use. Not only did he work out the characteristic phases of passive immunity, but he also applied the information to the natural case of homologous passive immunization of the human foetus *in utero*. Here he showed that the immunity transferred passively from the mother may interfere with active immunization of the newborn child, and that, on the average, the interference falls almost to nothing by 6 weeks after birth.

Glenny also showed that combined antigens were a practical proposition, but that they had to be made and used intelligently. Above all, he showed that basic immunity to one antigen in a mixture may reduce antibody response to other components of which the subject has had no experience—a development of earlier work in which he had shown that horses sensitive to horse serum respond poorly to diphtheria toxin-(horse)-antitoxin floccules. By all these methods Glenny laid down the rules that govern modern immunological practice, especially against those diseases in which bacterial toxins are important.

He made considerable advances in assaying antitoxins, both by introducing new methods or improvements on old ones, and, most important, by determining what was being assayed. To this end he developed many of the means of detecting multiple toxins in bacterial filtrates, and of assaying antitoxins against them singly. Besides this, he did excellent work on the avidity of antitoxins—the intensity with which they are bound to their toxic antigens. Most of this work was carried out while he was in charge of the production and testing of antitoxins and prophylactics; it is an astonishing performance for a man so strenuously occupied.

He was not easy to get on with; shy, diffident, but very conscious of his own capacity, and (often justifiably, but not always sensibly) very critical of that of others. He was almost unbelievably thorough in his own work, tidy, and constantly occupied with the best and most useful form of recording for routine immunization and testing and experimental work.

He was elected Fellow of the Royal Society in 1944, and awarded the Addingham Gold Medal and the Jenner Medal in 1953. He married Emma Blanche Lilian Gibbs in 1910; she and two of their three children survive him. He retired from the headship of the Department of Immunology at the Wellcome Physiological Research Laboratories in 1947, but continued working there until 1959.

C. L. OAKLEY

W. R. Spurrell

WALTER ROWORTH SPURRELL, emeritus professor of physiology in the University of London, died at his home in Dorset on June 7, 1966, at the age of sixty-nine.

He belonged to the generation which was depleted of so many of its best men in the First World War, but Spurrell survived three years of active service as a gunner officer and returned to his medical studies in 1919. His career as a student was brilliant. He carried off all the best prizes at Guy's Hospital Medical School and found time to take an honours degree in physiology before he qualified M.B., B.S., with the university gold medal. He then embarked on a career of surgery, gained an M.S. and his F.R.C.S., and within a few years his scientific training and his clinical excellence marked him out as a surgeon of the highest promise. But a long illness forced him to give up his clinical career.

With characteristic courage and enthusiasm he turned to physiology and, after spending some happy years in McSwiney's department in the University of Leeds, he was invited to return to his old school to take charge of the Department of Physiology at Guy's when M. S. Pembrey retired in 1933. Spurrell retired from his chair in 1962, so that for 30 years he directed the teaching of physiology; no one ever did more to bring together the pre-clinical and clinical activities of Guy's Hospital and its School. His experience and understanding of patients which he gained as a surgeon in his earlier years gave him a unique insight into the teaching of fundamental physiology to medical students.

He had a simplicity of expression which came from profound knowledge and clarity of thought and the most difficult subjects seemed simple when he expounded them. His own work included subjects as diverse as gastric function and endocrinology. He generously encouraged the lecturers in his department and guided them past fallacies to sound work. In the development of the Medical School at Guy's he was a uniting force. His own personal modesty and unselfishness gave him an authority that was often the means of settling conflicting views and interests. His wise advice was sought by individuals in their personal problems no less than by committees in their difficulties over big issues.

G. F. GIBBERD

Continued from previous page

At a special session, a gold medal, cast in honour of Poiseuille, "the first haemorheologist", was presented to Professor Robin Fåhraeus (Sweden) in recognition of his pioneer work on blood flow and sedimentation.

The secretary of the new International Society of Haemorheology is Professor George Bugliarello, Department of Civil Engineering, Carnegie Institute of Technology, Pittsburgh, Pennsylvania.

G. W. SCOTT BLAIR

A MODEL FOR VARIABLE EXTRAGALACTIC RADIO SOURCES

By PROF. H. VAN DER LAAN*

National Radio Astronomy Observatory†, Charlottesville, Virginia

THE recently discovered[1] temporal variations in the millimetre and centimetre radiation from a number of quasi-stellar radio sources and one Seyfert galaxy[2-5] provide radio astronomy with a potentially rich source of information on the physics of non-thermal radio sources. It has been suggested[5,6] that the varying components are sources of synchrotron radiation which are initially optically thick but, as they expand, become optically thin at progressively longer wavelengths. Indeed, data now available[5] suggest that the variability in the high frequency part of the radio spectrum has a systematic character. The purpose of this article is to present a quantitative discussion of the evolving synchrotron self-absorption model. The time-dependence of the radio spectrum is derived, and it is shown how variations observed at one frequency may be used to predict the behaviour at any other frequency.

The attitude here is to admit the present mysterious nature of the initial event(s) giving rise to the relativistic electron flux. Rather than add to the multi-parameter speculation concerning such events, a definite model for the subsequent evolution of the radiation source is considered, which has a number of features accessible to direct observational tests. In this manner it may be possible, as additional and refined data are obtained, to approach the initial event by imposing well defined boundary conditions and other requirements.

Properties of the model. Consider a uniform and spherical cloud of radius r, expanding at the rate $\dot{r}$, filled with a flux of electrons at relativistic energies. Let these electrons have an isotropic velocity distribution and an energy distribution $N(E)\mathrm{d}E = K(t)E^{-\gamma}\mathrm{d}E$ (cm^{-3}) confined to a range $E_1(t) \leqslant E \leqslant E_2(t)$. They radiate as they are accelerated in a magnetic field of strength B gauss (G). Initially, the cloud is sufficiently compact to be optically thick at all radio frequencies. The condition that the brightness temperature of the radio source cannot exceed the equivalent temperature of the electrons chiefly responsible for the synchrotron radiation at any given frequency yields the well known relation[7,8]

$$\nu_m = CB^{1/5}\,\theta^{-4/5}\left\{S(\nu_t)\,[\nu_t/\nu_m]^{(\gamma-1)/2}\right\}^{2/5} \qquad (1)$$

where ν_m is the frequency at which the spectral curve reaches a maximum, ν_t is some frequency at which the source is transparent, $S(\nu_t)$ is the flux density at frequency ν_t, θ is the angular diameter, and C is a numerical constant dependent on the units used. For synchrotron radiation the volume emissivity $p(\nu) \propto \nu^{-(\gamma-1)/2}$ while the absorption coefficient $\mu(\nu) \propto \nu^{-(\gamma+4)/4}$, and for this reason it follows that the frequency dependence of the spectral curve takes the form

$$S(\nu) \propto \frac{p(\nu)}{\mu(\nu)}\,[1-\mathrm{e}^{-\tau(\nu)}] \propto \nu^{5/2}\,[1-\mathrm{e}^{-\tau(\nu)}] \qquad (2)$$

where the optical depth $\tau(\nu) = \int\mu(\nu)\mathrm{d}l \propto \nu^{-(\gamma+4)/2}$.

For frequencies $\nu \ll \nu_m$ the flux density is given by

$$S(\nu) = k_1 B^{-1/2}\,\theta^2\,\nu^{5/2}. \qquad (3a)$$

while at $\nu \gg \nu_m$

$$S(\nu) = k_2 K B^{(\gamma+1)/2}\,\theta^2\,\nu^{-(\gamma-1)/2} \qquad (3b)$$

where k_1 and k_2 are constants.

The parameters change as in the adiabatic expansion model first proposed by Shklovsky[9] to represent the early phase of supernova remnant evolution. Magnetic flux is conserved

$$B = B_0(r/r_0)^{-2} \qquad (4a)$$

and the relativistic gas cools adiabatically, so that for an individual particle

$$E = E_0(r/r_0)^{-1} \qquad (4b)$$

while the angular diameter, of course, varies as

$$\theta = \theta_0(r/r_0) \qquad (4c)$$

In the model, particles neither enter nor escape the reservoir after the initiating event, so that

$$\frac{\mathrm{d}}{\mathrm{d}t}\left\{r^3(t)K(t)\int_{E_1(t)}^{E_2(t)} E^{-\gamma}\,\mathrm{d}E\right\} = 0 \qquad (4d)$$

The subscript 0 denotes parameter values at a specified instant. From relations (3) and (4) it follows that for $\nu \ll \nu_m$

$$S(\nu,\rho) = S_0(\nu)\,\rho^3 \qquad (5)$$

and for $\nu \gg \nu_m$

$$S(\nu,\rho) = S_0(\nu)\,\rho^{-2\gamma} \qquad (6)$$

where $\rho = r/r_0$ is the relative radius of the source. From relations (1), (4) and (6) the dependence of ν_m, the frequency of maximum flux density, on radius is seen to be

$$\nu_m(\rho) = \nu_{m0}\,\rho^{-(4\gamma+6)/(\gamma+4)} \qquad (7)$$

From equations (7) and (5) or (6) the variation of the maximum flux density follows:

$$S_m(\rho) = S_{m0}\,\rho^{-(7\gamma+3)/(\gamma+4)} \qquad (8)$$

The evolution of the spectrum is thus seen to be very simple. The spectral curve, as given in the usual $\log S(\nu) - \log\nu$ plane, does not change, but moves down and towards the left, that is, to lower flux densities and lower frequencies. Observing such a source at one frequency will show the flux density to increase rapidly at first, reach a maximum and then decrease more gently. Simultaneous observation at a lower frequency will show the same fractional rate of increase, but the maximum will be reached later and have a smaller value.

Secular variations take the form

$$\dot{\nu}_m/\nu_m = -\left(\frac{4\gamma+6}{\gamma+4}\right)\dot{r}/r;\quad \dot{S}_m/S_m = -\left(\frac{7\gamma+3}{\gamma+4}\right)\dot{r}/r \qquad (9)$$

and for $\nu \ll \nu_m$ $\quad \nu \gg \nu_m$

$$\dot{S}/S = 3\dot{r}/r\ ;\ \dot{S}/S = -2\gamma\dot{r}/r \qquad (10)$$

To calculate $S(\nu,\rho)$, the flux density at a given frequency and radius, use expressions (2), (7) and (8). It is noted that the spectral curve has no identifiable features other than the curvature associated with the turnover, which

* Permanent address: Department of Astronomy, University of Western Ontario.

† Operated by Associated Universities, Inc., under contract with the National Science Foundation.

provides the point of reference. The flux density and frequency are therefore given relative to their values at the spectral maximum when $\rho = 1$. Then

$$S(\nu,\rho) = S_m\left(\frac{\nu}{\nu_m}\right)^{5/2}\left[\frac{1-\exp(-\tau)}{1-\exp(-\tau_m)}\right]$$

$$= S_{m0}\,(\nu/\nu_{m0})^{5/2}\,\rho^3\,\frac{\left[1-\exp\left\{-\tau_m\left(\frac{\nu}{\nu_{m0}}\right)^{-(\gamma+1)/2}\rho^{-(2\gamma+3)}\right\}\right]}{[1-\exp(-\tau_m)]} \qquad (11)$$

where τ_m, the optical depth corresponding to the frequency at which the flux density is a maximum, is the solution of

$$e^x - \left(\frac{\gamma+4}{5}\right)x - 1 = 0 \qquad (12)$$

which is the condition for expression (2) to be a maximum.

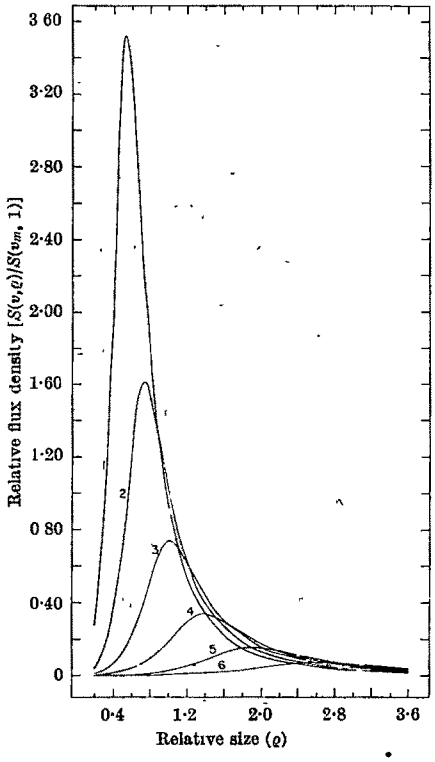

Fig. 1. The radial dependence of flux density. The frequencies of successive curves differ by a factor of two. The spectral index (α) in this case is 0·25. Values for the various curves are ν_{m_0}/ν : (1) 1/2; (2) 1; (3) 2; (4) 4; (5) 8; (6) 16.

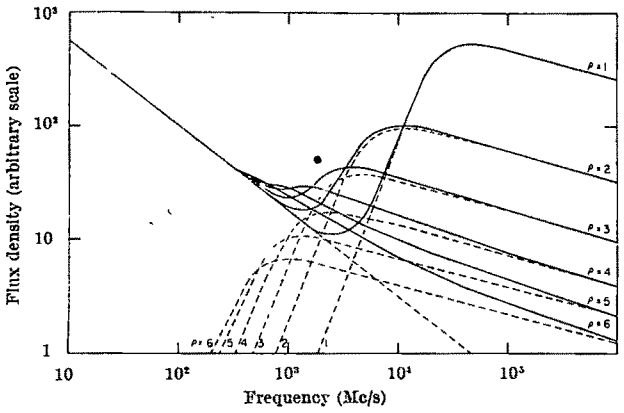

Fig. 2. The evolution of a typical variable radio source spectrum. The variable source spectrum is added to that of the constant source and the resultant is shown at successive integer values of ρ.

Flux density as a function of frequency and time. In order to obtain the flux density at any frequency as a function of time, it is necessary to specify the time dependence of the expansion velocity. Let $t_0 = r_0/\dot{r}_0$ be the "apparent age" of the source when its radius is r_0. Suppose $\rho = (t/\beta t_0)^\beta$ and define βt_0 as the "expansion age" at radius r_0. (The "true age" is not defined when the circumstances that give rise to the source are unknown.) Two cases will be referred to in particular: (*a*) constant expansion velocity, that is, $\beta = 1$; and (*b*) deceleration in the manner of a relativistic gas cloud expanding into a uniform gaseous medium[10], asymptotically $\beta = 2/5$.

The function $S(\nu,\rho)/S_{m_0}$, as given in equation (11), is presented graphically in Figs. 1 and 2 for several values of ν/ν_{m_0} and a range of ρ. These curves were computed using a spectral index $\alpha = (\gamma - 1)/2 = 0{\cdot}25$. If the frequency of maximum flux ν_{m_0} is known and S_{m_0} is obtained from measurement or from equation (11), then the vertical scale of curves such as in Fig. 1 can be specified in flux units and each curve can be assigned a definite frequency.

The time scale factor t_0 can be determined from a measurement of one observable and its rate of change. Any of the equations (9) and (10) is an expression for the apparent age when $1/t_0$ is substituted for $(\dot{r}/r)_0$. If, for example, the flux density and its rate of change are measured at a frequency $\nu_0 \ll \nu$

$$t_0 = 3S_0/\dot{S}_0 \qquad (13)$$

In order to relate radius and age, let the time t' be measured from the instant $t' = 0$ when S_0, $\dot{S}_0$ and ν_{m_0} are specified. Then

$$\rho = (1 + t'/\beta t_0)^\beta \simeq 1 + t'/t_0 \text{ for } |t'| \ll \beta t_0 \qquad (14)$$

The function (14) is sketched in Fig. 3 for several values of the deceleration parameter β. For times small compared with βt_0, before and after the instant $t' = 0$, the model can be compared with given sources at any frequency and time. For times separated from the instant $t' = 0$ by intervals of order βt_0 the curves in Fig. 3 serve to relate ρ and t' for a chosen β.

If the maximum of the spectral curve is at frequency ν_1 when $t' = t_1$, then this maximum reaches another frequency ν_2 at

$$t'(\nu_{m_2}) \equiv t_2 = (\beta t_0 + t_1)\,(\nu_1/\nu_2)^{(\gamma+4)/\beta(4\gamma+6)} - \beta t_0 \qquad (15)$$

If at $t' = t_1$ the maximum flux is $S_m(\nu_1)$, then at the time given by relation (15) the flux density maximum is at ν_2 and is given by

$$S_m(t_2) = S_m(t_1)\left(\frac{\beta t_0 + t_2}{\beta t_0 + t_1}\right)^{-\beta(7\gamma+3)/(\gamma+4)} \qquad (16a)$$

or the equivalent expression

$$S_m(\nu_2) = S_m(\nu_1)(\nu_1/\nu_2)^{-(7\gamma+3)/(4\gamma+6)} \qquad (16b)$$

These relations together can be applied to any source the spectrum of which is variable and known over a fraction of the expansion age. Spectral changes in the immediate future are then predictable; for later times they depend on the expansion mode. Prolonged observations can be expected to provide information about the dynamics of expansion and to yield a value for β.

The applicability of the model *überhaupt* can be tested by the requirement that the expressions for t_0 equivalent to expression (13), given by each observable and its rate

of change as given in equations (9) and (10), result in values equal within experimental errors. Data now available are spread too thinly in time and wavelength to attempt as yet quantitative tests; qualitatively the model conforms to observed radio source behaviour[1,4,5].

There are ways other than synchrotron self-absorption which can give rise to a turnover in the spectral curve[11]. A magneto-ionic medium dense enough to cause significant dispersion leads an otherwise inverse power law spectrum to decrease sharply on the low frequency side of $\nu = 20\, n_e/B$ Mc/s where n_e is the free electron number density in cm^{-3} (Tsytovich effect). In that case the adiabatic expansion model without synchrotron self-absorption gives

$$\nu_m \propto n_e/B \propto \rho^{-1}$$

Qualitatively the alternatives are similar, but quantitatively they differ considerably. Compare, for example, the following ratio in the two cases:

$$\left\{\frac{\dot{S}(\nu_m)/S(\nu_m)}{\dot{\nu}_m/\nu_m}\right\} = (3\gamma + 1)/2 \text{ (dispersive medium)} \qquad (17a)$$

$$= (7\gamma + 3)/(4\gamma + 6) \text{ (synchrotron self-absorption)} \qquad (17b)$$

Because for most sources $\gamma \simeq 1{\cdot}5$–$2{\cdot}5$, spectral information over a time $\sim t_0$ will enable such cases to be distinguished.

Multiple bursts. Although current spectral data are incomplete, in a few instances the spectral information is sufficient to indicate that the observed spectrum is a superposition of two or more time-varying remnants of "bursts" and a constant component with the usual inverse power law spectrum. Such is the case for 3*C* 273 and 3*C* 279, for example. Very homogeneous data, at closely spaced time and frequency intervals, will make it possible to separate the contributions of each component, to which the method here outlined can be applied to predict the evolution of the composite spectrum.

The presence of more than one variable component in a single radio source has interesting implications. It cannot be ruled out *a priori* that the magnetic field is an attendant result of the event that produced the relativistic particles, but it is simpler to regard the former as an ambient field, present before the event in which energy is released. If this were indeed the case, then the spectra would indicate that the events occur at spatially separate points. Repeated outbursts at the same position would result in the following sequence of events: the first burst sweeps out the surrounding magneto-ionic medium, leaving an explosion vacuum. Particles produced in a second burst at that point would travel in a vacuum and not radiate until they entered the expanding shell owing to the preceding event. The result would be a shift in the spectral curve towards higher frequencies and an intensity increase. The observed spectra show, however, that the frequency spectra rather than the energy spectra are superimposed. It is therefore probable that regions exist in the quasi-stellar radio sources where conditions favour the occurrence of many independent outbursts. The available data show separate components which become observable only 2–5 years apart[6]; the regions of explosive activity may therefore be only a fraction of a kiloparsec in extent. The cumulative effect of many outbursts is expected to be a non-varying radio source with a conventional spectrum[12], resulting when the expansion volumes overlap and the energy spectra are superposed.

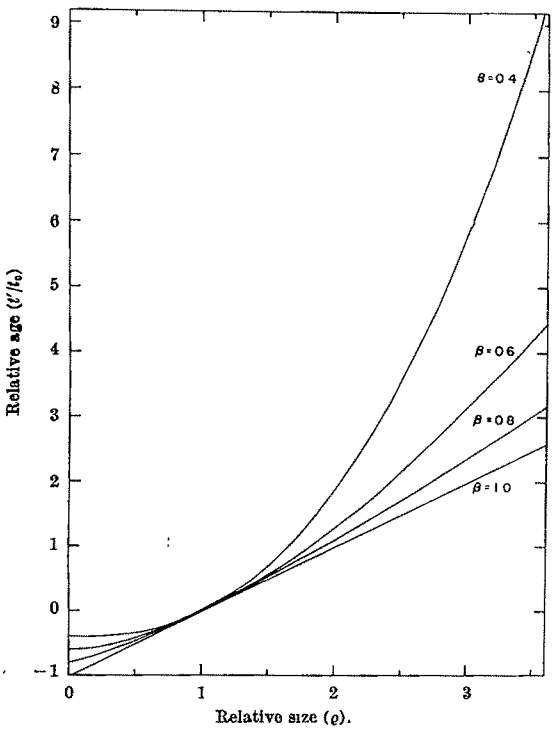

Fig. 3. The relation between the radius and the age of the source for several values of the deceleration parameter β.

Discussion. In the first instance the model is intended to account for and to predict the gross features of early radio source evolution. Departures from the predicted behaviour will occur to the extent that the complexity of the radio source exceeds that of the model. Such discrepancies will either show that the model is not related to the phenomenon observed or suggest what additional structure the model requires for a more adequate representation.

It should be noted that the higher the frequency at which the variation is detected, the shorter the time scale factor t_0. This shortens the time interval over which predicted variations can be compared and different expansion modes can be distinguished, proportionately. Millimetre and centimetre observations will yield the parameter values required to predict expected variations at longer wavelengths. Because the measurements cannot be repeated, it is highly desirable that at least two instruments are used for simultaneous observations at (nearly) equal frequencies. Systematic monitoring of the variable sources at many frequencies is necessary to acquire homogeneous data[13], so that theoretical suggestions can be tested. Optical and X-ray data are equally necessary; correlated variations at widely separated regions of the electromagnetic spectrum could shed much light on the nature of these sources. Such correlations are expected for plausible parameter ratios, where some radio photons, by inverse Compton interaction with the relativistic electrons, are converted to hard radiation.

Homogeneous radio data will make it possible to obtain reliable life times and linear diameters of the varying components. This information may then enable radio interferometry with baselines of several thousand kilometres to settle the controversial question of quasi-stellar distances.

I thank Drs. K. I. Kellermann and I. I. K. Pauliny-Toth for informative discussions and a preprint of their paper. I also thank Dr. D. S. Heeschen, director of the National Radio Astronomy Observatory, Charlottesville, for the hospitality of this institution.

ORIGIN OF METEORITES, IN THE LIGHT OF RECENT ROCKET PHOTOGRAPHY OF THE MOON AND MARS

By PROF. G. MUELLER
University of Concepcion, Chile

THE theories of the origin of meteorites have been summarized by Mason[1] and Anders[2]. Parent bodies of cometary, asteroidal or moon dimensions are visualized in the most generally discussed up to date hypothesis of genesis. Urey[3] suggests a "complex" origin through the break-up of a moon-sized object and the re-formation of smaller bodies within the range of dimension of the asteroids. Other possible theories suggesting a "complex" or "multiple" origin are (*a*) that diverse types of meteorites (irons, mesosiderites, chondrites, carbonaceous chondrites, achondrites) originate from two or more distinct types of parent bodies of markedly different dimensions; (*b*) that parent bodies of different dimensions may still produce identical or very similar types of meteorites, because certain geological processes may occur over a considerable range of conditions.

The presence of brecciated pieces of two or more of the main types within the same stone, and the existence of remarkably well defined interrelations between the volatile constituents within the stony meteorites[4,5], seem to favour, by and large, origin of all meteorites from a group of parent bodies of rather closely comparable dimensions and cosmological histories.

Attempts have been made to reconstruct the dimensions and cosmological histories of the hypothetical parent bodies on the basis of published work and a variety of observations. This article deals with certain features which, in my opinion, have been illuminated by recent rocket photography.

Implications of the observed lack of water-deposited sediments on the Moon and Mars. The absence of water-deposited sedimentary structures is, perhaps, the least controversial feature of the petrography of meteorites. This indicates that the parent body must have been too small to hold free water for prolonged periods. The actual critical gravitational mass below which water is not retained in adequate quantities and for an adequate time, under the climatological conditions which prevailed in our region of the Solar system, is not known. Preliminary analysis of the recent photographs of Mars produced by the *Mariner* space craft revealed no sedimentary structure which could readily be detected in the same scale on our planet. No trace of any layered rock appears on the photographs of the Moon from *Rangers* 7, 8 and 9, down to a resolution of some 25 cm (refs. 6 and 7). It appears, so far, that volcanic and impact features predominate on both Mars and the Moon and sediments are very subordinate or not present at all. These observations seem to indicate that a "random" assemblage of fragments from the Moon or even from Mars, of 6·620 km diameter, could resemble the meteorites in our hands, at least in respect of absence or relative scarcity of water-deposited sediments.

Comparison of statistical petrography of the Moon with that of the meteorites. It appears that the distribution of inferred rock-types on the Moon surface differs to a considerable degree from that represented in our present collection of meteorites.

Nothing is seen of the high albedo of nickel-iron or even of material of mesosideritic composition on any of the lunar photographs, down to stones 10 in. across. This would seem to indicate that nickel-iron may be present on the surface of the Moon either in fractional percentages or not at all. As against this, the parent body—or mean of parent bodies—produced an overall percentage of approximately 6 per cent nickel-iron and 2 per cent mesosideritic fragments[1].

The literature would seem to lead to the conclusion that the chondritic meteorites have a tuff-like structure, formed through processes resembling terrestrial eruptions of ash or welded tuff, at least to the degree of the accumulation of finely divided matter from a gaseous suspension, that is, a cloud. The achondrites, on the other hand, seem to originate from molten lavas or intrusions. 954 chondrites and 64 achondrites are known to date[1], the latter forming only about 7 per cent of the stony meteorites. According to Kuiper[6], it appears from photographs of the Moon that its surface has lava flows far in excess of the 7 per cent indicated, as a first approximation, for the parent body of the meteorites. In this connexion it should be mentioned that the fact that the "fragments" may originate from locations deeper in the parent body, which may afterwards have become covered by debris, or from rare but exceptionally violent volcanic activity, may tend to change the proportion of the petrographical types, compared with their distribution on the surface. Judging from the terrestrial features of igneous structures, however, we would anticipate an even greater proportion of lavas from the deeper zones of the parent body.

It seems that the tuff lava ratio on the Moon may prove to be intermediate between that of the Earth and that indicated for the parent bodies of meteorites. An explanation of this might be that the parent bodies of the meteorites were objects smaller than the Moon. It may be expected that with the decreasing dimensions of a celestial body, its tuff lava ratio would tend to increase (*a*) if cooling occurred relatively soon to temperatures below the melting-point of silicates, before degassing reached an advanced stage, or (*b*) if escape of gases from the interior is impeded by the lower gravitational field. The second factor caused the formation of better preserved, solidified spray particles, the chondri[4].

Kuiper[6] showed that collapse structures are prominent in the higher-resolution photographs of the Moon. This indicates that the material just beneath the surface of the Moon consisted of numerous cavities and the partial collapse of these formed the karst-like structures. Although most of the meteorites contain a considerable volume of microscopic pores, no larger partially collapsed vesicles are seen in any of the achondrites although such structures abound in all the terrestrial lavas and even the shallow intrusives.

Some of the lunar lava flows are markedly red (apart from the observed red phosphorescence), indicating the presence of tri-valent iron. None of the thousand or so available meteorites contains enough tri-valent iron to account for the observed red colour which is characteristic of a significant percentage of the total lunar surface.

Mechanical properties of lunar rocks. It was estimated by Kuiper[6], from the size and apparent partial burial of loose rocks on the lunar surface, that the average lava flow floor of the maria supports about 1 ton/ft.^{2}. In this connexion it is worth noting that great diurnal changes of temperature and bombardment by micrometeorites may cause the fragmentation of rocks, leading to the impression of a deeper burial than the original penetration of the surface, and it is possible that the lunar surface in question may be stronger. The same factor may also contribute to the apparent rounding of the fissures, rilles, which were interpreted by Kuiper[6] as indications of a rather softer surface material.

It would appear that experiments on the behaviour of diverse terrestrial igneous rocks and meteorites in re-

peated changes of temperature of the lunar range must be completed before we can obtain the necessary information regarding the mechanical properties of the different types of surface of the Moon. Another experiment, which seems technically feasible in the future, could be the ejection through a recoil mechanism of a small explosive charge some 10–30 sec before the impact of the space craft. If the charge leaves the space craft in the direction of its motion with, say, an additional velocity of 1 km/sec, the results of the impact and explosion of the charge could be photographed with the subsequent frames of the space craft. Photographs of the explosion of similar charges in different types of rocks and meteorites, or objects with simulated mechanical properties of these, may give us a clearer impression of the mechanical properties of the surface of the Moon, and also which rock or meteorite these resemble the most closely.

Contributions to the problem of origin of carbonaceous chondrites. The smooth transition between chondrites and carbonaceous chondrites as well as the considerable uniformity of the group seem to indicate[4] that these latter may have formed in the close-to-surface zones of the parent bodies of the rest of the meteorites. They subdivide into three rather well distinguishable zones, the zone of the parent body closest to the surface producing the Type 1 carbonaceous chondrites, which are characterized by the highest volatile content with 3·54 per cent carbon and 20·08 per cent water. Type 2 stones, with 2·46 per cent carbon and 13·35 per cent water, and Type 3 stones, with 0·46 per cent carbon and 0·99 per cent water[5], may originate from successively deeper zones of the parent body, which were heated to correspondingly higher temperatures in the course of their cosmological history. All the twenty-five or so stones hitherto recorded consist of a porous ground mass of hydrated silicates and carbonaceous matter in which are embedded the mainly globular grains of high temperature minerals: olivine, pyroxene, magnetite, troilite, some nickel-iron, etc. It is possible that their markedly loose consistency causes a high proportion of these stones to disintegrate during fall and the overall percentage in space may be considerably larger than the 2 per cent attributed to them on the basis of their observed falls.

The Type 1 stones, as well as some of the Type 2, contain some magnesium sulphate and also some gypsum, the salts of which readily form white efflorescences on the surface of the stones. In this connexion, the white snow-like substance on the peak of the Alphonsus crater was interpreted by Kuiper[6] as a fumarola product which traversed the apparently tuff-like material of pyroclastics. Kuiper further drew attention to the interesting terrestrial analogy of a white efflorescence after the eruption of the Laimana volcano on Hawaii, which proved to consist of gypsum and "a compound of calcium oxide". It is also worth noting that the salts in Type 1 meteorites were interpreted[4] as of fumarolic origin on the grounds that, like terrestrial fumaroles, they contain minute grains of iron sulphides, mainly FeS in the meteorites and mainly FeS_2 in terrestrial rocks, as a result of reactions between the Fe^{++} of the ash and the hydrogen sulphide and sulphur vapours which traverse it. In the terrestrial "evaporite" type, salt deposits such as crystals of iron sulphide are not at all characteristic. It appears that these salt-impregnated ashes can be found in abundance on all these relatively small celestial bodies, in which there is inadequate water to leach them out and eventually to re-deposit them in oceans or in smaller accumulations of water. It would appear that this feature, which is common to certain lunar rocks and the carbonaceous chondrites, does not necessarily indicate a lunar origin for the chondrites.

A high proportion of the Type 2 and Type 3 carbonaceous chondrite material contains too low a percentage of salts for these to appear as efflorescences. Certain vague criteria may, however, enable us to distinguish some indications for carbonaceous material. For example, certain types of carbonaceous complexes might be expelled through solar distillation, and the resulting more graphitized residues would give the rock a darker appearance, or, if the carbonaceous material were highly volatile, the rock might be leached. There is hardly a carbonaceous rock on the surface of our planet which would not show some change of shade on exposure. In the case of the Moon, portions of the craters and other inclinations which are more shaded or more heated by the Sun may show different shades, but such features are not evident from the lunar photographs taken. Another point worth noting is that the basic silicates in a finely divided form, that is, as pyroclastics, are markedly lighter than their fused (lava) equivalents, whereas carbonaceous rocks do not show such a strong tendency to become lighter in shade with sub-division. The fact that some of the minor craters on the floors of maria are seen surrounded by considerably darker ejecta seems to indicate, rather, more intensive darkening with fusion, characteristic of silicates without a high proportion of carbonaceous matter.

Conclusions. It appears that not all or even the majority of the meteorites are of lunar origin; however, it should be emphasized that the evidence noted and discussed here is of an inconclusive nature. The main aim of the present article is rather to create interest in the interpretation of rocket photographs of the Moon and other celestial bodies, in considering the problem of the origin of meteorites. It is possible that the petrography and other geological aspects of celestial bodies may prove to depend essentially on a few parameters such as mass, temperature and other properties of the material in the course of condensation, etc. We must look for additional clues in the specification of the parent bodies of meteorites to help us to establish the main laws governing the condensation of matter, that is, what we may term "cosmic geology".

ELECTRIC AND THERMAL CONDUCTIVITY OF A MEDIUM CONTAINING ARRAYS OF SPHERICAL AND CYLINDRICAL PARTICLES

By D. S. PARASNIS

Department of Geophysical Research, Boliden Mining Co., Sweden

THE problem of finding the effective electric conductivity of an infinite medium loaded with spherical or cylindrical particles was proposed by Clerk Maxwell[1]. Interest in the problem has revived recently because of its wide applicability[2,3]. For a cubic array of spherical particles (conductivity σ_1) embedded in a matrix (conductivity σ_0) Maxwell obtained the expression

$$\sigma/\sigma_0 = \frac{(2-2f)\varkappa + 1 + 2f}{(2+f)\varkappa + 1 - f} \qquad (1)$$

for the effective conductivity σ of the composite medium. Here f is the fractional volume occupied by the particles and $\varkappa = \sigma_0/\sigma_1$. Putting $\varepsilon = (1 - f)/f$ where ε is the "voids-ratio" (ratio of the matrix volume to particle volume in a unit cell) equation (1) reduces to

$$\sigma/\sigma_0 = \frac{2\varepsilon\varkappa + 3 + \varepsilon}{(2\varepsilon + 3)\varkappa + \varepsilon} \qquad (2)$$

The same expression has been derived by other methods[2].

Maxwell emphasizes that equation (1) is essentially true only for small values of f (large dilutions). The equation was improved on by Lord Rayleigh by taking into consideration the effect of neighbouring particles and further by Meredith and Tobias[3].

Equations (1) and (2) and their improved versions fail to reveal the essential discontinuity in σ for perfectly conducting spheres as $f \to \pi/6$, that is when the gaps between the spheres tend to zero. J. Keller[4] re-examined the problem and derived the result, valid near the singularity, that

$$\sigma/\sigma_0 = -(\pi/2)\ln[\tfrac{1}{2}(4\pi/3f)^{\frac{1}{2}} - 1] + \ldots, (\pi/6) - f \ll 1 \qquad (3)$$

For $f = 0{\cdot}5161$, equation (3) yields $\sigma/\sigma_0 = 7{\cdot}65$ which agrees with the experimental value (7·6) of Meredith and Tobias. (Their calculations give 5·8, Rayleigh's 4·6 and equations (1) or (2) 4·3 for this case.)

For a square array of perfectly conducting cylinders (Fig. 1) Keller derived an analogous expression, namely,

$$\sigma/\sigma_0 = \pi[(\pi/f)^{\frac{1}{2}} - 2]^{-\frac{1}{2}} + \ldots, (\pi/4) - f \ll 1 \qquad (4)$$

He also proved the general theorem that for any value of f, σ/σ_0 for a medium containing a square array of non-conducting cylinders is the reciprocal of σ/σ_0 for the same array of perfectly conducting cylinders.

H. B. Keller and Sachs[5] modified equation (4) by estimating its second term, which they state as "approximately $-1{\cdot}95$". They also attacked the present boundary value problem by the finite difference method and calculated a table of σ/σ_0 using the IBM 7090 computer.

Neither Keller nor Keller and Sachs cite any experiments on cylindrical particles in support of their calculations. This test has been undertaken in our laboratory and the results are discussed below.

Curve 1 in Fig. 2 shows σ/σ_0, calculated by Keller and Sachs, for a medium containing non-conducting cylinders. The abscissa in the figure is the ratio y/a (gap/radius, compare Fig. 1). We have $f = \pi a^2/(y + 2a)^2$ where a is the radius of the cylinders. Curve 2 is drawn after the Keller-Sachs modified form of equation (4). For $y/a < \sim 0{\cdot}3$ it differs insignificantly from curve 1. Strictly speaking, curve 2 cannot represent a correct solution in any range since its asymptote for $y/a = \infty$ is 0·27 instead of 1·00.

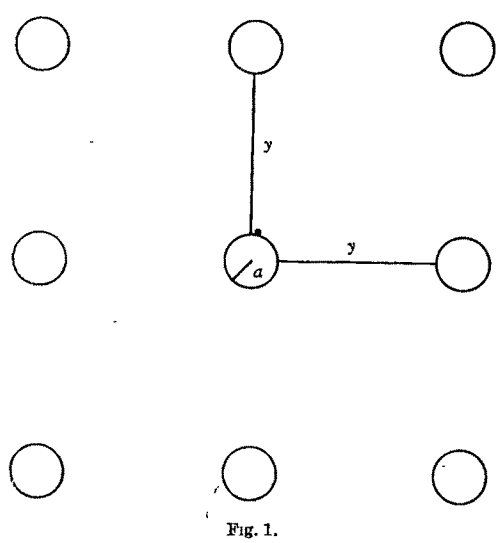

Fig. 1.

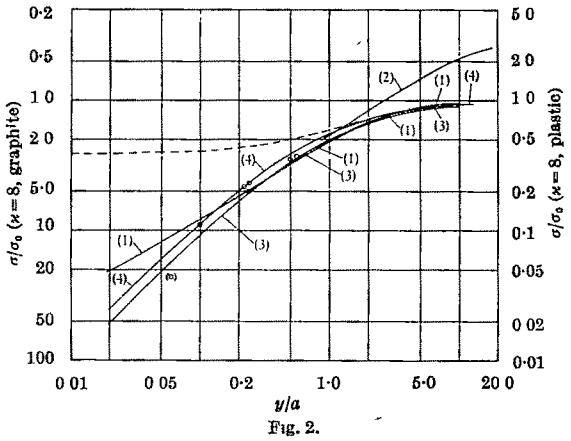

Fig. 2.

The experimental points obtained in the laboratory in measurements on blocks of accurately machined plastic and graphite rods (diameter 10 mm, mounted in a square array on a basal plate) are shown in Fig 2 by circles. (The results on plastic and graphite rods may be plotted on the same diagram in view of Keller's theorem.)

It should be noted that the various points do not fall on curve 1 and it seems that the observed σ/σ_0 for $y/a < \sim 0{\cdot}2$ is systematically less, and for $y/a > \sim 0{\cdot}2$ systematically greater, than the value calculated by Keller and Sachs. The position of the point for $y/a = 0{\cdot}06$ is uncertain since the gap in this case could not be measured accurately Also, there is some doubt whether all the gaps in this block were absolutely equal, although metal foils of appropriate thickness, which were later removed, were inserted as usual between the rods during the construction of the block. If the observed point for $y/a = 0{\cdot}06$ is to fall on curve 1 the nominal width of the gaps must be larger than the effective mean width by a factor of between 3 and 4. An error of this size is conceivable but unlikely.

As an alternative approach to explaining the experimental results the conductivity formula derived[2] by the "self-consistent" method was tried. For a medium containing cylindrical particles we have:

$$\sigma/\sigma_0 = \frac{\varepsilon\varkappa + 2 + \varepsilon}{(\varepsilon + 2)\varkappa + \varepsilon} \qquad (5)$$

For $\varkappa \to 0$ (perfectly conducting cylinders) equation (5) reduced to

$$\sigma/\sigma_0 = 1 + (2/\varepsilon) \qquad (6)$$

It is obvious furthermore that the solution (5) satisfies Keller's theorem since σ/σ_0 for $\varkappa = \infty$ (non-conducting cylinders) is equal to $\{1 + (2/\varepsilon)\}^{-1}$.

At first sight it seems plausible to put $\varepsilon = (1/f) - 1 = 4\pi^{-1}\{1 + (y/2a)\}^2$; however, this substitution in (6) yields the broken curve in Fig. 2 which is definitely not the correct solution. The following explanation can be adduced for this failure.

The assumption concerning the voids-ratio ε implies a current flow that is perpendicular to the plane of Fig. 1 (along the axial direction of the cylinders). But ε as experienced by a current which is flowing perpendicular to the axial direction must be of the form $\varepsilon = \alpha_1 (y/a) + \alpha_2(y/a)^2 + \ldots$ where α_1, α_2, ... are factors of a geometrical nature. For cylinders in contact with each other, this expression yields $\varepsilon = 0$ and hence the correct limit $\sigma/\sigma_0 = \infty$.

Retaining only the first term in the proposed expression for ε the curves 3 and 4 in Fig. 2 were calculated by postulating $\varepsilon = 2(y/a)$ and $\varepsilon = (8/\pi)(y/a)$. Thus

$$\sigma/\sigma_0 = 1 + 1/(y/a) \text{ for curve 3} \qquad (7a)$$

$$\sigma/\sigma_0 = 1 + (\pi/4)/(y/a) \text{ for curve 4} \qquad (7b)$$

The two curves enclose a narrow strip. Moreover, all the observed points except the doubtful one for $y/a = 0{\cdot}06$ lie between them. It appears then that the mean of the

conductivities given by the simple semi-empirical formulas (7*a*) and (7*b*) is as good a practical approximation to the effective conductivity of a medium containing a square array of perfectly conducting cylinders, as the value obtained[5] from the considerably more complicated expressions of Keller and Sachs, Rayleigh, and Runge. The position of the point for $y/a = 0{\cdot}06$ seems to indicate that equations (7*a*) and (7*b*) may even be nearer to the truth, over the entire range of y/a, than any of the expressions proposed so far. This question cannot be settled, however, without measurements on arrays of nearly touching parallel cylinders.

It was also of interest to look for the physico-geometrical significance of the two postulates $\varepsilon = 2\ (y/a)$ and $\varepsilon = (8/\pi)\ (y/a)$.

The gist of the self-consistent method is that we fix attention on a single particle of the array and consider it to be uniformly coated with a film (of conductivity σ_0) the thickness of which depends on the voids-ratio ε, and the composite particle is supposed to be embedded in a homogeneous medium of conductivity σ, which is to be determined from the boundary conditions at the sphere-film and film-medium interfaces. The details are given in ref. 2.

Let b be the radius of the film coating the cylindrical particle of radius a so that the thickness of the film is $t = b - a$. Then the voids-ratio $\varepsilon = (b^2 - a^2)/a^2$, from which $t = \{a^2(1 + \varepsilon)\}^{\frac{1}{2}} - a$.

For $\varepsilon = 2y/a$, $t = \{a(a + 2y)\}^{\frac{1}{2}} - a$. In Fig. 3, RP = a, MR = y, and PQ is perpendicular to RR′ meeting the semicircle with RR′ ($= 2y + 2a$) as diameter. Since PR′ $= 2y + a$, PQ $= \{a(a + 2y)\}^{\frac{1}{2}}$. Hence SQ = S′Q′ represents the thickness t of the fictitious cylindrical film by which a single particle may be supposed to be coated in being embedded in a medium of conductivity σ.

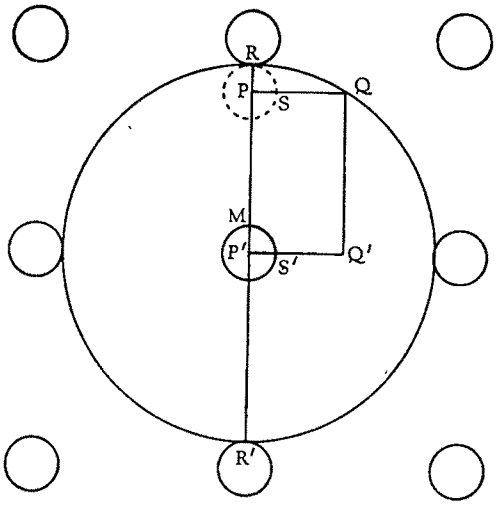

Fig. 3.

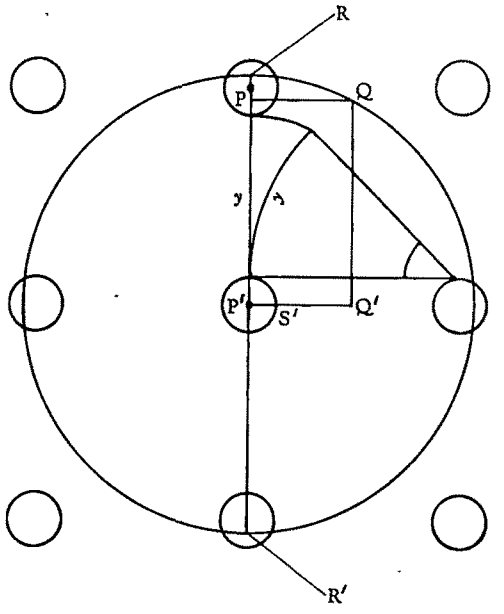

Fig. 4.

For $\varepsilon = (8/\pi)\ (y/a)$, $t = \{a(a + 8y/\pi)\}^{\frac{1}{2}} - a$. The construction in Fig. 4 is similar to that in Fig. 3 except that MR $= (4/\pi)y$ and hence is equal to the radius of the circle in which an arc of length MR subtends an angle of $\pi/4$ at the centre.

There is no potential-theory explanation for the apparently plausible forms postulated for ε. In any case, the agreement with experimental results indicates that the coefficient of y/a in equations (7*a*) and (7*b*) lies between 1 and $4/\pi$.

A simple modification of equation (2) (for spheres) on these lines does not, on the other hand, lead to any improvement over the expression obtained by Meredith and Tobias[3] for large gaps and by J. Keller[4] for vanishingly small gaps between the spheres. Moreover, equation (2) yields the result that for an array of perfectly conducting spheres σ/σ_0 is the reciprocal of the same array of non-conducting spheres for all ε. This is obviously false. A more sophisticated form of the self-consistent method is probably needed in this case.

The calculations and experiments reported here were made in the course of scale model work on resistivity prospecting methods, the expenses of which were defrayed from a grant from the State Technical Research Council in Sweden.

PRESSURE DISTRIBUTION IN A PLANE FLUID FILM SUBJECTED TO NORMAL SINUSOIDAL EXCITATION*

By Dr. J. B. HUNT
Department of Mechanical Engineering, University of Southampton

Consider a plane circular bearing comprising two parallel disks of radius R, distance h apart. A lubricating fluid at atmospheric temperature and pressure completely fills the space between the disks.

* The following notation is used throughout this article: R, bearing radius; p, pressure, u, v, w, linear velocity components; r, z, cylindrical polar co-ordinates, μ, absolute viscosity; ν, kinematic viscosity, ϱ, density; h, film thickness: ω, frequency of excitation; a, amplitude.

Then using cylindrical polar co-ordinates with axial symmetry the equations of motion for an element of the incompressible fluid are

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial r} + w\frac{\partial u}{\partial z} = -\frac{1}{\rho}\cdot\frac{\partial p}{\partial r} + \nu\left(\nabla^2 u - \frac{u}{r^2}\right) \quad (1)$$

$$\frac{\partial w}{\partial t} + u\frac{\partial w}{\partial r} + w\frac{\partial w}{\partial z} = -\frac{1}{\rho}\cdot\frac{\partial p}{\partial z} + \nu\nabla^2 w \qquad (2)$$

and the continuity equation is

$$\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z} = 0 \qquad (3)$$

Eliminating p between 1 and 2

$$\frac{\partial}{\partial t}\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial r}\right) + u\frac{\partial^2 u}{\partial r\partial z} + \frac{\partial u}{\partial r}\cdot\frac{\partial u}{\partial z} + w\frac{\partial^2 u}{\partial z^2} + \frac{\partial w}{\partial z}\cdot\frac{\partial u}{\partial z} - u\frac{\partial^2 w}{\partial r^2} - \frac{\partial u}{\partial r}\cdot\frac{\partial w}{\partial r} - w\frac{\partial^2 w}{\partial r^2} - \frac{\partial w}{\partial r}\cdot\frac{\partial w}{\partial z} = \nu\left[\nabla^2\frac{\partial u}{\partial z} - \frac{1}{r^2}\cdot\frac{\partial u}{\partial z} - \nabla^2\frac{\partial w}{\partial r}\right] \qquad (4)$$

Now consider one surface to be moving normally in such a way that its position ε at any instant is given by

$$\varepsilon = h + a\sin\omega t \qquad (5)$$

Thus the boundary conditions are

$$\left.\begin{aligned} u = w = 0 \text{ at } z = 0 \quad &\text{(i)} \\ u = 0,\ w = a\,\omega\cos\omega t \text{ at } z = \varepsilon \quad &\text{(ii)} \end{aligned}\right\} (6)$$

From 6(ii) it can be seen that an r independent form for w is required, so that the equation

$$\frac{\partial}{\partial r}\left(\frac{\partial u}{\partial r} + \frac{u}{r}\right) = 0$$

has to be satisfied.

The general solution is $u = Ar + B/r$. But at $r = 0$, $u = 0$, and therefore $B = 0$.

So let $u = \dfrac{\partial}{\partial z}u_0(z,t)\,r$

Therefore, $w = -2u_0$ from 3.

Expanding 4 in full and ignoring second-order terms

$$\frac{\partial}{\partial t}\cdot\frac{\partial^2 u_0}{\partial z^2}\cdot r - 2u_0\frac{\partial^2 u_0}{\partial z^2}r = \nu\left(\frac{\partial^3 u_0}{\partial z^3} + r\frac{\partial^4 u_0}{\partial z^4}\right) \qquad (7)$$

Comparing coefficients of r

$$\frac{\partial}{\partial t}\cdot\frac{\partial^2 u_0}{\partial z^2} - 2u_0\frac{\partial^3 u_0}{\partial z^3} = \nu\frac{\partial^4 u_0}{\partial z^4} \qquad (8)$$

It is necessary to make a tentative solution for u_0. Since u_0 and $\dfrac{\partial u_0}{\partial z}$ both vanish at $z = 0$, z^2 is a factor of u_0 and so

$$u_0 = z^2\varphi_0 + z^3\varphi_1 + \ldots. \qquad (9)$$

where φ is a function of t only. Equation 8 may therefore be expanded in full, and comparing coefficients of z,

$$\left.\begin{aligned} 2\dot{\varphi}_0 &= 24\,\nu\,\varphi_2 \quad &\text{(i)} \\ 6\dot{\varphi}_1 &= 120\,\nu\,\varphi_3 \quad &\text{(ii)} \\ 12\varphi_2 - 12\varphi_0\varphi_1 &= 360\,\nu\,\varphi_4 \quad &\text{(iii)} \end{aligned}\right\} (10)$$

The boundary condition at $z = \varepsilon$ has still to be satisfied. Suppose for the time being that the successive terms of the series decrease in magnitude and solve for φ_0 and φ_1 by equating u_0 to $\frac{1}{2}a\,\omega\cos\omega t$ and $\dfrac{\partial u_0}{\partial z}$ to zero. Thus

$$(h + a\sin\omega t)^2\varphi_0 + (h + a\sin\omega t)^3\varphi_1 = \tfrac{1}{2}a\,\omega\cos\omega t$$

and

$$2\varphi_0 + 3(h + a\sin\omega t)\varphi_1 = 0$$

whence

$$\varphi_0 = \frac{3a\,\omega\cos\omega t}{2(h + a\sin\omega t)^2}$$

and

$$\varphi_1 = \frac{-a\,\omega\cos\omega t}{(h + a\sin\omega t)^3}$$

Therefore $\varphi_2 = \dfrac{-a\omega^2}{8\nu}\left[\dfrac{h\sin\omega t + a(1 + \cos^2\omega t)}{(h + a\sin\omega t)^3}\right]$

Now each term in u_0 achieves a maximum value when $z = \varepsilon$ and thus the magnitude of the third and first terms is, relatively,

$$\left|\frac{a\omega^2}{8\nu}[h\sin\omega t + a(1 + \cos^2\omega t)](h + a\sin\omega t)\right|$$

and

$$\left|\frac{3}{2}a\,\omega\cos\omega t\right|$$

Now write $\dfrac{h}{a} = \lambda$ and then consider the maximum value of

$$V = (\lambda\sin\theta + 1 + \cos^2\theta)(\lambda + \sin\theta)$$

so that $\dfrac{dV}{d\theta} = \cos\theta\,(\lambda^2 + 2 - 3\sin^2\theta)$

Now since $\lambda > 1$, $\lambda^2 + 2 > 3$ and therefore the factor in brackets can never be zero, and the maximum and minimum values of V occur when $\cos\theta$ is zero, in which case $\sin\theta = \pm 1$. The maximum is clearly when $\sin\theta = 1$ so that $V_{max} = (\lambda + 1)^2$. Consequently the ratio of the maxima of the third to first terms is $(\omega/12\,\nu)(h + a)^2$, which is certainly small in this case.

Similar arguments apply to the higher terms in the series for u_0. Thus those terms in the expression for u_0 may be safely neglected so that

$$u_0 = \tfrac{1}{2}a\,\omega\cos\omega t\left[\frac{3z^2}{(h + a\sin\omega t)^2} - \frac{2z^3}{(h + a\sin\omega t)^3}\right] \qquad (11)$$

$$\text{Thus } u = \tfrac{1}{2}a\,\omega\,r\cos\omega t\left[\frac{6z}{(h + a\sin\omega t)^2} - \frac{6z^2}{(h + a\sin\omega t)^3}\right] \qquad (12)$$

Substituting in equation 1,

$$\frac{1}{\rho}\cdot\frac{\partial p}{\partial r} = \frac{3r(a\,\omega\cos\omega t)^2}{(h + a\sin\omega t)^2} - \frac{6a\,\omega\,r\,\nu\cos\omega t}{(h + a\sin\omega t)^2}$$

Integrating

$$p_{max} = \frac{\frac{3}{2}R^2\rho(a\,\omega\cos\omega t)^2}{(h + a\sin\omega t)^2} - \frac{3a\,\omega\,R^2\mu\cos\omega t}{(h + a\sin\omega t)^3} \qquad (13)$$

The maximum value of the second term in this expression is very much greater than the corresponding maximum of the first term, so that when maximum pressures are considered the second term only need be taken into account.

This can be written

$$\frac{p_{max}}{\mu\omega} = -3\left(\frac{a}{h}\right)\left(\frac{R}{h}\right)^2\cos\omega t\left[1 - 3\left(\frac{a}{h}\right)\sin\omega t\right] \qquad (14)$$

Now if $\dfrac{p_{max}}{\mu\omega}$ is plotted against ωt for a fixed value of $\dfrac{R}{h}$ (= 1,000) and varying values of $\dfrac{a}{h}$, Fig. 1 is obtained. It can be seen that for all values of $\dfrac{a}{h}$ the greatest negative pressure occurs, at 330°, and the greatest positive pressure at 210°. So that the maximum pressures are given by

$$\frac{p_{max}}{\mu\omega} = \pm 2{\cdot}6\left(\frac{a}{h}\right)\left(\frac{R}{h}\right)^2\left[1 + 1{\cdot}5\left(\frac{a}{h}\right)\right] \qquad (15)$$

When the non-dimensional factor $\frac{p_{max}}{\mu\omega}$ is plotted against $\frac{a}{h}$ for varying values of $\frac{R}{h}$ Fig. 2 is obtained.

From a practical point of view the two extreme values of p_{max}, the maximum positive and maximum negative values, are of interest. Apart from the obvious examples of thrust and collar bearings, situations similar to that considered theoretically can arise in gear teeth and journal bearings. Consider a pair of meshing gear teeth under load separated by an oil film of 10^{-4} in. If the natural frequency of one of the gear teeth is 3 kc/s, typically, the dimension R for an equivalent circular area of contact is 0·25 in., the lubricating oil viscosity is 5×10^{-6} Reyn and the ratio of vibration amplitude to oil film thickness $\frac{a}{h}$ is $\frac{1}{10}$, then from Fig. 2, p_{max} is 24,000 lb./in.^{2}. This pressure on the tooth face is unlikely to cause damage, but it can be seen that any slight variation in any of these parameters could bring the stress level up to that which could cause a short fatigue life. Before an amplitude/thickness ratio of $\frac{1}{10}$ is reached, however, an even more dangerous condition could be encountered, that is the condition of cavitation in the fluid. In this case cavitation will commence when $\frac{p_{max}}{\mu\omega} = 10^3$. It can be seen from Fig. 2 that cavitation would occur with $\frac{a}{h}$ ratios of much less than 10^{-3}. This means that cavitation and the subsequent fatigue damage would, in practice, be unavoidable in this particular case.

Experimental Work

It was decided to check the validity of equation 15 by observing the onset of cavitation in a fluid in circumstances similar to those outlined in the analysis. A mild steel plate of $\frac{3}{8}$ in. diameter polished to 2μ in. was rigidly fixed. A similar mating plate was attached to the thrust rod of an electromagnetic vibrator in such a way that it was parallel to the fixed plate and that its distance from the fixed plate could be varied within the range 0–0·010 in. The two plates were immersed in a liquid contained in a transparent vessel. It was intended to observe the onset of cavitation characterized by the formation of bubbles in the fluid at the centre of the bearing by the naked eye. It was found that for film thicknesses less than 2×10^{-3} in. the onset of the formation of bubbles could not easily

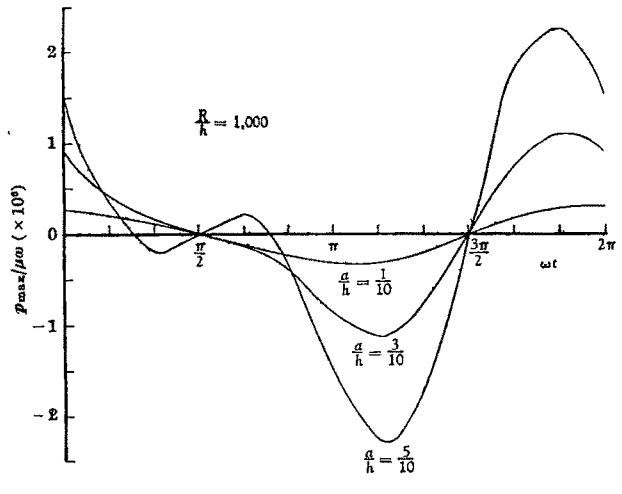

Fig. 1.

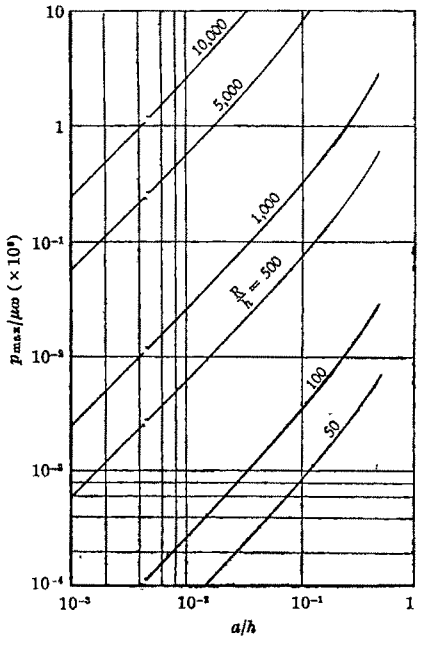

Fig. 2.

be distinguished. It was therefore out of the question to test, by this method, films of the thicknesses actually found in gears. It was decided, however, that the curves in Fig. 2 could still be checked experimentally over a useful range. The film thicknesses and amplitudes of vibration were measured by capacitance probes. The fluids used in the experiment were 'Shell Tellus 27', 'Shell Vitrea 79', gas oil, liquid paraffin (B.P.) and tap water. The viscosities of these liquids are evenly spaced throughout the range 10^{-1} to $10^2 \times 10^{-6}$ Reyn at 20° C.

It was found that the experimental values of $\frac{a}{h}$ at which cavitation occurred tended to be up to 20 per cent higher than the theoretical values at the lower ratios. This is because the criterion for the onset of cavitation was that cavitation was deemed to occur at that amplitude at which a bubble would span the gap between the plates. It is undoubtedly true that cavitation had occurred before this stage was reached, but it was not measurably evident.

After allowing vigorous cavitation to ensue for about 10^6 cycles of lateral excitation extensive "pitting" damage was present on both plate surfaces. The moving plate was replaced by a $\frac{1}{2}$ in diameter steel ball at a later stage in the experimental work; this enabled a gap of 10^{-4} in. to be easily maintained. Cavitation could not be observed in such a small gap, but by allowing vibration to proceed for 10^6 cycles again extensive damage was caused to the mating surfaces.

The intention now is to increase R, μ and ω so that stress levels high enough to cause surface damage will be imposed on the plate centres. But, even so, it may be difficult to decide whether damage is caused by the high stress levels or by cavitation though possibly at high frequencies the onset of cavitation may be suppressed. It is also intended to produce more realistic gear tooth conditions by using a two-disk machine, one disk of which would be caused to vibrate in a diametral direction. In this way the normal excitation of very thin films can be studied. In order to improve the accuracy of the detection of cavitation an attempt will be made to detect the noise which ensues when a bubble collapses.

I thank the Science Research Council for financial support and Mr. A. J. Sherin of the Dynamic Analysis Laboratory, University of Southampton, for practical assistance.

BINDING OF CALCIUM, YTTRIUM AND THORIUM TO A GLYCOPROTEIN FROM BOVINE CORTICAL BONE

By DR. A. R. PEACOCKE and P. A. WILLIAMS
University of Oxford, Nuffield Department of Clinical Biochemistry, Radcliffe Infirmary, Oxford

THERE is a considerable radiobiological interest in those elements which, when they reach the blood stream, have an affinity for bone. These have been called "bone-seeking" isotopes and include strontium[1], yttrium[2], americium[3], radium[4], plutonium[3,5] and thorium[6]. The exact distribution of these elements in the bone varies. Strontium and radium are concentrated on active surfaces beneath the osteoid border and are spread diffusely throughout the bone mineral, probably replacing calcium isomorphously in the growing apatite lattice[7]. Americium and yttrium, on the other hand, are mainly taken up on the resting and resorbing surfaces of the bone[3,8] and plutonium is concentrated particularly on the endosteal resorbing surfaces[3,5]. However, the surfaces on which yttrium, americium and plutonium are deposited all react strongly in the periodic acid–Schiff (PAS) staining procedure. It has been suggested that this procedure is specific to materials containing carbohydrates[9] and consequently the binding of these elements in bone has been linked with the possible presence of a carbohydrate moiety in the matrix at the resting and resorbing surfaces[10].

Herring and Kent[11] have isolated four fractions containing carbohydrate residues from bovine cortical bone, one of which is a glycoprotein containing about 20 per cent by weight of sialic acid, which has been named bone sialoprotein. The chemical[12,13] and physical properties[14] of this substance have been described. We now report studies of the binding of bone-seeking metal ions to this sialoprotein, extracted from bone by the ethylene diamine tetra-acetic acid method[12].

The binding of yttrium and calcium has been studied by a titration method similar to that reported by Gilbert and Myers[15]. The titration curves of bone sialoprotein were determined in the presence of increasing concentrations of yttrium chloride (0·1–20 mM) and at one concentration of calcium chloride (40 mM), with sufficient sodium chloride present to bring the ionic strength up to 0·2. Bone sialoprotein (about 6 mg in 5 ml.) solutions were titrated under an atmosphere of nitrogen within the *p*H range 2·2–10·5 (accuracy of *p*H measurement ± 0·002 units). Water corrections were made and the hydrogen ions bound to bone sialoprotein were calculated. All titrations were found to be completely reproducible and reversible. Titrations in the presence of Y^{3+} were only carried out in the range *p*H 5–2·2 because at *p*H > 5 there was precipitation of either hydrated oxide or a complex of yttrium and the glycoprotein. The depression of *p*H, ΔpH, caused by the metal ions, was taken to be the result of competition between metal ions and hydrogen ions for negative sites on the glycoprotein, that is, carboxylate anions, and depends on the degree of binding. The degree of binding, a_m, defined as the fraction of total carboxyl groups to which metal ions were bound, was calculated from the value of ΔpH at constant hydrogen ion binding and this was determined as the difference, parallel to the *p*H axis, between the titration curves in the presence of Ca^{2+} or Y^{3+} and that in the presence of 0·2 *M* sodium chloride alone. Two assumptions were made: (i) that the titration of carboxyl groups could be represented by the expression

$$pK_0 = p\mathrm{H} - \log\frac{\alpha}{1-\alpha} + f(Z, \mu, s)$$

where K_0 is the intrinsic dissociation constant of the bone sialoprotein carboxyl groups, α is the average degree of dissociation and f (Z, μ, s) is a function of charge (Z), ionic strength (μ), and a shape factor (s): (ii) that binding of a metal ion caused a neutralization of charge on bone sialoprotein equal to its own charge. Calculation of the binding is possible because $[f(Z, \mu, s) - pK_0]$ can be determined empirically from the titration curves, typical examples of which are shown in Fig. 1.

The dependence of the binding (a_m) of yttrium and calcium on *p*H is shown in Fig. 2, and it can be seen that

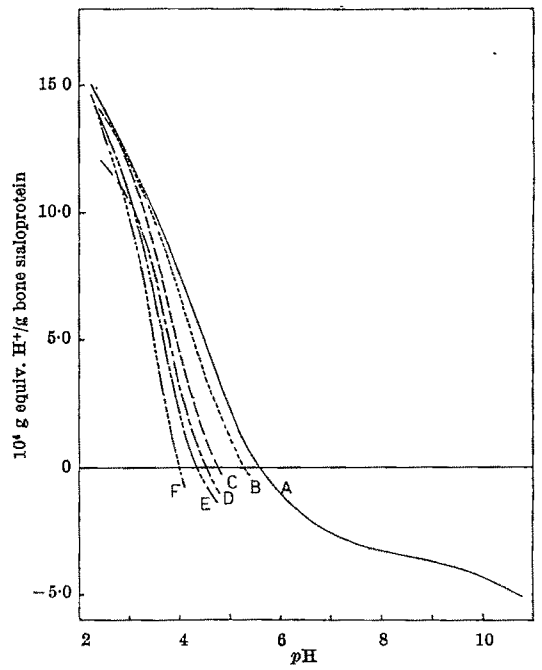

Fig. 1. Titration curves of bone sialoprotein at 25° C. Ionic strength 0·2. *A*, 0·2 M sodium chloride; *B*, 0·1 mM yttrium chloride + 199 mM sodium chloride; *C*, 0·5 mM yttrium chloride + 197 mM sodium chloride; *D*, 1 mM yttrium chloride + 194 mM sodium chloride; *E*, 3·25 mM yttrium chloride + 180 mM sodium chloride; *F*, 20 mM yttrium chloride + 80 mM sodium chloride.

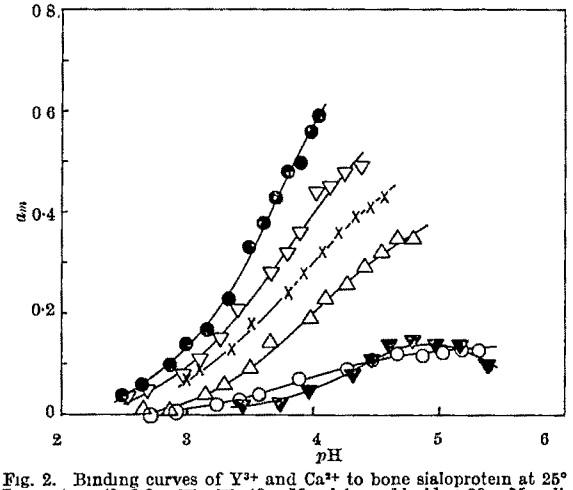

Fig. 2. Binding curves of Y^{3+} and Ca^{2+} to bone sialoprotein at 25° C. Ionic strength 0·2. ▼—▼, 40 mM calcium chloride + 80 mM sodium chloride; ○—○, 0·1 mM yttrium chloride + 199 mM sodium chloride, △—△, 0·5 mM yttrium chloride + 197 mM sodium chloride; ×—×, 1 mM yttrium chloride + 194 mM sodium chloride; ▽—▽, 3·25 mM yttrium chloride + 180 mM sodium chloride; ●—●, 20 mM yttrium chloride + 80 mM sodium chloride. Ordinate: a_m, fraction of carboxyl groups involved in binding.

almost the same curves are obtained with calcium at a total concentration of 40 mM as with yttrium at a total concentration of 0·1 mM.

Bone sialoprotein contains about fifteen sialic acid residues, fifteen aspartic acid residues and twenty glutamic acid residues per molecule[13]. To determine if the binding of yttrium was specific to any of these carboxylic acids, three model systems were titrated in 0·2 M sodium chloride, in 20 mM yttrium chloride + 80 mM sodium chloride*, and in 40 mM calcium chloride + 80 mM sodium chloride. These model systems were sodium poly-L-glutamate, sodium poly-L-aspartate and sodium *N*-acetyl neuraminate. The two polyamino acids showed the same gross effects as bone sialoprotein, ΔpH being large for Y^{3+} but small for Ca^{2+}, whereas the ΔpH of the sialic acid solutions was small in the presence of Y^{3+} or Ca^{2+}, and almost the same with the two ions. This suggests that the sialic acid was not involved in the stronger binding to bone sialoprotein of Y^{3+} compared with Ca^{2+} and this inference was confirmed by removing the sialic acid residues from bone sialoprotein (by hydrolysis in 0·1 N hydrochloric acid for 1 h at 80° C). The titration curve of the resulting de-sialated glycoprotein was displaced by Y^{3+} and Ca^{2+} to the same extent as was that of the original bone sialoprotein. Thus binding was not diminished by loss of the sialic acid, and was therefore mainly on the carboxylate anion of the acidic amino-acid residues.

A similar series of titrations were carried out with crystalline bovine serum albumin (Fig. 3) and crystalline ribonuclease and also with ribonuclease which had been treated with mercaptoethanol in 6 M urea, followed by iodoacetic acid to convert the disulphide bonds to —S—CH_2COOH groups (this treatment destroyed the native secondary structure of the enzyme and increased the number of carboxylate groups available for titration). In no case was the depression of *p*H caused by the 20 mM yttrium chloride + 80 mM sodium chloride solution greater than 0·3, and the 40 mM calcium chloride + 80 mM sodium chloride did not alter the titration curve within the experimental errors.

Because of the ease of hydrolysis of thorium, even in acid solutions, the binding of thorium had to be measured in a different way. By adding acid to a 20 mM solution of thorium nitrate and comparing the results with the addition of acid to 0·2 M sodium chloride, it was found that below *p*H 2·35 the two solutions behaved identically, but above *p*H 2·35 the change of *p*H with added acid was less for the thorium solution than for the water. Therefore, for titration purposes only at *p*H $\leqslant$ 2·35 could the thorium be considered ionic. On mixing 3 ml. of 20 mM thorium nitrate (μ 0·2) at *p*H 2·35 to 2 ml. of a bone sialoprotein solution in 0·2 M sodium chloride also at *p*H 2·35, the *p*H dropped to 2·207 and a diffuse suspension was formed. From the titration of an identical solution of bone sialoprotein with 3 ml. of 0·2 M sodium chloride added in place of the thorium, it was calculated that the drop in *p*H was equivalent to the release of $1{\cdot}22 \times 10^{-5}$ moles of H^+; moreover, the amount of hydrogen ions bound by the sialoprotein from *p*H 7·0 to 2·35 was also $1{\cdot}22 \times 10^{-5}$ moles. This indicates that all the hydrogen ions bound to carboxylic acid groups at *p*H 2·35 are released on addition of thorium, and that the thorium therefore binds to all the carboxylic acid groups on the molecule. This binding is apparently much stronger than that of Y^{3+}, which has already been shown to be stronger than that of Ca^{2+}.

The common structural factor in the macromolecules which, by this criterion, are able to bind Y^{3+} strongly, namely, bone sialoprotein, de-sialated bone sialoprotein, poly-L-glutamate and poly-L-aspartate, is a high density of distribution of carboxyl groups along the protein chain (42 per cent of the amino-acids in bone sialoprotein are either aspartic or glutamic acids[13]). Proteins which have a much lower proportion of acidic amino-acids (bovine serum albumin, ribonuclease), do not bind Y^{3+} strongly. This suggests that the highly acidic protein component in bone sialoprotein is mainly responsible for its binding of the highly charged ions of the bone-seeking elements.

* + Indicates that the solution is 20 mM in yttrium chloride and 80 mM in sodium chloride. This notation is used throughout the article.

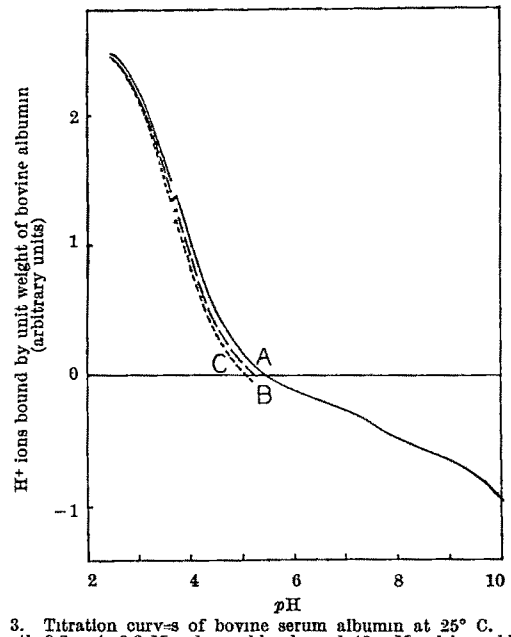

Fig. 3. Titration curves of bovine serum albumin at 25° C. Ionic strength 0·2. *A*, 0·2 M sodium chloride and 40 mM calcium chloride +80 mM sodium chloride; *B*, 5 mM yttrium chloride +170 mM sodium chloride; *C*, 20 mM yttrium chloride + 80 mM sodium chloride. Ordinate: Gram-equiv. H^+ bound by unit weight of bovine serum albumin (arbitrary units).

Preliminary experiments show that the chondroitin sulphate-protein fraction isolated from bovine cortical bone by Herring[16] also binds yttrium strongly, and calcium to a lesser extent, although the relative binding of the two appears to differ from that of bone sialoprotein.

Because bone sialoprotein stains in the PAS reaction and also binds yttrium (and thorium) more strongly than calcium it is likely to contribute substantially to the uptake of those bone-seeking elements which are preferentially deposited at the resting and resorbing surfaces.

We thank Dame Janet Vaughan for her interest and encouragement, Drs. G. M. Herring and A. T. Andrews for invaluable help in the production and supply of material, and Mr. J. R. P. O'Brien, director of this Department, for the provision of facilities. The support of the Medical Research Council to one of us (P. A. W.) is gratefully acknowledged.

DISSOCIATION OF SODIUM CARBONATE AND SODIUM SULPHITE IN ALCOHOL PLATING SOLUTIONS

By W. PARKER and W. GULLHOLMER
Institute of Physics, Chalmers University of Technology, Gothenburg, Sweden

THE electrodeposition of inorganic compounds from alcohol and other organic media has found few if any applications in industry. The main reason for this is that it is frequently difficult to obtain a coating of pure metal on the surface of the material to be plated[1]. There are, however, applications where this need not be a disadvantage—for example, in the nuclear sciences where thin layers of radioactive material are frequently required. Usually, in such situations the major concern is the production of a homogeneous layer of metal, and not the chemical form of the material[2–6]. The successful electrodeposition of layers of actinium and thorium has been reported by Haissinsky[7], and by Cottelle and Haissinsky[8], who used acetone as well as alcohol solutions. In this instance, however, ordinary electrolysis was reported and a voltage of about 10–12 V, d.c. was used. (Parker *et al.*[9] were unable to obtain the near quantitative results reported by these workers. Yields were found to vary between 45 per cent and 60 per cent.)

Following a series of experiments aimed at the preparation of colloidal solutions[10], Parker and Falk[11] found that with the help of high voltage (> 500 V, d.c.), almost any water-soluble compound could be electrodeposited from isopropanol on to the cathode. The material was deposited, not as the metal, but in a more basic form. The process proved to be quantitative for a given amount of material, and was found suitable for the production of thin layers of radioactive material of excellent uniformity. As a result of these observations we have named the process "molecular plating". In other reports we have described the application of molecular plating to experiments in nuclear physics[12–16] and also to the preparation of electron microscope specimens[17]. (A general review is given in ref. 6.) The experimental results which now follow are those obtained from an investigation of the nature of the deposits formed and of the degree of dissociation which ensued.

Two chemical compounds were chosen for this study: sodium carbonate and sodium sulphite. Both compounds are soluble in water but are somewhat less soluble in alcohol. They have the additional advantage of lending themselves to radioactive tracer studies in the form of $^{24}Na_2{}^{14}CO_3$ and $^{24}Na_2{}^{35}SO_3$. Chemical methods and quantitative titration analysis were used to determine the nature of the material deposited at the cathode.

The radioactive tracer studies were divided into the following groups: (1) $Na_2{}^{14}CO_3\beta^-$; (2) $^{24}Na_2CO_3\gamma,\beta^-$; (3) $Na_2{}^{35}SO_3\beta^-$; (4) $^{24}Na_2SO_3\gamma,\beta^-$; (5) $^{24}Na_2{}^{14}CO_3\gamma,\beta^- + \beta^-$; (6) $^{24}Na_2{}^{35}SO_3\gamma,\beta^- + \beta^-$.

For the preparation of plating solutions of (1) and (3) the radioactive material was obtained from the Radiochemical Centre, Amersham. Solutions of (2) and (4) were prepared by irradiating quantities of (1) and (3) for 5 h periods with slow neutrons in the *R*1 nuclear reactor at Stockholm. Because of the short time of irradiation and because slow neutron flux was used, sulphur-35 was only produced in very small quantities. For the same reasons, the quantities of $^{34}S(n,p)^{34}P$ were also very small. Finally, solutions of (5) and (6) were prepared by simply mixing equal proportions of (1) and (2), and (3) and (4), respectively.

Measurements of the β-ray activity were made by means of a liquid scintillation counter, while γ-ray activity was determined by means of a γ-scintillation spectrometer. The two counting solutions used for the measurement of sulphur-35 and carbon-14 were originally described by Eastman *et al.*[18] and had the following composition: for sulphur-35, 1·5 g of 2·5-diphenyloxazole and 0·08 g of 2·2-p.-henylene-*bis*-(5-phenyloxazole) were dissolved in a mixture of 100 ml. of dimethylformamide and 200 ml. of anisole; for carbon-14, 15 ml. of the same solution as used for sulphur-35 was mixed with 1 ml. of methanol. In all the measurements reported here 15 ml. counting vials were used. For measurement of the γ-rays a thallium doped sodium iodide crystal (2 in. × 2 in.) was used together with a 400 channel analyser. All combinations of labelled compounds which we tested in this investigation were subject to the same experimental conditions during electrodeposition; only the final measurements differed.

Stock solutions of the various labelled combinations were prepared with concentrations of 10 mg/ml. in water. When preparing the plating solution, a 50 μl. portion of a given solution was added to 25 ml. of isopropanol and thoroughly mixed. A 50 μl. portion of this (*a*) was added to a 15 ml. vial of the appropriate counting solution, and the plating solution then transferred to a plating cell (Fig. 1) provided with a platinum anode and stainless steel cathode. A high voltage (1,000 V, d.c.) was connected across the cell and the electrodeposition was allowed to proceed for 30 min. For an anode/cathode distance of 30 mm a current of about 250 μamp passed through the cell. During the last few seconds of the deposition period another 50 μl. portion (*b*) was taken from the solution and added to a second counting vial. The platinum anode was withdrawn from the solution without disconnecting the high voltage, and the solution was rapidly poured off. On removal, the cathode disk was

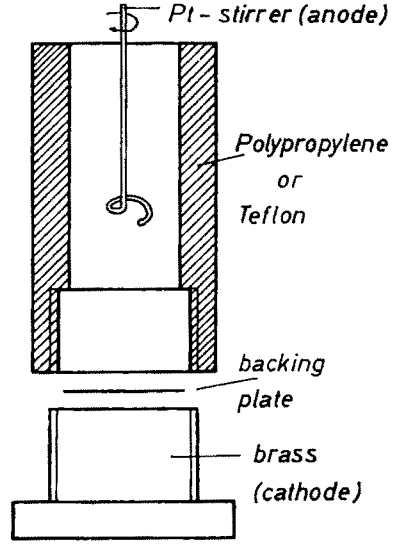

Fig. 1. Diagram of the electrodeposition cell used for the preparation of the $^{24}Na_2{}^{14}CO_3$ and $^{24}Na_2{}^{35}SO_3$ samples. The samples were first subject to measurement by means of a γ-ray scintillation spectrometer. After decaying, the deposits were washed into vials and the β-activity measured by a liquid scintillation technique

quickly washed with alcohol and allowed to dry. The plated area (10 mm diameter) was dissolved in 50 μl. of water and washed into a counting vial (*c*) with the appropriate amount of counting solution. For labelled compounds[5] (5) and (6), the comparatively short-lived sodium activity was measured first and after a suitable decay period (8 days) the relative sulphur and carbon activities determined in the same way.

Measurement of more than thirty samples of each of (*a*), (*b*) and (*c*) showed that in all cases 32 per cent of the total radioactive material in solution was deposited at the cathode after 30 min and that the ratio between sodium and carbon, and sodium and sulphur, remained the same provided the water content did not increase to more than 2 or 3 per cent of the total cell volume. This was verified as follows: A 500 μl. portion of the stock solution in question was thoroughly mixed with 150 ml. of isopropanol and transferred to a 200 ml. platinum beaker. The beaker constituted the cathode, and a platinum wire in the form of a spiral acted as the anode. The experimental arrangement is shown in Fig. 2. A current of about 4 m.amp was passed through the cell at a voltage of 1,000 V, and each deposition run lasted for 30 min. The anode wire was then removed from the solution and the plating solution rapidly poured off. Any deposits obtained were washed quickly but carefully in a few millilitres of isopropanol, and after drying were dissolved from the beaker with about 10 ml. of distilled and boiled water.

The dissolved deposits of sodium carbonate gave an alkaline reaction and also precipitated barium carbonate from a solution of barium chloride. The samples were analysed by quantitative titration with 0·05 N hydrochloric acid, both with and without the removal of any barium carbonate present. The dissolved deposits of sodium sulphite gave an alkaline reaction and precipitated barium sulphite from a solution of barium chloride: they also reduced a solution of potassium permanganate. The samples of sodium sulphite were analysed quantitatively by titration with hydrochloric acid and with sodium hydroxide after they had been subjected to oxidation with hydrogen peroxide and passed through a column of 'Dowex 50' (H^+ form). In the case of the sodium carbonate samples, analysis showed that they contained a mixture of sodium carbonate and sodium hydroxide in the ratio 1 : 2. Likewise the sodium sulphite samples were found to be mixtures of sodium sulphite and sodium hydroxide in a molecular ratio between 1 : 0 and 1 : 2.

These findings indicate that dissociation does not occur during electrodeposition of sodium carbonate and sodium sulphite from isopropanol solution when high voltage is used—provided the water content of the solution is kept to a minimum. More recent investigations have shown

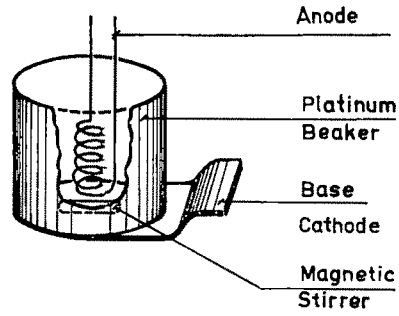

Fig. 2. Experimental arrangement used for plating milligram quantities of inactive sodium carbonate and sodium sulphate used for the chemical analysis described in the text.

that when the water content is increased to about 4–5 per cent, the deposition ratios between sodium and carbon and sodium and sulphur tend to increase in favour of the sodium. At higher levels, dissociation becomes complete, that is, the deposition of carbon and sulphur ceases, and in the case of sodium sulphite, sulphur is liberated at the anode as sulphur dioxide.

In future attempts to achieve a better understanding of the phenomena involved we intend to use tritium-labelled water and isopropanol.

We thank Prof. Nils Ryde for his interest and support in this work. We also thank Mr. H. Riedl of the Institute of Technical Chemistry for his help with the chemical analysis. The liquid scintillation equipment was kindly lent to us by LKB Produkter *AB*, Stockholm.

GROUPING OF NOCTURNAL MIGRANTS

By E. EASTWOOD and G. C. RIDER
The Marconi Company, Ltd., Marconi House, Chelmsford, Essex

"ONLY birds and fools fly—and birds don't fly by night" was one of the sayings of the men of wartime Bomber Command. The first and, perhaps, the most surprising discovery made by the radar method of bird watching introduced by Lack and Varley in 1945 (ref. 1) refuted this statement—birds do fly by night and sometimes in vast numbers. By means of radar it has now been established that many of the largest mass bird movements of the spring and autumn take place by night[2,3]. Nevertheless, many problems of bird flight at night remain unresolved—including the question of whether a migrant stream is composed of flocks of birds, each of which constitutes one of the "angel echoes" seen on the plan position indicator of a radar, or whether a random distribution of individual birds only is involved, each bird flying in the general direction of migration.

Many pictures have been published of bird migration recorded from the plan position indicator of a surveillance radar, and these illustrate the fact that discrete angels occur both by day and by night (see, for example, ref. 4). It is well known, however, that in daytime many species, such as the chaffinch (*Fringilla coelebs*), migrate in large flocks, the members of which move together in a coherent group by keeping each other in sight. Direct association of such visible bird flocks with diurnal radar angels has been reported[5,6]. The possibility therefore exists that

nocturnal angels can be similarly attributed to real groups of birds.

If this proves to be the case, then it would be interesting to know how the birds which compose such a group are able to stay together at night, and whether there is any form of social relationship between them. On the other hand, the possibility that radar angels are merely a result of the imperfect resolution by the radar of a mass of randomly distributed birds must also be considered.

The spatial resolving power of a pulsed radar signal depends on the pulse length and the shape of the beam radiated by the antenna. If τ is the time duration of the transmitted pulse, then targets lying on the same radius, and separated by less than $\frac{1}{2} c\tau$, will be shown as a single echo on the plan position indicator (c is the velocity of light). Similarly, if θ and φ are the horizontal and vertical beam-widths, then the limits of linear resolution in the azimuthal and meridional planes are $r\theta$ and $r\varphi$, respectively, where r is the range from the radar. It follows that targets contained within the so-called pulsed-volume $\frac{1}{8} c\tau r^2 \theta \varphi$ at range r will be unresolved and will be recorded on the plan position indicator as a single point echo. For the surveillance radar at the Marconi Experimental Station at Bushy Hill, Essex, which has been used for many years to observe bird migration across the North Sea, $\lambda = 23$ cm, $\tau = 5$ μsec, $\frac{1}{2} c\tau = 2{,}450$ ft., $\theta = 0.8°$ and φ is expressed by the vertical performance diagram of the radar given in Fig. 1. The inner contour of limiting visibility on Fig. 1 is plotted for a target of cross-sectional area 2 cm², which corresponds to a small bird such as a warbler; the outer contour refers to a target having an echoing area of 100 cm², which would be roughly the echoing area produced by a flight of about twenty starlings (*Sturnus vulgaris*). In such a random formation of birds the radio energy is scattered incoherently and the effective echoing area of the group is the arithmetic sum of the echoing areas of the individual birds.

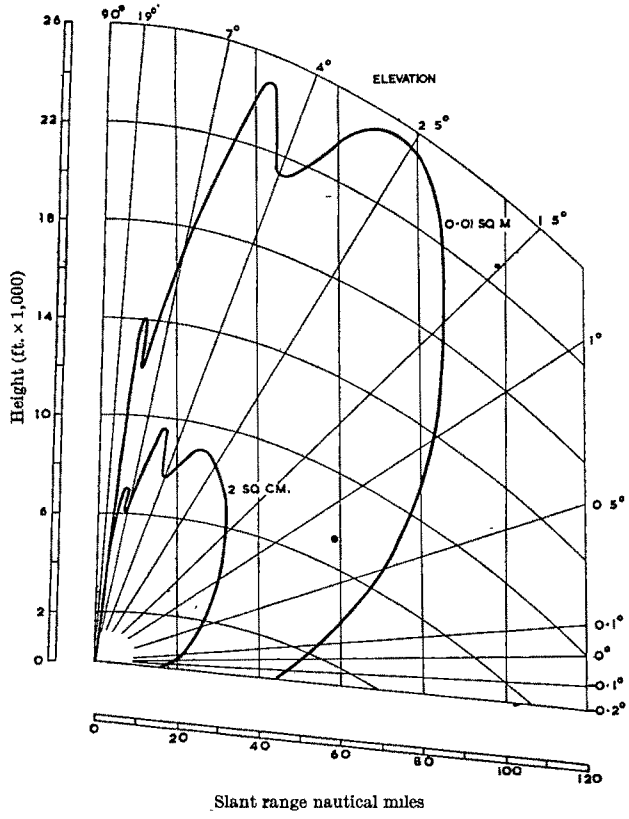

Fig. 1. Cover diagrams, Bushy Hill radar ($\lambda = 23$ cm).

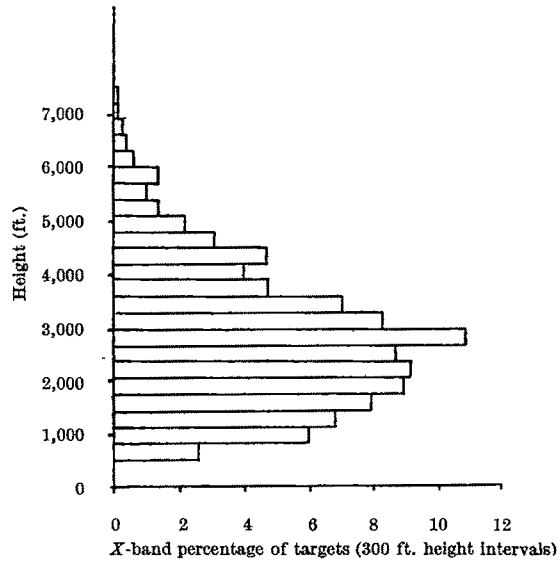

Fig. 2. Height distribution histogram. $\lambda = 3$ cm, 3,562 observations in 32·5 h in spring 1966.

For bird migration over the North Sea, the vertical resolution limit of $r\varphi$ is not reached owing to the limited height of the birds[7]. The easterly passage of nocturnal migrants at the Essex coast during the period January–May 1966 was observed from Bushy Hill using a high resolution 3 cm radar which had its beam directed vertically upwards. This radar was recording the passage of single birds through the beam, and frequencies of transits were measured as well as altitudes. The pattern of the height distribution is given in Fig. 2, which shows that the most frequently occurring altitude band was 2,700–3,000 ft.; very few birds were observed above 7,000 ft. and 90 per cent were below 4,500 ft. Fig. 1 indicates that birds flying at 4,500 ft. will cross the radio horizon at 77 nautical miles, and so the magnitude of the pulse volume occupied by birds will not vary with the range in accordance with the foregoing simple expression, but will pass through a maximum before decreasing to zero at $r = 77$ nautical miles.

As all the birds contained within the pulse-volume contribute to the echo signal it will be seen that the granular appearance of an angel display could arise from the interaction between the polar diagram of the aerial, the parameters of the radar and a random distribution of migrants within the permitted altitude band. According to this view, nocturnal angels would not correspond to true groups of birds, but would merely be the echoes from those pulse-volumes in which the number of birds happened to provide a total echoing area sufficient to produce a signal at the radar, exceeding the receiver noise level (4×10^{-15} W) by about 10 dB. The inevitable diminution of angel density at longer ranges is a consequence of the pulse-volume effect, combined with the rapid fall-off of signal power with range as expressed by the radar equation ($1/r^4$).

Examples of radar displays of birds which show the pulse volume effect are not lacking. Warblers on migration have the appearance on the plan position indicator of a hazy continuum of light in which are embedded transient echoes of low intensity[4]. A similar diffuse display is also typical of night ascended swifts (*Apus apus*) during late June[8]. These displays are in marked contrast with the assembly of bright point echoes which are characteristic of discrete angels. It seems fairly certain that such a diffuse type of display is caused by incoherent scattering from the mass of small targets contained within the pulse-volume; together, these provide a fluctuating, weak signal that only occasionally exceeds the noise level. Sutter[6] reported that his nocturnal angels

appeared weaker and less sharp than the diurnal angels; this, he explained, is because the birds are grouped into tight flocks by day but not by night. Lack[2] also thought that the evidence did not point to the existence of night groups; on the other hand, he also reported tracking strong, discrete nocturnal angels at long range. Bergmann and Donner[9], however, in their study of the migration of the common scoter (*Melanitta nigra*) and longtailed duck (*Clangula hyemalis*) in the Gulf of Finland, considered that these birds were grouped into flocks by night as well as by day.

Observations were made from Bushy Hill during 1964–66 in the hope of resolving the nature of nocturnal angels. Various radar equipments were used which operate at wavelengths of 23 cm, 10 cm or 3 cm (*L*, *S* and *X* microwave bands, respectively). Use was also made of the signature analysis technique—the study of the pulse-to-pulse variations in amplitude of the signal received from a target in order to deduce information about its scattering characteristics. A number of strong, discrete, nocturnal angels were examined with the aid of a steerable, *L*-band tracker radar the beam-width of which was 1·8°. Signature analysis shows that the amplitudes of successive pulses from such angels followed a Rayleigh distribution typical of a target composed of a number of scattering centres moving randomly with respect to each other—that is, the strong angels in the vicinity of East Anglia were usually composed of a number of birds. In contrast, signature analysis applied to the signals received by the *X*-band radar showed them to be typical of single-bird targets—this was to be expected in view of the high resolution of the equipment and the short range at which the observations were made (the pulse-volume used was small).

The average echoing areas of a number of angels were also measured with the *L*-band tracker, and the echoing area distribution function which was obtained for both day and night angels of this type is shown in Fig. 3. The distribution pattern is not symmetrical and suggests that angels having echoing areas of 500 cm² or more are markedly more rare than those having echoing areas less than this. If we take the most probable value of the echoing area suggested by this figure to be about 70 cm² it is possible to estimate the average number of birds per angel between five and thirty-five, because the echoing area of those birds likely to be airborne at the time of the measurements would probably range from 2–14 cm².

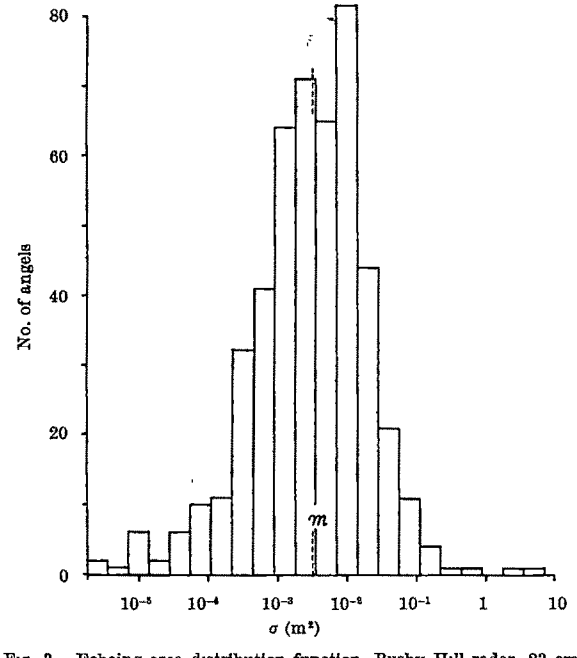

Fig. 3. Echoing area distribution function, Bushy Hill radar, 23 cm; July 1962.

A different method was used to estimate the average bird content of nocturnal angels observed during the easterly emigration from East Anglia of winter visitors such as the blackbird (*Turdus merula*), redwing (*T. musicus*), fieldfare (*T. pilaris*), lapwing (*Vanellus vanellus*), chaffinch (*Fringilla coelebs*) and starling. An *L*-band surveillance radar supplied data on angel densities at a known range, while the rate of passage and density of birds overhead were derived from the *X*-band radar counts. After making appropriate correction for the thinning of angel densities with range, in a manner similar to that described by Nisbet[10], the number of birds per angel appeared to lie between four and twenty.

The application of a mixed radar and Moon-watching technique by Nisbet[10] showed that the average number of birds per nocturnal angel which he observed during the autumn migration in the region of Cape Cod was usually between two and twelve. After a careful review of the data, and noting particularly the fact that the average composition of an angel increases only very slowly with the migration density, Nisbet concluded that many birds migrate in well-defined groups.

Bearing in mind the uncertainties attached to radar measurements of this kind, it will be seen that the number of birds per angel determined by Nisbet does not differ significantly from the value suggested by the two independent methods of assessment used at Bushy Hill. But this rough agreement does not prove the group nature of the angels observed in the two regions. One method of testing the existence of such angel groups would be to record and to compare the angels which occur in a particular region by means of two radars with different pulse-volumes over the area examined. Real groups of birds should then be seen as such on both radars. This experiment was, in fact, performed by Eastwood and Rider, when angels observed on the plan position indicator of an *L*-band surveillance radar were also photographed simultaneously from the display of an *S*-band nodding height-finder. It can be concluded from this varied evidence that many of the strong angels must correspond to groups of birds. Such a conclusion is supported by the comparatively long lives which many angels often possess on films of the plan position indicator when viewed by the time compression method, and the long distances, often 10–20 miles, over which they may be tracked. The fact that angels on a magnified plan position indicator display rarely split further supports the conclusion; this would be surprising if angels were only a pulse-volume effect[11].

Do these data suggesting the existence of groups of migrant birds at night necessarily contradict the idea of migration as made up of random distributions of birds? Counts made with the *X*-band radar at Bushy Hill showed that the rate of passage overhead of individual birds during nights of the spring migration was far from uniform. While observations were being made it was particularly noticeable that the number of transits during successive 15 min intervals changed greatly, and even that the rate of passage could vary from minute to minute. In other words, the birds tended to make their appearance in bursts, so that their spatial distribution was very granular and areas of concentration were present among the general spread of the migrants. The distances between the members of such closely packed sections were well within the pulse-volume of the *L*-band surveillance radar and would have been seen as a single angel on the plan position indicator. If such a local concentration of birds were to remain contained within the gradually expanding pulse volume during the outward flight, then the single angel which would result could be tracked on the plan position indicator, even though the birds might not constitute a true group—there being no form of social relationship between them.

That this possibility can indeed happen is supported by other radar evidence. Time compression films of the surveillance radar plan position indicator have shown that the mass autumn departure of warblers at night from the south-eastern region of England can cause the outlines of the Essex, Kent and Sussex coasts to advance out to sea like a wall in the direction of migration, which is towards the south-south-east. Although these warbler echoes almost certainly arise from a pulse-volume effect there is a continuity to the geographical distribution of the birds at take-off which is maintained during the first part of the migratory flight and takes a surprisingly long time to disappear[4]. Similarly, films of the vesper flights of swifts show that the denser regions which correspond to the places of origin of the birds continue to show for quite a long time, presumably because the individual birds perform similar tight spiral movements[8].

This continuity of pattern is even more marked in the night movement of waves of starlings which were reported by Lack and Eastwood[4]. Furthermore, the dispersals of starlings from their roosts at sunrise to join the migrant stream to the continent showed that the parallel waves of birds, sometimes extending over a front 20 miles long in a north–south direction, moved towards the east but were still distinguishable as waves an hour later, and some 60 miles to the east[12].

These examples suggest that some form of station-keeping is practised by the birds which can supplement the migration direction "programme" with which all the birds are endowed. This station-keeping would ensure the continuity of their initial distribution pattern over quite long periods. More probably, the birds perform similar movements in response to the same stimuli. But there will inevitably be scatter in respect of speeds flown by individual birds and on the headings which they take up. The effect of these variances will cause the initial distribution to become blurred and more extended as the flight proceeds. Finally, the pattern will merge with the general background of birds—which is, in fact, observed in all the foregoing examples.

The radar evidence as a whole suggests that while some of the nocturnal angels which give good echoes at long range are probably true groups of birds analogous to those observed by day, others, and perhaps the majority, are pseudo-groups which result from the pulse-volume effect. Even the "true groups" may only be groups in the sense that the birds composing them have taken off from a common locality or a common roost; the group form is roughly maintained because the birds fly at roughly the same speed and in the same direction. Nevertheless, the well known visual acuity of the birds may serve to bind them into some sort of a unified group; the well known phenomenon of acoustic calling on the wing would also assist in this. If such were indeed the explanation of nocturnal angels it would mean that the appearance of discrete angels only differs from the appearance of warblers by reason of the echoing areas of the birds involved and the intensity of the distribution.

Radar is perhaps the only method available for counting the numbers of birds flying by night, but it is still in need of refinement before it can be regarded as a precise counting instrument. One further tentative result which has emerged from this investigation is of sufficient interest to be mentioned here; this concerns an estimate made of the total number of birds taking part in the springtime migratory movement which corresponds to the return to the Continent of many of the winter visitors to these islands. Lack[2] has shown that this is the major migration of the spring in the south-eastern region of England. Undoubtedly the most accurate way of counting the passage of migrant birds by night is to use the vertical incidence *X*-band radar technique. This method gives an accurate value for the rate of passage of birds across a 1 mile front at the position occupied by the radar, but it cannot supply information about the flow of birds at points remote from the radar. Many such radars would be needed to cover an extended front and the method would be prohibitively expensive to apply to a broad front migration. The *L*-band surveillance radar, however, can map the general progress of angel activity across a front extending from the north coast of Norfolk down to the Pas de Calais. Combination of the *L* and *X* radar techniques translates the angel echoes into numbers of birds and permits useful estimates to be made of the rates of flow of birds across the whole of this front. When these average rates are associated with the pattern of activity for the spring migration as a whole, which was established by Lack for this easterly movement, it becomes possible to estimate the total number of birds involved as 2×10^7. These heavy migrations do not denude the countryside of birds, of course, and their place is largely taken by the summer visitors which come to these islands to breed. The figure of 2×10^7 may be compared with Harper's[5] estimate of 3×10^6 birds taking part in a heavy migration over Hertfordshire in one spring night.

We thank Mr J. D. Bell, Mr. N. R. Phelp and Mr. J. Franklin, of the Marconi Research Laboratory, for assistance in making the measurements.

GROWTH AND STRUCTURE OF THE SHELL OF LIVING ARTICULATE BRACHIOPODS

By Prof. ALWYN WILLIAMS
Department of Geology, Queen's University, Belfast

The relationship between the triple-layered shell and the underlying outer epithelium of the mantle of living articulate brachiopods has been known for some time[1]. It involves the production of epithelial cells in a generative zone at the mantle edge and the secretion of each of the three layers in turn by the cells as they become incorporated within the expanding mantle. The morphological consequences of this process have not hitherto been completely established, but electron microscope studies of the shell fabric of the terebratulides, *Macandrevia* and *Terebratulina*, and the rhynchonellides, *Hemithyris* and *Notosaria*, have now shown the full sequence of events.

The site of the generative zone for each valve is a circumferential groove dividing the mantle edge into two lobes. Newly proliferated cells, which are ultimately added to the outer epithelium, first become part of the

inner surface of the outer lobe and are then conveyed forward towards the tip of the lobe by the addition of new cells behind them. At this juncture they exude the outermost shell layer, the periostracum, composed exclusively of protein[2]. The previously reported[1] differential thickening of the periostracum is related to the external morphology of the cells, in that thickened bands forming a reticulate mesh on the inner surface of the periostracum usually correspond to boundaries between cells.

When cells reach the mantle tip they start secreting calcite crystallites between the periostracum and the underlying cell walls. This crystallite mat is the first formed part of the calcareous primary layer. It is built up more or less continuously across intercellular boundaries and bears no recognizable imprint of cell outlines. But its strongly pitted appearance at the shell edge, with pits up to 0·4μ in diameter, indicates that the outer surfaces of the cells responsible for deposition of calcite bear microvilli intruding into the primary layer. Thus the cells are already anchored in position relative to one another on the calcareous exoskeleton, and any differential movement away from these original loci of attachment depends on variation in the rate of secretion for each cell. The rigidity and continuity of the calcareous primary layer also control the disposition of the outer mantle lobe; enlargement of the shell is thus effected by a "conveyor belt" system whereby proliferated epithelial cells forming the inner surface of the outer lobe are successively brought into position to extend the primary layer by extracellular calcareous secretion.

The thickness of the primary layer is a function of the number of rows of epithelial cells involved in its secretion, with the innermost, oldest cells underlying the thickest part of that layer at the shell edge. In general, the number of concentric rows making up this zone in adult shells is fairly constant; in *Terebratulina*, for example, there are about fifteen, so that the thickness of the primary layer underlain by secondary shell does not vary very much. This stability is maintained because each row of cells undergoes profound changes in secretory habit when, through addition of new cells at the tip of the outer lobe, they come to form the innermost rows underlying the primary layer. The changes are two-fold. They involve a reversion to the exudation of protein, now restricted to narrow arcs more or less coincident with the anterior intercellular boundaries, and also the secretion of calcite crystallites as a uniformly continuous plaster laid down within the protein boundaries. At this stage the cells, each with a convex anterior boundary, alternate in slightly overlapping rows so that their intercellular boundaries approximate to an anterior semicircle subtended between two adjacent arcs which are shared with the cells immediately behind (Figs. 1 and 2). The protein strips underlain by the boundaries in common with the two older cells are usually completed, at least as contiguous strands, before traces of protein exuded by the anterior boundary can be seen. Plastering of secondary calcite over the comparatively porous primary layer usually starts in the re-entrant angle between the two older cells and soon coalesces with any isolated deposits that may appear elsewhere within the protein boundaries. In this way the secondary calcareous layer of the articulate brachiopod shell is formed by cells that were initially responsible for the secretion of the periostracum and then for the calcareous primary layer (Figs. 3 and 4).

Continuous deposition of protein along the intercellular boundaries segregates the calcite of the secondary shell into fibres, each of which is contained in a protein sheath with only rare lacunae. Thus each fibre is controlled in its further growth by the outer surface of a cell which is characteristically concave outwards and more pronouncedly so towards the front, so that the internal surface of the fibre is convexly lobate with an outline determined by its protein boundary (Fig. 4). In this manner, the inner surface of the secondary shell, unlike that of the primary layer, is fashioned into the so-called shell mosaic (Figs. 1 and 2) which is in reality a protein–calcite cast of the outer surface of the epithelium[3]. This pattern is so consistent that even cell division taking place after the deposition of secondary shell can be identified by variation in the morphology of the mosaic.

The mosaic has a discernible lineation reflecting the growth relationship between fibres at the moment of death, which can be graphically represented by plotting the long axes of exposed parts of fibres as growth vectors. Such growth charts show that, in convex valves at least, an extension of fibres normal to the shell edge is only characteristic of a narrow peripheral zone, because the overlapping ends of fibres comprising the inner part of the mosaic are rapidly re-orientated more or less parallel to the valve margin. Thus each fibre tends to grow in a spiral and is directed clockwise in the right half of a valve and anticlockwise in the left half. Some modification of the mosaic occurs when the fibres form skeletal outgrowths, but in general the pattern is blurred only when

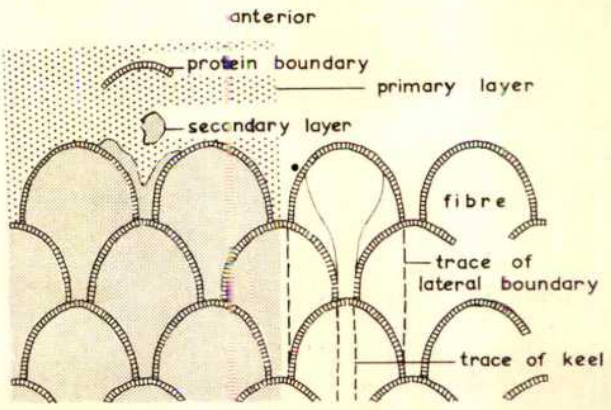

Fig. 2. Diagrammatic internal surface view of the junction between the primary and secondary layers of the articulate brachiopod shell.

excessive calcite deposition interrupts the laying down of protein boundaries as, for example, in muscle bases.

The arrangement of the cells of the outer epithelium relative to one another is also responsible for the distinctive stacking of fibres as seen in any random section of the shell. In longitudinal section, fibres appear as blades gradually increasing in width towards the inner surface of the valve and, when not involved in accommodating puncta or contributing to the formation of internal features, are inclined at about 10° to the inner surface of the primary layer (Fig. 3). A transverse section of a typical fibre, however, shows that the inner surface is flatly to roundly convex inwardly, usually with a medial keel, while the outer surface is made up of two lateral areas joined by a medial saddle, all concave outwardly (Figs. 5 and 6). The inner surface corresponds to the outwardly concave, anterio-median surface of a cell, the lateral areas to the two contiguous halves of alternating cells in the immediately younger row, and the saddle to the keel laid down by a cell belonging to the next younger row (compare Figs. 1 and 5). This arrangement facilitates the overlapping growth of fibres. It also enables any shell fragment to be orientated because all concave surfaces face outwards.

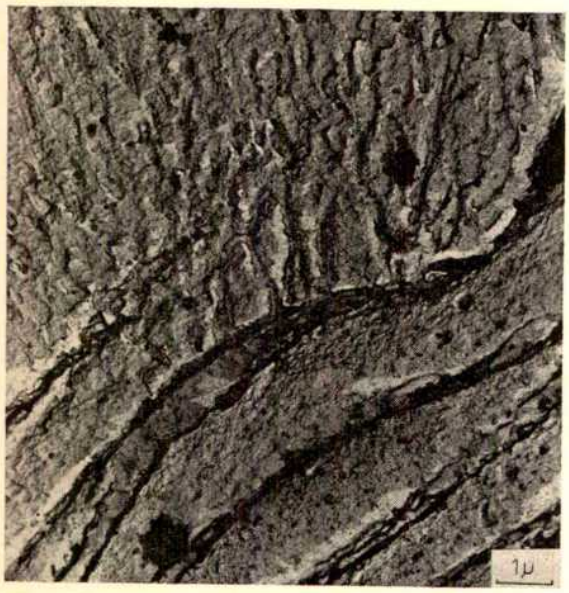

Fig. 3. Single stage negative replica of a longitudinal section of the junction between the primary and secondary layers of *Laqueus californicus* (Koch): shadowed with gold-palladium at 1 in 1.

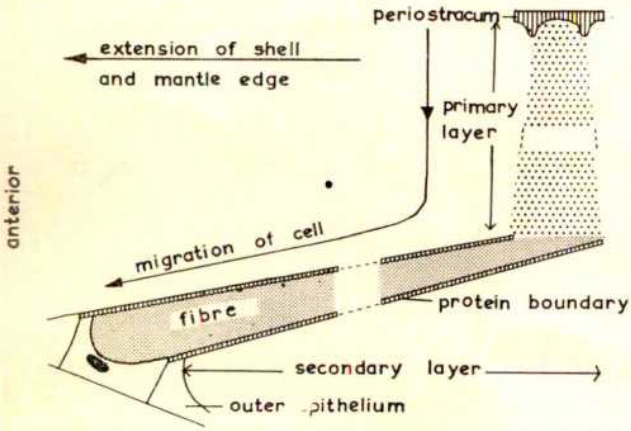

Fig. 4. Diagrammatic longitudinal section showing the relationship between an outer epithelial cell and the three layers of an articulate brachiopod shell.

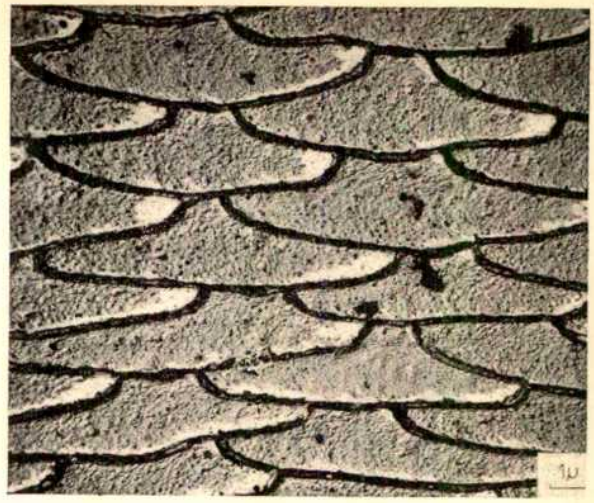

Fig. 5. Single stage negative replica of a transverse section of the fibres of the secondary layer of *Macandrevia crania* (Muller): shadowed with gold-palladium at 1 in 1.

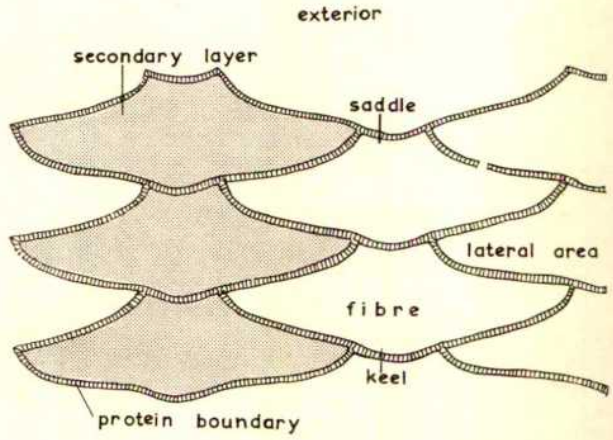

Fig. 6. Diagrammatic transverse section showing the relationship between fibres of the secondary layer of an articulate brachiopod shell.

The different appearances of transverse and longitudinal sections, the incremental increase in size and the spirally arcuate traces of fibres growing away from the primary layer have led to misinterpretations of sections of the brachiopod shell. Thus Sass, Monroe and Gerace[4] were puzzled by their electron micrographs of sections of the terebratulids *Gryphus* and *Pictothyris*. In fact, a segment of any section through the shell will normally show an inward increase in size of fibres because those adjacent to the primary layer will have been deposited by small epithelial cells at the mantle edge, whereas the inner fibres will have been secreted by progressively older, larger cells as successively overlapping extensions from their original loci of attachment. Moreover, in segments of longitudinal sections away from the shell edge, it is likely that fibres immediately underlying the primary layer will be seen in transverse section, and those towards the inner surface of the shell in oblique sections which may be parallel for part of their lengths with the long axes of the fibres.

MODEL OF THE MEMBRANE OF SMOOTH MUSCLE CELLS OF THE GUINEA-PIG TAENIA COLI MUSCLE DURING TRANSMISSION FROM INHIBITORY AND EXCITATORY NERVES

By M. R. BENNETT
Department of Zoology, University of Melbourne, Australia

THE changes in membrane potential which occur in the smooth muscle cells of the guinea-pig taenia coli muscle during transmission from inhibitory and excitatory nerves have been described recently[1-4]. This smooth muscle was selected for these investigations because the ionic properties of the membrane, the ionic content of the cell, and the effect of transmitter substance on the cell membrane had already been examined[5-12]. On the basis of these investigations a tentative model of the membrane during transmission to smooth muscle cells may be proposed.

Membrane theory. Before a model of transmission can be presented, the ionic properties of the smooth muscle membrane need to be known. An attempt has therefore been made to determine if the membrane theory of Boyle and Conway[13], which has been shown to hold for the skeletal muscle membrane[14,15], also holds for the membrane of the smooth muscle cells of the taenia coli.

From the theory of Boyle and Conway

$$(\mathrm{Na})_i + (\mathrm{K})_i + (\mathrm{Cl})_i + \frac{D}{V} = C \qquad (1)$$

$$(\mathrm{Na})_i + (\mathrm{K})_i - (\mathrm{Cl})_i + \frac{DZ}{V} = 0 \qquad (2)$$

$$(\mathrm{K})_o\,(\mathrm{Cl})_o = (\mathrm{K})_i\,(\mathrm{Cl})_i \qquad (3)$$

From (1) and (2):

$$(\mathrm{Na})_i = \frac{(\mathrm{K})_i\,(Z-1) + (\mathrm{Cl})_i\,(1+Z) - ZC}{(1-Z)}$$

if $Z = -1$ (ref. 16).

$$(\mathrm{Na})_i = \frac{C}{2} - (\mathrm{K})_i \qquad (4)$$

where i refers to intracellular concentrations; o refers to extracellular concentrations; D is the number of indiffusible molecules inside the cell; Z is their average valency; V is the cell volume; and C is the total concentration of all the molecules in the external solution.

In skeletal muscle the Donnan equilibrium exists for external potassium concentrations above 10 mM[14,15], and so

$$E_m = E_{\mathrm{K}} = \frac{RT}{F} \ln \frac{(\mathrm{K})_o}{(\mathrm{K})_i} = E_{\mathrm{Cl}} = \frac{RT}{F} \ln \frac{(\mathrm{Cl})_i}{(\mathrm{Cl})_o} \qquad (5)$$

where E_m is the membrane potential; E_{K} and E_{Cl} the equilibrium potentials for potassium and chloride ions, respectively; and R, T, F have their usual meaning. Hodgkin and Horowicz[14] have shown that in a chloride-free solution the deviation of the membrane potential from the potassium electrode for $(\mathrm{K})_o$ greater than 10 mM can be predicted by the Goldman[17] equation

$$E_m = \frac{RT}{F} \ln \frac{(\mathrm{K})_o + \alpha(\mathrm{Na})_i}{(\mathrm{K})_i + \alpha(\mathrm{Na})_i} \qquad (6)$$

where α is the ratio of the permeability coefficient of sodium to that of potassium. Hence

$$\alpha = \frac{(\mathrm{K})_o - (\mathrm{K})_i\, 10^{\frac{E_m}{62}}}{(\mathrm{Na})_i\, 10^{\frac{E_m}{62}} - (\mathrm{Na})_o} \qquad (7)$$

The investigations of the smooth muscle membrane of the taenia coli in high-potassium solutions $(\mathrm{K})_o > 25$ mM and in chloride-free solutions $(\mathrm{Cl})_o = 0$ made by Holman[9] and Kuriyama[10] can now be interpreted in terms of equations 1–7.

$(\mathrm{K})_o$ greater than 25 mM. In this case it has been assumed that the potassium and chloride ions were in a Donnan equilibrium at the highest potassium concentration, and from equations 3 and 5 $(\mathrm{K})_i$ and $(\mathrm{Cl})_i$ have been obtained. Then for lower concentrations of potassium, if Donnan equilibrium continued to hold, potassium and chloride ions should have moved across the membrane in equal numbers until equation (3) holds. Therefore, equation (3) has been used to find the new values of $(\mathrm{K})_i$ and $(\mathrm{Cl})_i$, and if the assumption of a Donnan equilibrium is correct then the predictions of the value of the potassium electrode from equation (5) should agree with the measured value of the membrane potential. Tables 1 and 2 summarize the values of E_m, $(\mathrm{K})_o$ and $(\mathrm{Cl})_o$ taken from Holman's[9] results on page 470 of her paper and Kuriyama's[10] results on page 17 of his paper. All values are expressed in mM or mV. The predicted value of E_{K} agrees well with the value of E_m measured with microelectrodes. It is therefore probable that in high potassium concentrations, potassium and chloride ions are in Donnan equilibrium across the membrane.

Table 1

E_m	$(\mathrm{K})_o$	$(\mathrm{Cl})_o$	$(\mathrm{Cl})_i$	$(\mathrm{K})_i$	E_{K}

−33	40	180	54	134	−33
−42	25	165	35	115	−42

Table 2

E_m	$(\mathrm{K})_o$	$(\mathrm{Cl})_o$	$(\mathrm{Cl})_i$	$(\mathrm{K})_i$	E_{K}
−17·5	118	258	137	220	−17
−27·5	59	199	74	157	−26·5
−40	29	169	40	123	−39

According to the Boyle and Conway theory, there should be little or no change in the intracellular concentration of sodium when the potassium and chloride concentrations outside the cell are changed, since the membrane is supposed to be largely impermeable to sodium. If this is the case, then $(\mathrm{Na})_i$ in equation (4) should remain constant with changes in $(\mathrm{K})_i$ and in the total external concentrations of ions, C. The $(\mathrm{K})_i$ at various values for C can be obtained from Tables 1 and 2, and these are summarized in Tables 3 and 4. $(\mathrm{Na})_i$ in each table is fairly constant at different $(\mathrm{K})_o$, and both tables show that the value of $(\mathrm{Na})_i$ is about 40 mM.

Table 3

E_m	$(\mathrm{K})_i$	C	$(\mathrm{Na})_i$
−20	200	480	40
−30	145	380	40
−33	134	360	44
−42	115	330	45

Table 4

E_m	$(\mathrm{K})_i$	C	$(\mathrm{Na})_i$
−17·5	220	516	38
−27·5	157	398	33
−40	123	338	36

Chloride-free solution. If the chloride ions normally present in Krebs solution are replaced by sulphate ions, keeping the potassium concentration constant, there will be a decrease in osmotic pressure outside the cell due to the decrease in the net number of ions, C. Ions will then leave the fibre together with water until osmotic equilibrium is regained and there will thus be a decrease in $(\mathrm{K})_i$. Kuriyama[10] has performed this experiment, as well

as changing the $(K)_o$ in a chloride-free Krebs solution. The changes in $(K)_i$ with elevation of $(K)_o$ in sulphate Ringer can be predicted by equation (4) with $(Na)_i$ = 40 mM. Table 5 summarizes values for E_m, $(K)_o$ and C from Kuriyama's results and the theoretical predictions of E_K. The membrane potential is shown to be close to the value of the potassium electrode for each value of $(K)_o$. It seems likely then that the chloride ion is in electrochemical equilibrium with the membrane potential for this range of potassium concentrations.

Table 5

E_m	$(K)_o$	C	$(K)_i$	E_K
−4	118	387	153	−6
−17·5	59	298	109	−17
−32	29	253	86	−30
−45	12	228	74	−49

For low values of $(K)_o$ the membrane potential E_m deviates from the potassium electrode, E_K, in sulphate solution. If we assume that this deviation is due to a small permeability to sodium, then the value of α should be the same over this range of membrane potentials. Using equation (4) to obtain $(K)_i$ and equation (7) to obtain α, Table 6 shows that α does remain constant at 0·05 for the two values given by Kuriyama[10] for E_m, $(K)_o$ and C.

Table 6

E_m	$(K)_o$	C	$(K)_i$	$(Na)_i$	$(Na)_o$	
−47·5	6	219	70	40	140	0·05
−53	3	214	67	40	140	0·05

The deviation of the membrane potential of smooth muscle from that predicted by the potassium electrode, which was reported by Holman[9] and Kuriyama[10], is probably due to their adding potassium chloride salt directly to the Krebs solution. This would probably increase the osmotic pressure outside the cells, so that potassium and chloride ions would move into the cell until osmotic equilibrium was regained. If allowance is made for this increase in $(K)_i$, it has been shown that the membrane potential they measured does obey the predictions of the potassium electrode. It is interesting that the normal $(K)_i$ predicted for the cell was about 120 mM, which agrees with the value of 120 mM obtained by photometric analysis by Freeman-Narrod and Goodford[5].

The concentration of intracellular sodium in the smooth muscle of the taenia coli is much larger than that found in nerve or skeletal muscle, being about 37 mM. This value can be obtained from the value of 70 mM of sodium/kg wet weight of muscle found by Goodford[6], assuming the extracellular space is 333 ml./kg wet weight of muscle[7] and that the intracellular space is 600 ml./kg wet weight of muscle[5]. This value of $(Na)_i$ agrees well with the value of about 40 mM obtained using the Boyle and Conway theory. The value of the intracellular sodium concentration remained constant with changes of the membrane potential, a result to be expected if the membrane remains mostly impermeable to sodium.

There was no deviation of the membrane potential from the potassium electrode for membrane potentials less than −40 mV. In high-potassium solutions, therefore, chloride ions are probably in electrochemical equilibrium with the membrane potential. The intracellular chloride concentration of 35 mM predicted on this basis agrees well with the value of 30 mM obtained by Daniels[8] using photometry techniques, this value being calculated on the basis of an intracellular volume of 333 ml./kg wet weight of muscle.

It is therefore concluded that for potassium concentrations above 25 mM, potassium and chloride are in a Donnan equilibrium, and for potassium concentrations less than 25 mM there is a small sodium permeability.

Transmission theory. Eccles[18] has suggested that transmission to the motoneurone can be represented by the sudden short-circuiting of the total membrane resistance and capacitance by a low resistance which selectively allows the ion species which carries the synaptic current to flow through it. The post-junctional membrane changes which occur during transmission to smooth muscle can be represented by an electrical model similar to that used for transmission to the motoneurone[18], if the following assumptions are made: the length of a single taenia coli smooth muscle cell is less than the length constant[19], each smooth muscle cell has receptors for both inhibitory and excitatory transmission[3,11], and the concentrations of transmitter artificially applied to the muscle are sufficient to maintain the maximum permeability changes at the receptors.

The electrical circuit model of the post-junctional membrane is shown in Fig. 1, where V is the membrane potential at time t; C_m the total membrane capacitance; G_m the total membrane conductance; G_i the maximum conductance at the inhibitory receptor region; G_e the maximum conductance at the excitatory receptor region; E_i the reversal potential for the ions which carry the inhibitory current; E_e the reversal potential for the ions which carry the excitatory current; and E_m the resting membrane potential.

Since there is no external source of current across the cell membrane

$$C_m V' + V(G_m + G_i + G_e) - (G_m E_m + G_i E_i + G_e E_e) = 0 \quad (8)$$

where $V' = \frac{dV}{dt}$, and since only steady membrane potential are considered, $V' = 0$.

Therefore

$$V = \frac{E_m + \frac{G_i}{G_m} E_i + \frac{G_e}{G_m} E_e}{1 + \frac{G_i}{G_m} + \frac{G_e}{G_m}} = \frac{E_m + aE_i + bE_e}{1 + a + b} \quad (9)$$

$$\text{where } a = \frac{G_i}{G_m} \text{ and } b = \frac{G_e}{G_m}$$

From (9)

$$(V - E_m) = \frac{aE_i + bE_e}{(1+a+b)} - \frac{E_m(a+b)}{(1+a+b)} \quad (10)$$

Equation (10) gives the maximal change in the membrane potential when the inhibitory and excitatory transmitters are simultaneously applied to the cells.

When the inhibitory transmitter is applied alone, $b = 0$ in (10) and:

$$(V - E_m) = \frac{aE_i}{(1+a)} - \frac{aE_m}{(1+a)} \quad (11)$$

When the excitatory transmitter acts alone, $a = 0$ in (10), and

$$(V - E_m) = \frac{bE_e}{(1+b)} - \frac{bE_m}{(1+b)} \quad (12)$$

Equations (10), (11) and (12) are shown plotted in the graph of Fig. 2.

Bulbring and Kuriyama[11] have examined the effects of adrenaline (10^{-7} g/ml.) on the membrane potential of cells with different initial resting potentials. Their results are

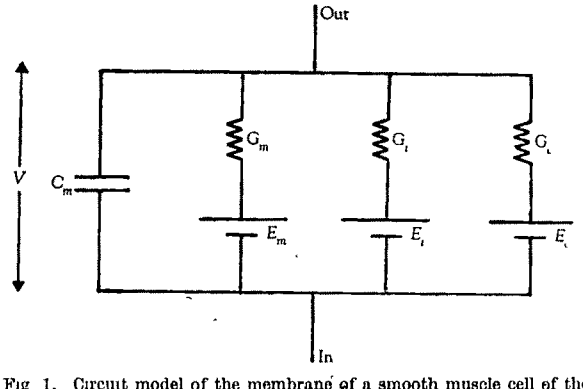

Fig 1. Circuit model of the membrane of a smooth muscle cell of the taenia coli during transmission from inhibitory and excitatory nerves.

summarized in the plot of $(V-E_m)$ versus E_m in Fig. 3. There is a linear relation between the change in membrane potential due to adrenaline $(V-E_m)$ and the initial resting potential E_m, the product moment correlation coefficient being 0·71. The regression line for these results is $(V-E_m) = -27 - 0{\cdot}37\ E_m$, and when this is compared with equation (11), the values of E_i and 'a' are found to be −73 mV and 0·6, respectively. This means that the reversal potential for inhibition is about −73 mV and that the ratio of the maximum conductance at the inhibitory receptors to the total membrane conductance is 0·6.

Bulbring and Kuriyama[11] have also examined the effects of acetylcholine (ACh) (10^{-6} g/ml.) on the membrane potential of cells with different initial resting potentials. Their results are summarized in the graph of $(V-E_m)$ versus E_m of Fig. 3. A linear relation exists between the changes in membrane potential to ACh $(V-E_m)$ and the initial resting potential E_m, the product moment correlation coefficient being 0·97. The regression line for these results is $(V-E_m) = 20 - 0{\cdot}77\ E_m$, which when compared with equation (12) gives E_e and b as −26 mV and 3·3, respectively. Thus the reversal potential for excitation is about −26 mV and the ratio of the maximum conductance at the excitator receptors to the total membrane conductance is about 3·3.

The values of a, b, E_e and E_i have been determined, and the graph of equation (10) can thus be drawn as in Fig. 3. This shows the membrane potential changes to be expected when both adrenaline and ACh are simultaneously applied to the muscle cells. Fig. 3 shows that simultaneous application of both transmitters brings the membrane potential from its resting value to a potential between −30 and −40 mV.

Recently, Jenkinson and Morton[12] have shown that noradrenaline produces an increase in the potassium permeability of smooth muscle cells of the taenia coli. If noradrenaline is the sympathetic inhibitory transmitter, then the equilibrium potential for sympathetic inhibition is about −80 mV. This value is close to the equilibrium potential of −73 mV determined by the present theory. The transmitter released from intramural inhibitory nerves to the taenia coli smooth muscle cells has not been identified[20,21]. This transmitter also increases the permeability of these cells to potassium ions[21], however, and therefore probably also has an inhibitory equilibrium potential of about −80 mV.

If potassium ions carry the inhibitory current, then according to equation (11), adrenaline will only cause a hyperpolarization of the membrane when the magnitude of the equilibrium potential for potassium (E_K) is greater than the resting potential (E_m). It has already been shown that in high external potassium solutions there is no difference in the value of E_K and E_m when the resting

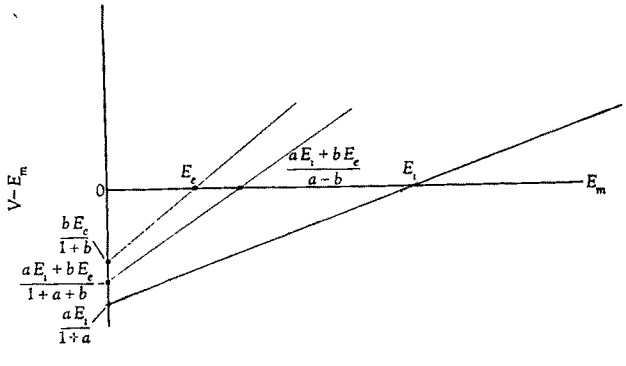

Fig. 2. Theoretical predictions of the relationships between the membrane potential change caused by the application of a transmitter substance to the smooth muscle cells of the taenia coli and the initial resting potential of these cells. Abscissa, E_m is the initial resting potential. Ordinate, $V-E_m$, is the membrane potential change produced by the transmitter substance For definition of symbols, see text.

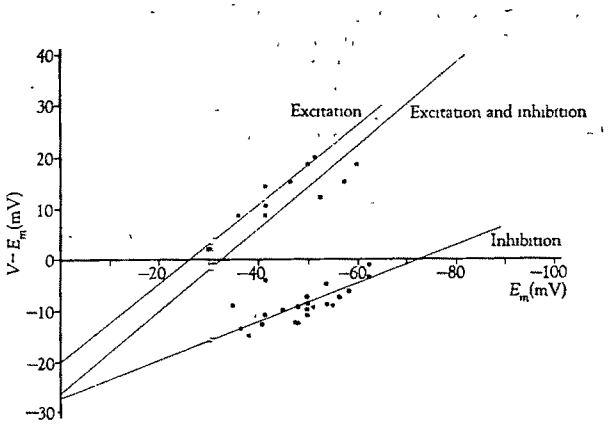

Fig. 3. Experimentally determined relationship between the membrane potential change caused by the application of a transmitter substance to the smooth muscle cells of the taenia coli and the initial resting potential of these cells. Co-ordinates as in Fig. 1. Closed squares, application of acetylcholine. Closed circles and open triangles, application of adrenaline. Curve marked "excitation" regression line for closed squares. Curve marked "inhibition" regression line for closed circles. The three closed squares from −50 to −60 mV are not included in the calculation of the regression line for excitation.

potential is smaller than about −40 mV. Hence, adrenaline should have no effect on the membrane potential when it has been depolarized beyond −40 mV by high external potassium solutions. This explains why Kuriyama[10] was unable to hyperpolarize the cells of the taenia coli with adrenaline when they had been depolarized beyond −40 mV with high external potassium solution.

Takeuchi[22] has shown that the end-plate current is carried by sodium and potassium ions. The reversal potential for the end-plate potential is therefore intermediate between the potassium electrode and the sodium electrode, being approximately −15 mV. In the case of the taenia coli the reversal potential determined for excitation was −26 mV, which is also intermediate between the sodium and potassium electrodes. It seems likely then that the excitatory current of the smooth muscle cells is also carried by both potassium and sodium ions.

If the external sodium concentration is increased, then the value of the sodium electrode will be increased. Since the excitatory junctional currents probably depend on the value of the sodium electrode, they will increase with an increase in external sodium concentration. This effect probably explains why Bulbring and Kuriyama[11] observed a potentiation of the depolarizing action of ACh when the external sodium concentration was increased.

If the external potassium concentration is increased, then the amplitude of the potassium electrode will decrease and so will the membrane potential. As the reversal potential for excitation probably depends on both potassium and sodium electrodes, high potassium solutions will enable the reversal potential more nearly to approach 0 V. Thus the action of high potassium will be to depolarize the membrane potential and shift E_e nearer to 0 V. There will be no excitation when $E_e = E_K = E_m$. This explains why Bulbring and Kuriyama[11] were unable to obtain any depolarizations of the membrane potential with ACh when the membrane had been depolarized to about −14 mV with high external potassium solutions. In this case $E_e = E_K = E_m = -14$ mV, which is smaller than the normal value of $E_e = -26$ mV.

This model has successfully predicted a near linear relation between the resting potential and the membrane potential changes caused by excitatory and inhibitory transmitter substances. It has also shown that the equilibrium potential for inhibition is close to the potassium electrode. The reversal potential for excitation has been shown to be close to that for the end-plate potential. The validity of the model remains partly in question, however, until the predictions of the membrane potential

changes during simultaneous application of both inhibitory and excitatory transmitters are verified experimentally.

TRANSPORT OF ALKALI IONS IN A MODEL SYSTEM DRIVEN BY WATER FLOW

By JUSSI RASTAS and AARNE EKMAN
Laboratory of Physical Chemistry, Institute of Technology, Helsinki
AND
DR. SIMO SALMINEN
Wihuri Research Institute, Helsinki

IT has been suggested that water movement in living systems might be an immediate driving force leading to unequal distribution of non-reactive substances with different mobilities[1-11]. Starting from this hypothesis, the problem of the distribution of alkali ions has been examined with the aid of relatively simple models, in which selective distribution of ions has been brought about[7-11]. Attempts to apply such models to biological problems indicate, however, that further investigations are required of certain characteristic properties of systems of this type.

In this work the rate of attainment of the stationary state for the distribution of ions as a function of water flow has been examined both experimentally and theoretically. The sodium/potassium selectivity coefficient values have been determined at high water velocities in order to ascertain whether the values in this range are in agreement with the earlier theoretical results[10]. Furthermore, values reported in the literature as having been obtained in a series of experiments with living cells have been compared with the theory.

Rate of attainment of the stationary state. The model system under consideration (Fig. 1) consists of two compartments, α and β, connected by a porous membrane. A constant flow of water is supplied to the smaller compartment α, which passes through the membrane to compartment β. At the moment $t = 0$, sodium chloride is added to the larger compartment β, which initially contained pure water. The concentration of the electrolyte in β, c^β, is kept constant during the experiment. The electrolyte diffuses through the membrane from compartment β to compartment α. The concentration of the electrolyte in the membrane is denoted by $c = c(x,t)$; thus $c(0,t) = c^\alpha$. The diffusion obeys the equations

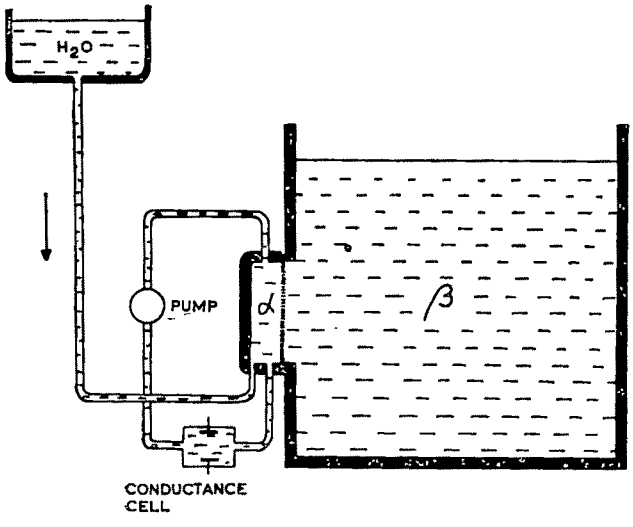

Fig. 1. The model system.

$$c(v_1 - v) = -D\frac{\partial c}{\partial x} \tag{1}$$

and

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} - v\frac{\partial c}{\partial x} \tag{2}$$

where v_1 is the velocity of the electrolyte, and v (constant) the velocity of water. D is the diffusion coefficient of the electrolyte, which is assumed to be a constant. The problem is to solve c^α as a function of time t from equations (1) and (2) with the initial and boundary conditions given.

Using the transformation

$$c = c^* \cdot \exp\left(\frac{v}{2D}(x - l) - \frac{v^2 t}{4D}\right) \tag{3}$$

equation (2) can be expressed in the form

$$\frac{\partial c^*}{\partial t} = D\frac{\partial^2 c^*}{\partial x^2} \tag{4}$$

The following initial and boundary conditions are valid in the system

$$\begin{aligned} c(x,0) &= 0 && 0 < x < l \\ c(l,t) &= c^\beta = \text{constant} && t > 0 \\ \frac{\partial c(0,t)}{\partial t} - \frac{DA}{V}\frac{\partial c(0,t)}{\partial x} &= -\frac{vA}{V}c(0,t) && t > 0 \end{aligned} \tag{5}$$

where A is the effective area of the membrane, and V the volume of compartment α. Equation (5) is obtained by substituting equation (1) into equation (6), which gives the time dependence of the concentration in compartment α

$$\frac{\partial c(0,t)}{\partial t} = \frac{dc^\alpha}{dt} = -cv_1\frac{A}{V} \tag{6}$$

The initial and boundary conditions corresponding to transformation (3) are respectively

$$c^*(x,0) = 0 \qquad 0<x<l$$
$$c^*(l,t) = c^\beta . \exp(v^2t/4D) \qquad t>0 \qquad (7)$$
$$\frac{\partial c^*(0,t)}{\partial t} - \frac{DA}{V}\frac{\partial c^*(0,t)}{x} = c^*\left(\frac{v^2}{4D} - \tfrac{1}{2}\frac{vA}{V}\right) \qquad t>0$$

The solution for $x = 0$:

$$c^\alpha(t) = c(0,t)$$
$$= c^\beta . \exp\left(-\frac{vl}{D}\right)\left[1 - \exp\left(-\frac{Avt}{V}\Big/\left(1 - \exp\left(-\frac{vl}{D}\right)\right)\right)\right] + \sum_{n=1}^{\infty} F_n(v,t,D,.....) \qquad (8)$$

where we have returned to the original variables, and where the initial and boundary conditions are satisfied by equation (7), was obtained by using the Laplace transformation. The last term can be neglected if the "free" volume of the membrane is small compared with the volume of compartment α, or $Al \ll V$, and we can write

$$c^\alpha(t) = c^\beta . \exp\left(-\frac{vl}{D}\right)\left[1 - \exp\left(-\frac{Avt}{V}\Big/\left(1 - \exp\left(-\frac{vl}{D}\right)\right)\right)\right] \qquad (9)$$

Equation (9) can also be obtained directly by assuming that a quasi-stationary state continually exists in the membrane. If $vl \gg D$, the exponent in parentheses in equation (9) takes the form $-\frac{Avt}{V}$ where Avt gives the volume of water that has flowed through the membrane. It is noticed from equation (9) that the decisive factor determining the rate at which the stationary state is attained is the ratio between the volume of water flowing through the membrane and the volume V of compartment α, the half-time being $t_{\frac{1}{2}} = \ln 2.\frac{V}{Av}$. When the volume of water flowing through the membrane exceeds the volume of compartment α by three to five times, the stationary state is virtually (95–99 per cent) attained.

The rate at which the stationary state could be reached was also studied experimentally at 25° C in the system depicted in Fig. 1. The electrolyte used was sodium chloride. The changes in the concentration of sodium chloride in compartment α were followed by conductance measurements. The porous membrane used in these and following experiments was '*MF* 30' (Membranfiltergesellschaft, Göttingen). Equation (9) was verified within the limits of experimental error. The results of one typical series of experiments are represented graphically in Fig. 2.

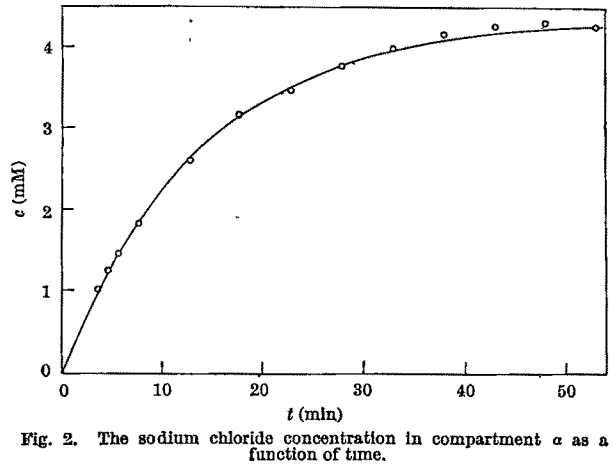

Fig. 2. The sodium chloride concentration in compartment α as a function of time.

The coefficients Av/V and vl/D can be obtained from equation (9) by substituting the experimental results. If the values of V, l, D and c^β are known, the values of v and A can be obtained. The values of l, A and v in the experiments were as follows: $l \sim 10^{-2}$ cm, $A \sim 2$–3 cm^2, and $v \sim 10^{-3} - 10^{-2}$ cm/s.

If the system contains several electrolytes, its exact mathematical treatment becomes complicated. In an approximate treatment the mutual effect of the electrolytes on their diffusion coefficients can be neglected. In this case every electrolyte obeys equation (9) independently, and the characteristic quantity that determines the rate at which the stationary state is reached, is still the ratio between the volume of water flowing through the membrane and the volume of compartment α.

Distribution of sodium and potassium ions in the stationary state. For the stationary-state distribution of sodium and potassium ions the following equation has been derived[12,3,10]:

$$\ln r_{Na,K} = \ln\left(\frac{c^\beta_{Na}}{c^\beta_K}\Big/\frac{c^\alpha_{Na}}{c^\alpha_K}\right) = 2\left(\frac{1}{D_{NaCl}} - \frac{1}{D_{KCl}}\right)vl \qquad (10)$$

where D_{NaCl} and D_{KCl} are the diffusion coefficients of sodium and potassium chlorides, and $r_{Na,K}$ is the selectivity coefficient, as defined in equation (10). This equation has been verified by the experiments of Nims and Thurber[8] with a similar system in the range $r_{Na,K} = 1$–4. The system lithium chloride–potassium chloride has been investigated by Rapoport[11] in the range $r_{Li,K} = 1$–7. In living systems, however, larger selectivity coefficients ($r_{Na,K}$ up to 2,000) are found. Thus it is of interest to examine the validity of the equation at higher values of $r_{Na,K}$. As can be seen from equation (10), if the diffusion coefficients and the thickness of the membrane, l, are constants, the selectivity coefficient $r_{Na,K}$ depends solely on the velocity of water.

Experiments were performed with the apparatus described in Fig. 1 at 25° C. The concentrations of sodium and potassium chlorides in compartment β were kept constant by adding calculated amounts of concentrated solutions. The concentrations of sodium and potassium ions were analysed with a flame photometer at the higher concentrations, and with neutron activation analysis at lower (10^{-5} moles/l) concentrations.

From equation (11):

$$D_{NaCl} \ln \frac{c^\beta_{Na}\, c^\beta_{Cl}}{c^\alpha_{Na}\, c^\alpha_{Cl}} = D_{KCl} \ln \frac{c^\beta_K\, c^\beta_{Cl}}{c^\alpha_K\, c^\alpha_{Cl}} \qquad (11)$$

derived previously[7,10] and from equation (10), it can be seen that the concentrations of sodium and potassium chlorides in compartment α decrease strongly as the water velocity v increases. This places an upper limit to the range at which $r_{Na,K}$ could be experimentally studied in the present system. When the value of $r_{Na,K}$ approached 100 the concentration of sodium ions became of the order of 10^{-6} moles/l., which is of the same order as the sodium impurities in the water used.

Fig. 3 shows that log $r_{Na,K}$ depends linearly on the rate of water flow, as equation (10) presupposes. The concentrations of the electrolytes should also obey equation (11). If we calculate the ratio

$$\mathrm{Log}\left(\frac{c^\beta_{Na}\, c^\beta_{Cl}}{c^\alpha_{Na}\, c^\alpha_{Cl}}\right)\Big/\mathrm{Log}\left(\frac{c^\beta_K\, c^\beta_{Cl}}{c^\alpha_K\, c^\alpha_{Cl}}\right)$$

from the experimental values (Table 1), we obtain values varying in the range 1·17–1·20. For the ratio D_{KCl}/D_{NaCl} we obtain the theoretical value 1·24, if we use the limiting values of diffusion coefficients at 25° C ($D_{KCl} = 1{\cdot}99 \times 10^{-5}$ cm^2/s, $D_{NaCl} = 1{\cdot}61 \times 10^{-5}$ cm^2/s).

These experiments demonstrate that in the system sodium chloride–potassium chloride–water it is possible, by increasing the value of the term vl, to obtain a high value for the selectivity coefficient $r_{Na,K}$. This happens,

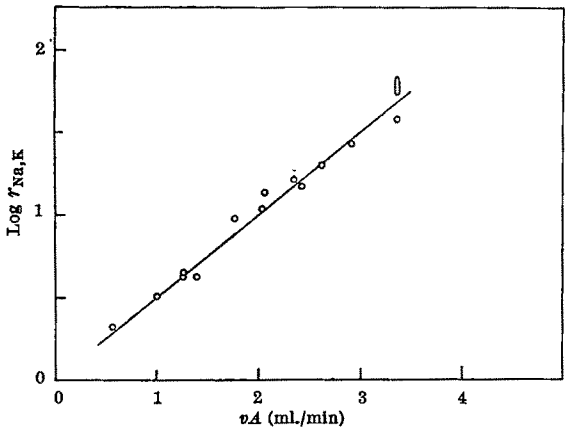

Fig. 3. The logarithm of the sodium/potassium selectivity coefficient as a function of the water flow rate.

however, at the expense of the decline of the concentrations not only of sodium ions but also of potassium ions in compartment α. Thus water flow alone cannot lead to the phenomenon characteristic of living cells, that is, accumulation of potassium ions with the concomitant extrusion of sodium ions. Equation (10) is valid even if compartment α contains ions other than sodium, potassium and chloride; however, the concentrations of sodium and potassium ions in compartment α do not now accord with equation (11)[10]. In connexion with the water flow, the hydrochloric acid in compartment α can lead to transport of sodium and potassium ions in opposite directions against their concentration gradients[9,10]. This effect may become pronounced when there are "fixed" anions in compartment α and when the concentration of hydrogen ions is low. Then the "fixed" anions determine the lowest concentration of the sodium and potassium ions in compartment α, regardless of magnitude of the water velocity and the membrane thickness, and thus the selectivity coefficient $r_{Na,K}$.

If the system under consideration contains more than two species of alkali cations, it is still possible to calculate approximately the selectivity coefficient between any two cations by inserting their mobilities into equation (10). Since, for example, the mobilities of rubidium and caesium ions are slightly higher than that of potassium, the selectivity coefficients between sodium and rubidium ions $r_{Na,Rb}$, or between sodium and caesium ions, $r_{Na,Cs}$, will become higher than the selectivity coefficient between sodium and potassium ions in the same system.

Biological applications. If compartments α and β are taken to represent intracellular and extracellular phases, respectively, and if the selectivity coefficients of alkali ions in the living systems are determined by equation (10), it is possible, with the aid of this equation and the experimental value given for $r_{Na,K}$, to calculate the expected values for $r_{Na,Rb}$ and $r_{Na,Cs}$ in living systems.

Relman *et al.*[13] have determined the distributions of sodium, potassium, rubidium and caesium ions between the intracellular and extracellular compartments of the rat. For 2 or 3 weeks, the test animals were given food

Table 1. STATIONARY STATE CONCENTRATIONS OF SODIUM AND POTASSIUM IONS AS FUNCTIONS OF WATER FLOW RATE

in which half the potassium was replaced with rubidium or caesium ions, after which the alkali ion distributions were analysed. The term vl in equation (10) was calculated from the concentrations reported for sodium and potassium ions in the extracellular and intracellular compartments, and further, by insertion of the diffusion coefficients[14] for rubidium chloride, $D_{Rb} = 2{\cdot}05 \times 10^{-5}$ cm^2/s, and caesium chloride, $D_{Cs} = 2{\cdot}04 \times 10^{-5}$ cm^2/s, into equation (10), the theoretical values for $r_{Na,Rb}$ and $r_{Na,Cs}$ were calculated.

Table 2 shows that in the case of sodium, potassium and rubidium ions the calculated selectivity coefficients are in satisfactory agreement with the experimental results, while a certain discrepancy exists in the case of sodium, potassium and caesium. It is to be noted that the diffusion coefficients used in the calculations are those of dilute aqueous solutions.

$$^{*}r_{Na,X} = \frac{c_{Na\ plasma}}{c_{X\ plasma}} \Big/ \frac{c_{Na\ muscle}}{c_{X\ muscle}} \quad (X = K^+, Rb^+, Cs^+)$$

According to equation (9), the water volume flow rate required to maintain a stationary state can be calculated from the half-exchange times for alkali ions and from the effective volume of the cell. Using a half-exchange time of 35 h for potassium in red blood cells[15], and assuming that the effective volume, V, is equal to the total cell volume, we obtain water volume flow rates of the order of 3×10^{-2} ml./ml. cells.h. These values, however, are several hundred times greater than the water volume flow rates which result from oxidative processes, as calculated from the measured oxygen consumption rates of red blood cells of 10–100 μl./ml. cells.h[16,17]. Thus the suggestion[9] that the cations could be driven by metabolic water seems to require that the effective volume of the cell should be several hundred times smaller than the total cell volume. It is unlikely that this condition would ever arise, and thus metabolic water seems to be inadequate as the sole source for the water volume flow rates required according to the theory. It is possible, however, that there is circulation of water both into and out of the cell. A metabolically induced water inflow along positively charged cation-impermeable sites might lead to a water outflow along the anionic "Na,K sites" and to a cation separation according to equation (10).

INDUCTION OF TOLERANCE IN ADULT MICE TO ALLOGENEIC RED CELLS

By Dr. JOHN S. THOMPSON, MARGARET CRAWFORD, CHARLES D. SEVERSON and HENRY P. RUSSE
Department of Medicine, University of Chicago, Illinois

It is now well established that specific immunological unresponsiveness—"tolerance"—can be elicited in normal adult animals by treatment with the specific antigen. Although tolerance to simple chemicals or soluble proteins is more easily produced in adult animals[1–5], the prolonged acceptance of skin homografts has been accomplished in mice by means of pre-treatment with large and/or repeated inocula of viable or disrupted spleen cells[6]. Recently, Rowley and Fitch[7] have demonstrated a state of partial unresponsiveness to sheep erythrocytes in rats exposed to a small and then repeated injections of this antigen. Examination of these reports reveals several variables which could well prove critical to the initiation of the non-reactive condition. First, the administration of a small quantity of specific antigen before or near the usually immunizing inoculum facilitates the development of tolerance[3–5]. Second, in addition to the small inoculum of antigen, a second larger injection incorporated in adjuvant partially eliminates the need for repeated closely spaced treatments to establish and perpetuate the tolerant state[3–5]. Third, the route of antigenic administration has been an important factor in some investigations[1,2].

This article describes the induction of tolerance to intravenously administered red blood cells labelled with chromium-51 in *H*-2 incompatible mice when the animals have been pre-treated with multiple intraperitoneal injections of adjuvant–antigen emulsions.

C57BL/6 female mice 12–16 weeks old served as hosts and *C3H/Anf* mice of the same age as donors throughout the investigation. These mice were purchased from the Cumberland View Farms, Oak Ridge, Tennessee, and maintained on the 'Rockland Mouse Diet' and water *ad libitum*. *C3H/Anf* red blood cells suspended in saline or incorporated in incomplete Freund's adjuvant (Difco) were administered to *C57BL/6* mice according to the following procedure. After separation of the plasma, donor *C3H/Anf* erythrocytes were washed three times and adjusted to a 50 per cent suspension in buffered saline. Some groups of *C57BL/6* recipients were injected with 0·2 ml. of this suspension subcutaneously or intravenously. Other groups were inoculated intraperitoneally, intradermally, or subcutaneously with 0·2 ml. of 50 per cent suspension of *C3H/Anf* red cells emulsified in 0·2 ml. incomplete Freund's adjuvant. Control mice received equal volumes of saline incorporated in adjuvant by these same routes, or saline injections alone subcutaneously and intravenously. The injections were repeated every 2 weeks for a total of 8 weeks.

Two weeks after the last injection, all the immunized and control recipients were injected with *C3H/Anf* erythrocytes labelled with chromium-51. The methods of chromation and estimation of survival of the donor labelled erythrocytes were identical to those previously reported[8]. Each mouse received 0·15 ml. of the labelled cells intravenously and samples were obtained at intervals thereafter and analysed for radioactivity in a Packard 'Autogamma' counter. In addition to these experimental groups, the survival of *C3H/Anf* and *C57BL/6* erythrocytes was determined in syngeneic recipients. The primary response of normal *C57BL/6* mice to labelled *C3H/Anf* red blood cells was also demonstrated by this same technique

Fig. 1 illustrates the survival of *C3H/Anf* and *C57BL/6* red cells in syngeneic recipients. The time at which 50 per cent of the radioactivity remained ($T\frac{1}{2}$) for *C3H/Anf* cells by this method was about 13 days while that of the *C57BL/6* cells was 15 days. In addition, Fig. 1 demonstrates the survival of *C3H/Anf* red cells in allogeneic *C57BL/6* hosts. For 6 days there was no evidence of decreased survival, but from this point accelerated elimination of the allogeneic red cell occurred. Thus, the primary response by *C57BL/6* mice to allogeneic *C3H/Anf* red cells was indicated by a reduced $T\frac{1}{2}$ of 8·5 days and by the fact that only 13 per cent of the labelled cells remained in circulation 20 days after they had been injected.

The pre-treatment of *C57BL/6* hosts with saline or saline–adjuvant emulsions administered by the aforementioned routes did not significantly alter the primary response and as such is not separately illustrated.

Fig. 2 demonstrates that some *C57BL/6* mice pre-treated with intraperitoneal injections of *C3H/Anf* red cells emulsified in incomplete Freund's adjuvant developed almost complete tolerance to this antigen. The survival of the labelled *C3H/Anf* erythrocytes in these

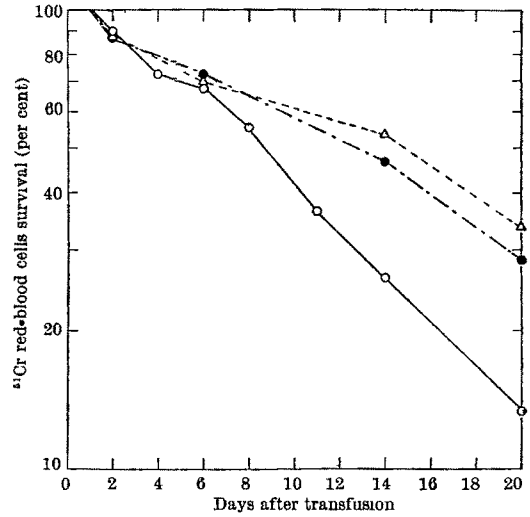

Fig. 1. The survival of *C3H/Anf* and *C57BL/6* erythrocytes labelled with chromium-51 in syngeneic recipients and of *C3H/Anf* erythrocytes in allogeneic *C57BL/6* hosts. △, *C57BL/6* red blood cells in *C57BL/6* hosts (fifteen mice), ●, *C3H* red blood cells in *C3H* hosts (eighteen mice); ○, *C3H* red blood cells in *C57BL/6* hosts (twenty-five mice).

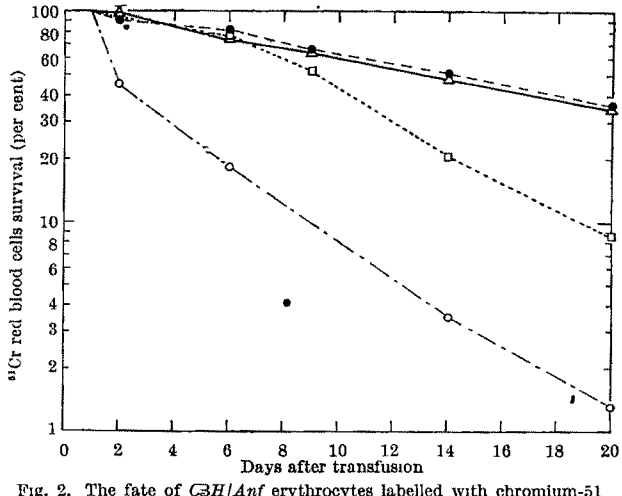

Fig. 2. The fate of *C3H/Anf* erythrocytes labelled with chromium-51 in syngeneic recipients and in allogeneic *C57BL/6* hosts pre-treated with multiple intraperitoneal or subcutaneous injections of *C3H/Anf* red blood cells incorporated in incomplete Freund's adjuvant ●, Normal *C3H* hosts (five mice); □, control *C57BL/6* hosts (ten mice), ○, *C57BL/6* hosts pre-immunized subcutaneously with *C3H* blood–incomplete adjuvant (eleven mice), △, *C57BL/6* hosts pre-immunized intraperitoneally with *C3H* blood–incomplete adjuvant (eleven mice).

allogeneic hosts was identical to that in syngeneic recipients. It should be emphasized that this represents the results in one experiment and that this non-reactive state did not occur in every mouse so treated. The induction of fully tolerant mice has varied in several experiments from 40 to 90 per cent. The remaining mice which did not develop tolerance fall into two categories. A few behaved as if this were the first exposure to the antigen, that is, the survival of the chromated red cell followed the pattern of a primary response, or they responded by accelerated immune elimination of the erythrocytes. The majority of the *C57BL/6* mice that were intradermally or subcutaneously inoculated with the antigen–adjuvant emulsion developed immunity, and no tolerant mice were produced with this procedure. The prior injection of red cells without adjuvant, either intravenously or subcutaneously, yielded a somewhat intermediate response between that of a primary and an immune reaction. Within each of these groups considerable variability occurred, but in no instance was a state of complete tolerance demonstrated.

In order to investigate further the condition of the immunized and tolerant *C57BL/6* host, serum and spleen cells were transferred to normal and sublethally (450 r.) irradiated syngeneic recipients. The methods of X-irradiation and the preparation of spleen cells have already been described[9]. Each recipient received either 0·2 ml. of Hanks's solution intravenously as the control, a suspension containing 25 million nucleated spleen cells in Hanks's, or 0·2 ml. of serum obtained from the appropriately indicated donors. Half the recipients were irradiated 48 h before the transfer of cells or serum and 24 h after the transfer all were injected with *C3H/Anf* erythrocytes labelled with chromium-51.

The mean survival in each group on the nineteenth day after transfusion is summarized in Table 1. At this time the primary response to *C3H/Anf* erythrocytes was reflected by a survival of 16·3 per cent in the untreated non-irradiated hosts. It is clear that 450 r. effectively blocked this response because *C3H/Anf* red cells survived fully as well in the irradiated *C57BL/6* hosts, 40·6 per cent, as in the control group of syngeneic recipients, 38·6 per cent. Serum obtained from normal, immune and tolerant *C57BL/6* mice had no effect on the survival of allogeneic red cells in irradiated and non-irradiated hosts.

Whereas the transfer of normal spleen cells had no additional action in the non-irradiated recipients, they were able to partially reconstitute the primary response in the irradiated hosts as was indicated by the fact that the survival of the allogeneic red cell was reduced to 24·3 per cent. Spleen cells collected from mice which had been exposed to the antigen on only one occasion, primary response spleen cells, produced a somewhat accelerated rejection, 13·1 per cent survival in the non-irradiated recipients, and 7·5 per cent in the irradiated recipients. Spleen cells obtained from immunized *C57BL/6* recipients also evoked accelerated elimination.

The observation that the cells transferred from tolerant mice behaved quite differently in the non-irradiated as compared with the irradiated hosts is of particular interest. They produced only partial reconstitution of the immune mechanism when transferred to irradiated recipients. Yet administration of these same cells to non-irradiated hosts caused an accelerated rejection—6 per cent survival of the labelled erythrocytes, which is an effect at least as potent as that obtained by the spleen cells collected from immune mice.

Thus, these results confirm the observation that the appropriate manipulation of several factors may be critical to the development of either the tolerant or hyperimmune state. The fact that neither condition could be elicited by the subcutaneous or intravenous injection of the same quantity of antigen in saline indicates that the antigen–adjuvant emulsion was one important factor. Furthermore, in preliminary investigations not reported here, the induction of immunological unresponsiveness was more easily accomplished with incomplete rather than complete Freund's adjuvant. The latter agent tended to further the production of immunity rather than tolerance. This may prove to be an important distinction because splenomegaly and reticulo-endothelial hyperplasia were greater in those mice injected with an emulsion of antigen in complete Freund's adjuvant than in those treated with emulsions lacking the mycobacteria.

The route of administration of the antigen–adjuvant emulsion appears to be another important factor. The fact that the subcutaneous and intradermal routes tend to favour the initiation of immunity rather than tolerance cannot be adequately explained at the present time. Perhaps the intraperitoneal route favours the early release into the circulation of a small quantity of antigen. If this were true, the early antigenic stimulation might act in concert with the other sustaining properties of the antigen–adjuvant emulsion to promote tolerance[3–5].

The mechanism whereby antigen, particularly in small amounts, may facilitate the development of immunological unresponsiveness has not been definitely ascertained, but the demonstrations by Uhr and Bauman[10] and Neiders, Rowley and Fitch[11] that passively transferred antibody depresses the primary response to antigen later administered may offer an explanation. It follows that the first inoculum of antigen elicits a humoral response which in turn serves to regulate the limits of the reaction to antigen later administered. Rowley and Fitch[7] also conclude that the persistence of antigen is important in the maintenance of tolerance because it may interfere with either the division or maturation of cells responsible for the formation of antibodies. They have demonstrated that repeated injections of sheep red cells given at short time intervals resulted in the stabilization of the number

Table 1. Effect of Immune and Tolerant Spleen Cells and Serum on the Survival of *C3H/Anf* Blood labelled with Chromium-51 in Normal and Sublethally Irradiated *C57BL/6* Mice

* Each group was composed of between four and eight mice.

† Serum recipients each received 0·2 ml. intravenously. Spleen cell recipients each received intravenously 25×10^6 nucleated cells. Primary response spleen cells refer to cells collected from mice reacting to *C3H/Anf* blood for the first time. Immune or tolerant spleen cells refer to cells collected from mice exhibiting either an immune or tolerant response to *C3H/Anf* blood.

of antibody forming cells in the host rat spleen, but as soon as the interval was lengthened a progressive increase in the number of antibody producing cells occurred. Adjuvant; by retarding and yet sustaining the release over prolonged periods, may accomplish this same purpose.

Although the survival of chromated red cells represents a useful method of detecting immunological phenomena[8,12], it does not help to ascertain whether the removal of the antigen is brought about by cellular or humoral reactions. Moller[13] has reported that the immune elimination of *H*-2 incompatible mouse erythrocytes may not occur in circumstances where both haemolytic and haemagglutinating isoantibodies are readily demonstrated *in vitro*. We can confirm that the passive transfer of serum from immunized mice was totally incapable of accelerating the elimination of labelled allogeneic red cells in normal and irradiated recipients; however, spleen cells collected from immunized mice were active in both the normal and X-irradiated syngeneic recipients. The ability of spleen cells transferred from tolerant mice to convey fully adoptive immunity on normal, but not on sublethally irradiated syngeneic recipients is of particular importance. This suggests that the inductive phase of immunization was intact in the tolerant spleen cells, but that the productive phase was limited. This observation does not agree with the findings of Dietrich and Weigle[5], Argyris[14] and Friedman[15], who indicate that the transfer of tolerant cells conveys adoptive tolerance on the recipient. Nossal and Larkin[16], however, have reported that the transfer of rat spleen and bone marrow cells made tolerant to mouse red cell antigens lost their tolerance on transfer to irradiated rat recipients. At the present time it is not possible to explain the difference.

EFFICIENCY OF SCINTILLATION COUNTING OF TRITIUM LABELLED DNA-PROTEIN IN THE MIXED LEUCOCYTE REACTION *IN VITRO*

By DR. JOHN F. MOORHEAD and DR. WILLIAM McFARLAND
Veterans Administration Hospital and Georgetown University, Washington, D.C.

IN the course of experiments on the incorporation of tritiated thymidine (thymidine methyl-^{3}H, specific activity 12·8 c./mmole, Nuclear Chicago Corporation) into deoxyribonucleic acid (DNA) in mixed leucocyte cultures[1] it was observed that the efficiency of scintillation counting varied considerably with the method of preparation of the sample. Investigations were therefore carried out to determine the reasons for this variation.

Mixed leucocyte cultures were prepared according to the method previously described[2], except that *TC* 199 (Grand Island Biological Co., Grand Island, New York) was substituted for *TC* 109 and 20 per cent plasma was used instead of 40 per cent. Three-millilitre cultures containing 1×10^6 cells ($0{\cdot}5 \times 10^6$ from each donor) were incubated for up to 7 days before adding tritiated thymidine (Th-^{3}H). In later experiments the cultures were usually collected on the sixth day, because under the experimental conditions described maximum DNA synthesis occurred at this time, and declined thereafter[1]. Radioactive samples were obtained by first incubating the cells for 6 h with Th-^{3}H (3 μc. per 3 ml. culture), then washing the cells three times in ice-cold 0·9 per cent saline before precipitation of the tritium-labelled DNA-protein by addition of excess ice-cold 5 per cent trichloroacetic acid (TCA). In some experiments precipitates were filtered on to membrane filters (Gelman 'Alpha-6-Metricel', pore size 0·45μ (about 0·3μ when wet), thickness about 70μ), and then dried (but not desiccated) overnight in room air (21° C). After this the precipitates were immersed in 0·5 ml. 0·6 N Nuclear Chicago 'Solubilizer' (NCS) and 0·3 ml. of spectroanalysed toluene and the surface precipitate was dissolved by shaking in a water bath for 4 h at 65° C. In a later group of experiments, the precipitates were not filtered, but were dissolved in 0·5 ml. of 0·6 N NCS, followed by gentle agitation for a few seconds in a stream of hot tap water before being transferred to a counting vial. Ten millilitres of scintillator fluid (100 mg 1,4-*bis*-2-(5-phenyloxazolyl)-benzene (POPOP), 4 g 2,5-diphenyloxazole (PPO), 1 l. spectroanalysed toluene) was then added to each counting vial. "Blank" vials were made up in an identical manner, but in these the DNA-protein precipitate was omitted. In some experiments DNA was extracted from TCA precipitate by heating in 5 per cent TCA for 15 min at 90° C or in 0·5 N perchloric acid for 20 min at 90° C; 100 μl. portions of the extract were then added to counting vials containing 0·5 ml. NCS and 10 ml. fluor. Radioactivity was measured in a Nuclear Chicago 720 series liquid scintillation counter at ambient temperature and counting efficiency was determined by the channels ratio method[3,4] from a standard quenching curve prepared in the laboratory using chloroform-quenched samples of known radioactivity.

To facilitate analysis, results of efficiencies for dry solubilized (dry-sol) and wet solubilized (wet-sol) precipitates were grouped separately and then arranged in classes depending on the radioactivity (d.p.m.) of the sample. Data from extracted DNA were included in the wet-sol groups. There were 285 dry-sol and 110 wet-sol samples.

It was found that the calculated counting efficiency for wet-sol precipitates was consistently higher than that of dry-sol precipitates; the differences were most marked in the low count range of 0–500 d.p.m. (Fig. 1). The distribution of counting efficiencies for wet-sol and dry-sol samples was determined and, by applying the χ^2 test for goodness of fit, it was found to differ significantly from normal in both cases ($P < 0{\cdot}001$). In each case the distribution was skewed (wet-sol $\sqrt{b_1} = 0{\cdot}999$, $P < 1$ per cent, dry-sol

Table 1. SIGNIFICANCE OF DIFFERENCES BETWEEN COUNTING EFFICIENCIES OF WET-SOL AND DRY-SOL SAMPLES IN GROUPS SELECTED FOR RADIOACTIVITY (D P.M.)

d.p.m.	(Wilcoxon 2-sample test) K^*	Probability
0– 500	−6·628	< 0·001
500–1000	−4·682	< 0 001
1000–2000	−2 327	0 02
2000–4000	−3·120	0 002
> 4000	−6·469	< 0·001

* K is the standardized statistic used in the Wilcoxon 2-sample test (ref. 6).

$\sqrt{b_1} = 0{\cdot}692$, $P < 1$ per cent). Further analysis showed that differences in efficiencies for wet-sol and dry-sol samples between classes selected on the basis of count rate were highly significant (Wilcoxon 2-sample test, Table 1).

It was found possible to count wet-sol samples and extracted DNA after short (3–4 h) stabilization periods, whereas dry-sol samples could not be counted for as long as 2 days after preparation because of prolonged spurious activity. It was at first suspected that the increased counting efficiency of wet-sol samples resulted from the presence of small quantities of acid, and samples of known radioactivity were therefore made up to contain either 5 per cent TCA, 0·5 N PCA, or hydrochloric acid in increasing volumes from 0 to 100 μl.; addition of volumes larger than 100 μl. resulted in cloudiness owing to phase separation. Controls consisted of NCS–PPO–POPOP–toluene without radioactive material. All samples were then counted at intervals for several days at ambient temperature. It was found that 50–100 μl. acid not only markedly increased the counting efficiencies of test samples but also led to rapid loss of spurious activity in controls. To determine whether acidification alone was responsible, the experiment was repeated using distilled, de-ionized water. Results were found to be the same as for acidification and are shown in Fig. 2. Small increments in efficiency (< 0·5 per cent) were noted for all samples when they were counted after several weeks. The effect of hydration was tested further by the addition of 50 μl. of water to dry-sol samples which had been counted previously; efficiency increased—notably in samples of low activity. It was found, however, that hydration of chloroform-quenched samples did not increase their counting efficiency.

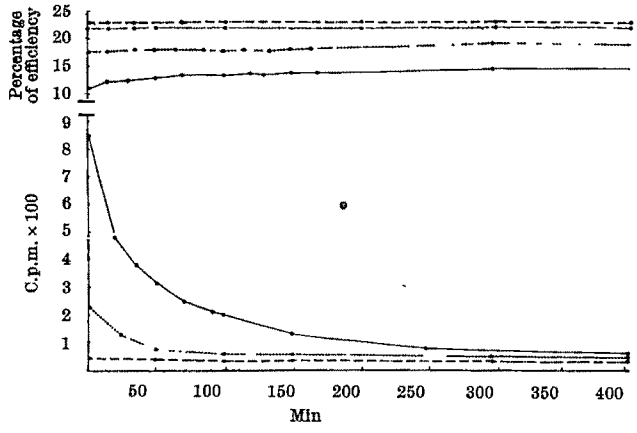

Fig. 2. Upper curves, counting efficiency of hydrated samples of known equal radioactivity. Lower curves, loss of spurious counts following hydration. —·—·—, 50 and 100 μl. water; ·····, 25 μl. water; – – – –, 10 μl. water; ————, no water.

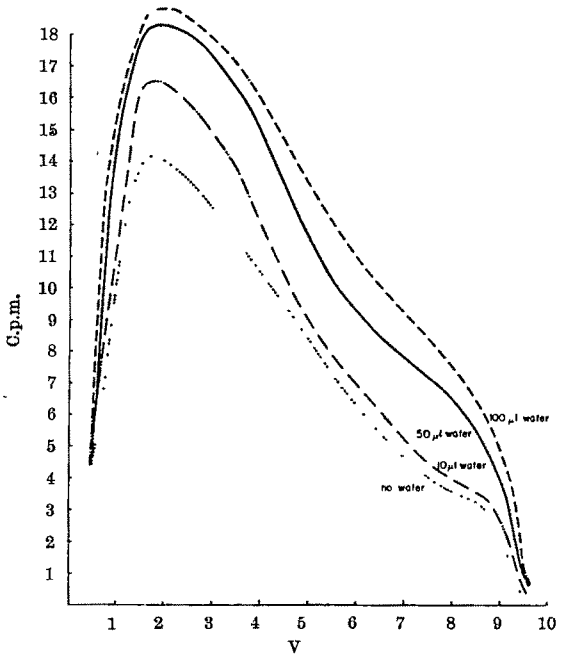

Fig. 3. Pulse height spectra of samples of equal radioactivity subjected to varying degrees of hydration. ....., No water, — — —, 10 μl. water, ————, 50 μl. water, — —·—, 100 μl. water.

In connexion with the deterioration in counting efficiency resulting from quenching, Baillie[3] has pointed out that, probably unique to tritium, small shifts in the pulse height spectrum result in large changes in counting efficiency when this is measured by the channels ratio technique. The possibility that this phenomenon was responsible for the increased efficiency observed was examined by scanning the spectra of increasingly hydrated samples containing equal amounts of tritiated thymidine but no protein or DNA, using a moving window between level 3 and level 5 (channel A and channel B). The results, which are presented in Fig. 3, indicate that hydration did not cause obvious major spectral shifts, but rather increased the total number of counts recorded, the principal increment being in the number of low-energy emissions recorded (Fig. 3, 3–10-V window). From this observation it seems likely that the increased number of low-energy emissions recorded resulted from enhanced sensitivity of the scintillator. Further, increased sensitivity was accompanied by early stabilization of the count rate. It is known that water acts as a quencher when its concentration in the scintillator is high[5], but to our knowledge a gain in efficiency resulting from the addition of small quantities of water up to (but not exceeding) the point of phase separation has not previously been recorded. Additional points of practical importance are that the count rate remains stable for long periods (more than 2 months) and does not appear to be adversely affected by long exposure to fluorescent light. Moreover, it is unnecessary to cool the samples in order to obtain normal background counts.

In conclusion, following the observation that tritium-labelled DNA protein samples could be counted at room temperature with greater efficiency if acidified, preliminary investigations suggest that addition of water alone to the NCS–PPO–POPOP–toluene scintillator system stabilizes the scintillator and enhances counting efficiency by increasing the total number of emissions recorded, the greatest relative increase being in the low energy part of the tritium spectrum. The site of action in the scintillator of small quantities of water is unknown, but is apparently different from that of chloroform and possibly other quenching agents. Small amounts (< 3 mg) of DNA labelled with tritiated thymidine have been counted within a predictable narrow range of efficiency despite wide variations in sample activity. We have so far applied this technique only to the measurement of radioactivity in the mixed leucocyte reaction and antigen stimulated cultures, but it is possible that it may find wider application in liquid scintillation counting of tritium.

We thank Dr. H. Maisel, director, Computation Center, Georgetown University, for assistance in the statistical analysis of data. This work was supported by a U.S. Public Health Service grant.

FAILURE TO DEMONSTRATE BLOCKING OF I ANTIGEN BY *Mycoplasma pneumoniae* IN VITRO AND IN VIVO

By Dr. T. FEIZI and Dr. J. H. DARRELL*
Department of Medicine and Department of Microbiology, Royal Free Hospital, London

Infection with *Mycoplasma pneumoniae* in man gives rise, in a large proportion of cases, to transiently elevated titres of cold agglutinin anti-I[1,2]. The chronic cold agglutinin syndrome, which is characterized by a prolonged elevation of anti-I level, is sometimes seen in association with malignant lymphomata[2]. Such observations have suggested a possible relationship between blood group I, mycoplasma infection and the malignant haemopoietic disorders. Furthermore, the blood of leukaemic patients has been reported to contain structures resembling mycoplasmas[3], and tissue cultures inoculated with leukaemic material have yielded mycoplasma species[4,5]; in addition a mycoplasma has been isolated directly, on agar, from a human leukaemic bone-marrow[6]. McGinniss *et al.* reported diminution of I antigen in fifteen out of forty patients with leukaemia[7] and suggested that this probably resulted from blocking or destruction of the I antigen by an infective or neoplastic agent. Further work apparently demonstrated that anti-I activity could be inhibited by treatment of normal I-positive red cells with various mycoplasmas[8]; *M. pneumoniae* was among those which produced "strong" inhibition.

M. pneumoniae is so far the only human mycoplasma of undoubted pathogenicity in man; the part played by other mycoplasmas in human disease is uncertain. We therefore chose to study the effect of this organism on the I antigen *in vitro* as well as *in vivo*.

In the investigations reported here we used red cells from a healthy group OI subject, from a healthy group Ai donor and from four group A patients with respiratory infections due to *M. pneumoniae*. The diagnosis in these latter four patients was based on the development of a four-fold or greater rise in titre of complement-fixing antibody to *M. pneumoniae* in association with a transient rise of cold agglutinin titre during the illness. We used anti-I sera from the following three persons, (*a*) a group A patient with *M. pneumoniae* infection who was bled at the time of a transient rise of her cold agglutinin titre to 128 at 4° C (titre 32 at 20° C), (*b*) a group A patient with the chronic cold agglutinin syndrome who had a cold agglutinin titre of 1,024 at 4° C (titre 256 at 20° C) and (*c*) a healthy donor of group Ai who had a cold agglutinin titre of 8 at 4° and at 20° C.

The strain of *M. pneumoniae* used by us was obtained from Dr. Sheila Stewart (Wellcome Laboratory, City Hospital, Edinburgh). In our laboratory it was maintained by weekly passage on solid media and when necessary reclaimed from cultures stored in sloppy pleuropneumonia-like organism (PPLO) agar at −30° C. Difco PPLO agar and Difco PPLO broth were used as basal culture media. To 70 ml. of each of these were added 20 ml. unheated horse serum, 10 ml. 10 per cent Oxoid yeast extract and 1 ml. 0·2 per cent calf thymus DNA (B.D.H.). Thallium acetate (final concentration 1/4000) and penicillin *G* (final concentration 50 units/ml.) were included as bacterial inhibitors. The inoculum was either 1 ml. of a 3 day broth culture or three blocks, 1 cm square, from solid cultures. The culture was incubated aerobically for 5 days at 36° C and then centrifuged at 12,000 r.p.m. at 4° C for 30 min. The deposit was resuspended in physiological saline to achieve a hundred-fold concentration and frozen and thawed twice before use. Before and after centrifugation subcultures of the material were prepared on agar medium and after incubation they were examined for typical colonial morphology, β-haemolysis of sheep red cells and for haemadsorption, and they were also tested against mycoplasma rabbit antisera using a paper disk technique to confirm the specific identity of the mycoplasma. The concentrated mycoplasma suspension contained between 10^7 and 10^8 colony forming units per ml. and it was shown to be capable of fixing complement with serum known to contain complement fixing antibody to *M. pneumoniae*. Uninoculated medium was incubated and concentrated in an exactly similar manner for use as a control suspension.

To test the effect of *M. pneumoniae* on the I antigen, one volume (measured as drops from a 0·025 ml. dropping pasteur pipette) of mycoplasma suspension was added to one volume of a 2 per cent saline suspension of washed OI cells. The mixture was incubated at 20° C for 30 min or at 4° C overnight, washed thrice in 5 times its volume of normal saline and reconstituted to a 2 per cent red cell suspension. As controls, 2 per cent suspensions of OI cells were similarly treated with a concentrate of uninoculated PPLO medium and with normal saline. Then the I antigen on the red cells was measured quantitatively by comparing the cold agglutinin titres of the three anti-I sera using control OI cells (incubated with saline or with a concentrate of uninoculated medium) with the titres obtained when OI cells were treated with *M. pneumoniae* suspension. For the titration of the anti-I sera glass precipitin tubes and 0·025 ml. dropping pasteur pipettes were used. The anti-I sera were initially diluted with normal saline so that serial two-fold dilutions of them would produce OI cell agglutination in 3–5 tubes (Table 1).

* Present address: Department of Clinical Bacteriology, Postgraduate Medical School, London

Table 1. DEGREE OF AGGLUTINATION* WITH ANTI-I OF CONTROL OI RED CELLS AND OF OI CELLS TREATED WITH *M. pneumoniae*

Treatment of OI cells	Agglutination of red cells (reciprocal of serum dilution)				
	Anti-I from a case of *M. pneumoniae* infection				
	(8)	(16)	(32)	(64)	(128)
OI cells + saline	++++	++++	+++	+++	++
OI cells + medium	++++	++++	+++	+++	++
OI cells + *M. pneumoniae*	++++	++++	+++	++	++
	Anti-I from a chronic cold agglutinin syndrome				
	(64)	(128)	(256)	(512)	(1024)
OI cells + saline	+++	++	++	+	+
OI cells + medium	+++	+++	+++	++	+
OI cells + *M. pneumoniae*	+++	+++	++	++	±
	Anti-I from group Ai donor				
	(2)	(4)	(8)	(16)	
OI cells + saline	+++	+++	+	±	
OI cells + medium	+++	+++	++	−	
OI cells + *M. pneumoniae*	+++	++	+	−	

Agglutination tests performed at 4° C.

* ±, 2 or 3 cells sticking together; +, agglutinates of 4–12 cells; ++, agglutinates of 12–20 cells; +++, large agglutinates but some free cells remaining, ++++, complete agglutination with no free cells.

To one drop of each dilution of anti-I serum one drop of red cell suspension was added and readings for grading of agglutination were performed under the low power of a microscope after incubation at 4° C for 2 h. In order to achieve an accurate comparison between the mycoplasma-treated and control cells, these agglutination tests were performed at the same session.

Table 1 shows that treatment of OI red cells with *M. pneumoniae* suspension did not affect the activity of any of the three anti-I sera. Furthermore, overnight incubation at 4° C of normal red cells with mycoplasma suspension did not affect the titre of these sera. Because Schmidt *et al.* performed their tests of anti-I activity at 22° C, we performed additional tests at this temperature; inhibition of anti-I activity was again not observed. In addition, the *F.H.* strain of *M. pneumoniae* provided by Dr. D. Taylor-Robinson failed to inhibit the anti-I activity of the three sera.

The agglutinability (I status) of red cells from patients with *M. pneumoniae* infection was compared with that of red cells from healthy OI and Ai donors in the following manner. Anti-I serum from the patient with the chronic cold agglutinin syndrome was initially diluted 1/32 and then serial two-fold dilutions were made to a dilution of 1/1024; to one volume of each dilution of anti-I serum an equal volume of a 2 per cent suspension of test red cells was added. After 2 h of incubation at 4° C the results of the tests were read microscopically and recorded as shown in Table 2.

The anti-I serum agglutinated the normal OI cells to a titre of 512. It reacted only weakly with the Ai cells, indicating the lack of I antigen in this donor. The cells of the patients with *M. pneumoniae* infection reacted with the anti-I serum in a manner indistinguishable from the normal OI cells. In other words infection with *M. pneumoniae* did not cause blocking of the I antigen *in vivo*.

The red cells of the patients with *M. pneumoniae* infection were obtained during the third to the seventh weeks of illness. Since none of these patients showed overt evidence of haemolytic anaemia during the course of their disease it would be expected that any destruction of the I antigen by the mycoplasma during the early phase of the disease would have persisted and would have been detectable at the time of the test. We have, in fact, tested red cells obtained from eight patients during the first week of illness due to *M. pneumoniae* infection. These were stored in glycerol at −20° C and were shown to be of normal I status.

Table 2. COMPARISON OF I STATUS RED CELLS FROM PATIENTS WITH *M. pneumoniae* INFECTION WITH THAT OF CELLS FROM A HEALTHY OI AND A HEALTHY Ai DONOR, USING ANTI-I SERUM FROM A PATIENT WITH CHRONIC COLD AGGLUTININ SYNDROME

Type of red cell tested	Agglutination* (reciprocal of serum dilution) (32)	(64)	(128)	(256)	(512)	(1,024)
Normal OI	++++	++++	++++	++	++	−
Ai	+	+	−	−	−	−
M. pneumoniae infection						
Patient 1	++++	++++	++++	+++	++	±
Patient 2	++++	++++	++++	+++	+	−
Patient 3	+++	+++	+++	+++	++	−
Patient 4	+++	+++	+++	+++	+	−

All agglutination tests were performed at 4° C and at same session.

* Grading of agglutination as in Table 1.

The cause of the discrepancy between our *in vitro* results and those of Schmidt *et al.*[8] is difficult to explain. The three anti-I sera used in our experiments also failed to detect loss of I antigen in patients with acute leukaemia[9]. During the preparation of this report we noted that Ducos *et al.*, using a quantitative technique, have also failed to detect I antigen loss in leukaemic patients[10].

Apart from our *in vitro* results, we have also failed to demonstrate the blocking effect of *M. pneumoniae in vivo*. Indeed, it would be difficult to envisage a mechanism whereby mycoplasma could block the I antigen of red cells and at the same time stimulate the production of I-specific cold agglutinins.

We thank Dr. W. J. Jenkins for the cells from an Ai donor, Dr. J. Wallace for the anti-I serum from an Ai donor and Dr. R. G. Sommerville for the *M. pneumoniae* complement fixation tests. We also thank Dr. D. Taylor-Robinson for his helpful criticism.

One of us (T. F.) is in receipt of a research fellowship from the Royal Free Hospital and of a grant for technical assistance and equipment from the Medical Research Council.

A THEORY OF THE NATURE OF MEMORY

By PROF. J. S. GRIFFITH
Department of Mathematics, Bedford College, London

IT appears to be generally believed that no really simple theory of memory is possible, which is based on synaptic facilitation, is physiologically plausible and is in agreement with the most basic properties of conditioned reflexes[1–3]. This article describes a mechanism which, although undoubtedly speculative, does seem to possess all these requirements.

It seems desirable not to have too narrow a view of the problems connected with memory. The nervous system of an animal can learn to do new things, but it also has a very considerable stability of organization. The slow, partial restoration of reflex action after transection of the spinal cord (recovery from "spinal shock") is a good example of this[4]. Whether such a phenomenon

should be called stability or learning is an irrelevant matter of semantics, but it is clear that any theory of memory should find a natural place for it. Even in the special case of human memory for material experienced consciously, it can be argued that some sort of stability criteria are operating. People forget. There is a tendency to think of long-term memory as indelibly engraved on the brain, but the experimental evidence suggests that it decays, although whether completely or not is uncertain[5]. Even our memories from early childhood are usually, if not always, reinforced by being "inspected" from time to time. The reciprocally related processes of learning and forgetting, as of damage to the nervous system and restoration of function, show the characteristics of the components of a servomechanism. I shall deal with this theme in this article.

I have investigated the proposal that learning is based on changes of threshold or synaptic linkage following the joint firing of two neurones and have found myself naturally led to quite a comprehensive theory of the basis of memory. This theory is much influenced by the earlier physiological discussions of the problem of memory[1,6-9], especially that of Burns[2], and by those which take into account our present knowledge of the biochemical organization of cells[10-13]. I shall not discuss the idea that memory is encoded in the nucleotide sequence of RNA or DNA. However, *m*RNA may be a necessary intermediate at one point. On account of the confused experimental position, no discussion will be entered into on the reports of transfer of learning between animals[14,15]; it will be apparent, however, that the present theory is not inconsistent with the transfer of some relatively unspecific effects.

Control of Synaptic Linkage

One way in which learning could operate is as follows. If a neurone A has a synapse from its axon to a cell B, and A and B fire together, then the synapse is strengthened. Hence the next time A fires, B is more likely to do so. It was pointed out by Burns[2] that, although this particular model of learning is popular among theorists, it does not really satisfy the requirements of psychologists. I shall retain it for the time being, however, because Burns's criticism can be met. A more serious point is that most experimental evidence, especially in the peripheral nervous system, suggests that use weakens synapses rather than strengthens them[16]. Because of this, I shall consider the more general question: how can the synaptic strength be altered as a consequence of the joint firing of neurones A and B?

The first point to note is that the alteration process involves a mechanism which only works when both neurones A and B have fired, otherwise it would not be specific for the relationship of A to B. This means it cannot depend simply on the transmitter substance ejected from A. For similar reasons, a mechanism assuming a regulatory action on enzyme synthesis[17] in the nucleus of either cell A or cell B is unsatisfactory. For example, supposing, through the effect on its nucleus, the threshold of B is lowered. Then B is fired more easily by all cells having excitatory synapses with it, and not just by A. On the other hand, an effect on the nucleus of A, which might be difficult, anyway, because of the expected axoplasmic flow down the axon[18,19], would affect all the synaptic terminals, not just those connecting with B.

These considerations suggest that the change must occur directly, not indirectly, at or near the synapse. It occurs just when or after the surface membrane on the two sides of the synaptic cleft has been disturbed (depolarized) and must involve both cells. This seems to suggest strongly that something passes between cell A and cell B, that this something can only pass through the two membranes when both have been recently disturbed, and that the "something" forms the basis of learning and memory. Let us call this "something" F. F passes between A and B and then alters the synapse, either by causing it to grow or atrophy or perhaps by affecting the enzyme-controlled production of transmitter[10]. Which way does F pass? There are several reasons for thinking it more likely to be from B to A. Synapses are usually on or near the cell body of the receiving cell B, but far from the body of the transmitting cell A. Thus the chief manufacturing district of B is near the synapse, while the synaptic region of cell A is distinctly isolated from its nucleus. Next, once F gets through into the axonal tip of cell A, it will tend to stay in that tip because of the axoplasmic flow already mentioned. Were the passage in the other direction, there would be less reason for F to remain in the tip (although there could, of course, be specific sites which would absorb it irreversibly). Finally, it is believed that in the formation of the nervous system cells find their correct partners by a process of axonal growth under the stimulation of some substance emitted from another cell[20,21]. All these things suggest, although not conclusively, that F passes from cell B to cell A and, having arrived there, stimulates or depresses the growth of the axonal tip.

Peripheral Learning

Much reliable information is available about learning at the cerebral level, but it does not relate to cellular change. It is therefore better to start with the peripheral system, where the experimental evidence appears to be clear: use causes atrophy, disuse causes growth[16]. If the argument of the previous section is accepted, then this evidence implies that there is a substance E produced in the receiving cell B which, on joint firing of A and B, passes across the synaptic cleft and into the adjacent axonal tip of A. E inhibits the growth of that axonal tip. On the other hand, the axon was provoked to grow there in the first place by an exudate from cell B. Thus it becomes necessary to postulate also a growth substance, F, which passes continually across the synaptic cleft from B to A. The maintenance and growth of the axonal tip are assumed to depend partly (or even wholly) on this supply of F. We also suppose that the rate of passage of F per unit area of synaptic cleft depends only on the metabolic activity of cell B but not directly at all on the number of times A and B fire jointly.

This gives a simple servomechanism which, provided A receives its normal input, keeps the rate of firing of B fairly constant even if the average input to B from other sources should change. It is instructive to write down an equation governing it, assuming that E and F compete in a proportional and additive manner. We can then write

$$\mu\alpha + \frac{d\alpha}{dt} = \lambda\alpha - \nu\alpha \qquad (1)$$

Here α is the synaptic area, μ the maintenance requirement of the axonal tip for F per unit area per unit time, and λ, ν are the rates of flow of F and E, respectively, across unit areas of the cleft. It is quite in accord with present-day theories of control mechanisms in cells[17] to suppose that the concentration of E and F within cell B is held constant, at least unless there is excessive demand for them. Hence we take λ as constant.

ν must depend on the rate of joint firing of the two cells, however, and hence on the area β of any other synaptic linkages to cell B. It also depends on the rate of bombardment of those other linkages, which for simplicity of exposition we suppose to be constant. Then ν is proportional to p, the rate of firing of A and to $P(\alpha,\beta)$, the probability that B fires when A does. Thus

$$\nu(\alpha,\beta) = \rho p P(\alpha,\beta) \qquad (2)$$

where ρ is a constant for a given cell, but may differ from cell to cell. $P(\alpha,\beta)$ is obviously a monotonic increasing function of α, for each fixed β.

If we assume that, in the absence of the inhibitory factor E, the synaptic area α grows, we must have $a = \lambda - \mu > 0$. Thus

$$\frac{d\alpha}{dt} = \alpha\,(a - \rho p P(\alpha,\beta)) \qquad (3)$$

Provided $\rho p P(0,\beta) < a < \rho p P(\infty,\beta)$, equation (3) shows that α tends towards the stable limiting value which is derived from setting $\frac{d\alpha}{dt} = 0$ in equation (3). (See Fig. 1, in which curve I crosses the horizontal line at height a at a stationary point.) This point is stable because of the monotonic increasing character of the continuous function $P(\alpha,\beta)$. The stable value for α is therefore determined from the equation

$$P(\alpha,\beta) = \frac{a}{\rho p} \qquad (4)$$

We see that α depends both on the area β of the other synaptic contacts and also on the afferent firing rate p. However, the rate at which B fires under the influence of A is $pP(\alpha,\beta) = a\rho^{-1}$ which is constant.

These conclusions only apply if the condition on the range of a is satisfied. If p is very large, then $a < \rho p P(0,\beta)$ and α decreases to zero. In our model, then, if the afferent bombardment is too great, the synapse dwindles and the axon finally drops off. The values of the constants a and ρ may, however, be such that this cannot occur. For p can scarcely be more than, say, 1,000/sec. If p is very small, then $a > \rho p P(\infty,\beta)$ and α increases without limit.

Of course, physically, α cannot actually become infinite and would ultimately be limited by the available area of contact with cell B or by the metabolic availability of F. As the total rate of flow of F across the area α is $\lambda\alpha$, then if the availability of F has an upper bound A, say, we have $\lambda\alpha < F$ and therefore, as $\alpha \to \infty$, so $\lambda \to 0$. Thus the curve for $\lambda-\mu$ must fall off and eventually become negative for large enough values of α. This means that α can never become larger than α_0, the value of α for which $\lambda-\mu = 0$. Two curves, II and III, for small p are shown in Fig. 1. Of course, for the stable points α_{II} and α_{III}, the firing rate of B following A is $(\lambda-\mu)\rho^{-1}$ which is no longer equal to $a\rho^{-1}$, but is less.

Not only can the condition $a > \rho p P(\infty,\beta)$ be satisfied with p small, but it can also be achieved with ρ small. If ρ is zero, then the stable value for α is α_0, independently of the firing rate. Thus in a cell which does not produce the inhibitory growth factor, the total synaptic area will be determined simply by the availability of F and hence by the cell B. As ρ passes from a value which gives a curve, like curve I in Fig. 1, which crosses $\lambda-\mu$ in its horizontal region, down to $\rho = 0$, so does the servomechanism pass between two limiting types. In the first,

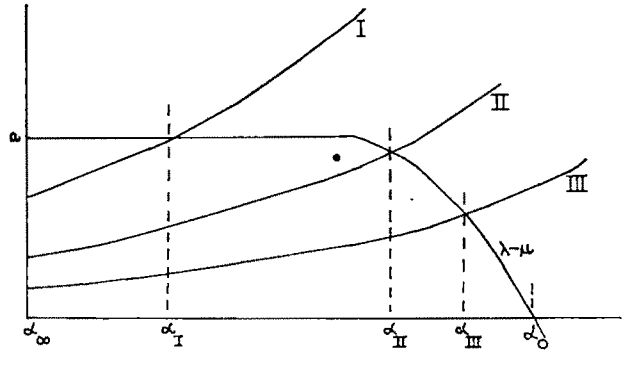

Fig. 1. Plots of $\rho p P(\alpha,\beta)$ against a for medium (I), small (II) and still smaller (III) values of ρp. The intersections with the curve of $\lambda-\mu$ give the stable values for the synaptic area, α_I, α_{II}, and α_{III}, respectively. α_∞ corresponds to $\rho p P(0,\beta) > a$ and α_0 to $\rho p = 0$.

it keeps the various conditional frequencies constant, while in the second it keeps the total synaptic area constant. For intermediate values of ρ, a mixed criterion operates. When the frequency is kept constant, the stable value of α is determined from equation (4) and is inversely related to p: as p decreases so α increases and so, therefore, does the excitability of cell B from that afferent pathway.

So far the discussion has implicitly referred to excitatory synapses. For an inhibitory synapse it is still necessary to suppose the existence of a growth substance F exuded from the cell, which first attracts the axon and then maintains it. To use equation (3) in this case would lead to difficulty, however, because at an inhibitory synapse an increase in α results in a decrease in the probability of firing for B and thus in $P(\alpha,\beta)$. Therefore, $P(\alpha,\beta)$ is a monotonically decreasing function of α and the point $P(\alpha,\beta) = a/\rho p$ is now stationary but metastable. α thus always goes towards 0 or ∞. The simplest way of getting around this is to suppose that, at such synapses, only the growth substance F passes. Thus F leaks across the synaptic cleft at a constant rate as before, but its motion is enhanced in proportion to the rate of joint firing. This idea rests on the entirely reasonable assumption that the two membranes are slightly permeable to F in the resting state, but when depolarized allow it to flow through more freely.

Then, in place of equation (3), we have

$$\frac{d\alpha}{dt} = \alpha(a + \rho p P(\alpha,\beta)) \qquad (5)$$

This has a stationary and stable point at $P(\alpha,\beta) = -a/\rho p$, which shows that we must assume a to be negative. This means that inhibitor axons are only attracted to cells which fire sufficiently often at about the same time as they do (in contrast to the excitatory axons discussed earlier). This seems quite reasonable as it implies that inhibitory interneurones only get attached to cells which "need" inhibiting, and which they can inhibit at the right time. On the other hand, it is again possible at an inhibitory synapse for the synapse to be maintained by a process which is independent of firing rate. This would occur if $\rho = 0$ in equation (5) and a is replaced with $\lambda-\mu$, which reproduces equation (1) with $\nu = 0$, as discussed earlier.

A plausible and simple theory has now been developed which goes far towards explaining both the formation and maintenance of structure and function in the peripheral nervous system. Although it does not give independent support to our theory, it is interesting to mention that the properties assumed for frequency-controlled synapses can explain the re-establishment of reflexes in the period of readjustment from the condition of "spinal shock". When one realizes that the effects of lesions in the brain often show a considerable parallel to the effect of spinal transection, the loss of specific function often being followed by at least a partial ultimate restoration of function, one is led to hypothesize that the mechanisms outlined operate at all levels in the nervous system (see, for example, ref. 22, p. 274). At the cerebral level, however, they are complicated by the presence of quite another mechanism for memory.

Before dealing with that, however, some consideration should be given to the question of what substances E and F are likely to be. It would be attractive to suppose that they are *m*RNA. If they were, however, there would need to be polyribosomes in the axonal tips in order to utilize them. Unfortunately, these have not been observed[23,24], and therefore, on these grounds alone, it seems unlikely that E and F are *m*RNA. Of course, the steady production of E and F must ultimately be under the control of *m*RNA formed in the nucleus of cell B. In this sense *m*RNA is implicated and there may well be some subsidiary control mechanism, relating to this production, which we have neglected to consider.

There is, however, another approach to the nature of F, at least. As F is a nerve growth factor, it is likely to be of the same nature as those factors which have already been found[21]. These appear to be protein and may be enzymes. In that case, E would not necessarily be protein but might either inactivate F or inactivate, or compete with the substrate of, some other quite independent enzyme in the axonal tip.

It should be borne in mind that the phenomenon of supersensitivity of deafferentiated nerve cells may duplicate some of the effects of servomechanism[25], and therefore complicate the interpretation of experimental data. It can scarcely duplicate them all, because it is a mechanism operating on cell B without distinguishing between the various attached cells A.

Cerebral Memory

The need for reinforcement to occur[26,27], the existence of Korsakoff's syndrome[28] and the effect of lesions in the hippocampal region[29], taken together, suggest strongly that, even if memory at the conscious level is mainly mediated by changes in synaptic strength at the cortex, it is nevertheless partially controlled by some quite localized subcortical centre or centres.

The control of synaptic strength now depends on three things—the firing of the cortical cells A and B and also, later, of some "reinforcing" cell C, the axon of which is apposed to the synapse in question. If it is assumed that the previous picture of synaptic control still holds, it is immediately apparent that the most natural way for the new control to be operated is by increasing the flow of F from cell B to cell A. For this to happen, there must still remain evidence, when cell C fires, that cell A and cell B have recently fired jointly. The firing of cell B depolarizes its membrane and so it is postulated that F passes into the synaptic cleft at this time. It would seem likely that this extra package of F, which now passes, is actively transported by a biochemical process requiring the transmitter, T, from cell A as a constituent or, at least, that the extra F can only pass in the presence of T. Finally, the firing of C mediates the passage of F across the second membrane into cell A, possibly by releasing another constituent necessary for an active transport process.

The picture may now seem a little complicated, but it is difficult to see how any essentially simpler process could show the right dependence on the three cells A, B and C. The part which is least clear is the precise mechanism of action of cell C. The model as we have described it would seem to imply that every synapse needs a separate axonal ending—some 10^{13} in all—a figure which is rather large, although perhaps not impossibly so. A way out of this difficulty would be if the cells C did not directly influence the synapses at all, but acted only indirectly through the glial cells. This is quite plausible in view of the fact that we do not require the cells C to carry specific messages to specific synapses, but merely the general instruction of "record". The cells C would then simply form a general glial activating system, whereupon the glia would exude the constituent which "helps" F across the axonal membrane of cell A. In that event, the exudate from C into the glial cells might be *m*RNA.

Burns's point[2] that a theory of memory must explain the classical Pavlovian conditioning experiments can now be discussed. Suppose two cells, A and A^1, both synapse on B and that the firing of A will fire B but of A^1 will not. A, then, is on the path of the unconditioned stimulus (US) and A^1 of the conditioned stimulus (CS). We may fire A^1 as many times as we like, without A, and no C-mediated learning will occur, because B does not fire. Once A and A^1 both fire, however, so does B. So the combination of the depolarization of the membrane of B, due to its firing under the influence of A, with the presence of the transmitter T from A^1, due to its firing, brings F into the synaptic cleft between B and A^1. Thus, providing reinforcement occurs through C, F passes ultimately into the axon of cell A^1.

Thus we can interpret the conditioning experiments in a general way. But note now that F can only cross the membrane of B into the synaptic cleft with A^1 if the transmitter T is already there when B fires. Thus the conditioning can only work if A^1 fires at the same time as B or earlier, providing it is not so much earlier that T has all disappeared. The time by which the firing of A precedes that of B is so small that this makes it possible to say, approximately, that A^1 must precede A for conditioning to occur. The CS must precede the US and thus it would seem that the model very satisfactorily fits the temporal requirements of the conditioning experiments. The ultimate decay of conditioning would be a consequence of the servomechanism described earlier.

Finally, note that this theory of cerebral memory implies the existence of several stages of memory storage, in general agreement with recent experimental work[30–32]. Also, as the strength of the influence of a synapse on the receiving cell depends on two quite independent things, T and the growth of the axonal tip, memory may be regarded as a sum of a short-term part and a long-term part. The time sequence of the two is very different. The short-term part is largest at first and decays monotonically. The long-term part must be zero at first, rise to a maximum and then decay. The sum of the two need not be monotonically decreasing, but might have a minimum at a time when the short-term part has largely decayed, but the long-term part has not yet become fully established. There is evidence that this does occur in the "reminiscence effect"[33], and an explanation of the general kind given previously has been advanced[5,34].

LETTERS TO THE EDITOR

PLANETARY SCIENCE

Ice-forming Nuclei in the Atmosphere

THERE is considerable meteorological interest in the nature and concentration of ice-forming nuclei in the atmosphere and their variation with time and weather situation[1]. Apart from their significance in natural precipitation processes, improved knowledge of their nature and occurrence is essential to any realistic assessment of weather modification by cloud seeding with artificial ice nuclei.

Most measurements of the concentration of ice nuclei have until now been made with mixing chamber and expansion chamber methods and the results have suggested that the concentration is extremely variable. It is probable, however, that much of this variability can be attributed to limitations in the methods of measurement, largely because the conditions under which the ice crystals are formed are unlike those in natural clouds. In addition, these methods are difficult to use in an aircraft, with the result that apart from those at ground level very few measurements have been made[2,3].

Recently, a much simpler method using 'Millipore' filters has been developed by Bigg[4]. In this method, the sample of air is drawn through the filter which collects all the particulate material down to at least 0·4μ in diameter. To determine the number of ice nuclei which are active at a certain temperature, for example, at $-15°$ C, ice crystals are grown on the nuclei by cooling the filter to $-15°$ C in an atmosphere saturated or supersaturated with respect to water. The use of a 'Millipore' filter has many advantages; it can be used to sample large volumes of air and it can readily be used for sampling from aircraft—the development of the filters can be carried out later in the laboratory. However, Bigg *et al.*[5] found that the results with this method are not wholly satisfactory, because the measured concentration of ice nuclei per unit volume depends on the volume sampled and also critically on the development technique. Also it was found that the background count could be large. Mossop[6] found that for 10 per cent of the filters the background count was more than ten, which was comparable with the number of ice crystals found on many of the exposed filters.

After reviewing the methods available for measuring the concentration of ice nuclei, we decided to investigate further the 'Millipore' filter method. We thought that it might be possible, by means of a different development technique, to obtain better results than those of Bigg *et al.* After 3 years of experiments, our method is now giving promising results and does not appear to suffer from some of the difficulties encountered by Bigg. The main differences between the two techniques are in the means of providing the water vapour and in the method used to observe the ice crystals when they have formed. In Bigg's method, a cloud of water droplets is formed above the cooled filter and allowed to fall on to it. A suitable supercooled solution is then poured over the filter so that the newly formed ice crystals are made large enough to be seen easily. In our method, before the filter is cooled it is placed on molten petroleum jelly, which partly fills the pores, so that water vapour cannot pass through them. The filter is then exposed to air which has been saturated with respect to the ice at the bottom of the chamber and, by cooling the filter further, the air in contact with the filter can be made saturated with respect to water. The filter is kept under these conditions for 30 min. The ice crystals in the central portion of the filter (about 40 per cent of the total area) are observed with a low-powered microscope.

Our preliminary results show that the ice crystal count does not depend on the length of time that the filter is exposed to air at water saturation—the count becomes nearly constant after 15 min—whereas Bigg *et al.* found that the number of ice crystals which formed on filters similarly exposed depended critically on the humidification time. With our apparatus we are able to keep the humidity within 2 per cent of water saturation indefinitely. Only if the air above the filter is made more than 5 per cent supersaturated with respect to water is there a significant increase in the number of ice crystals formed. In contrast to Bigg's results, we find that for samples of less than 150 l. there is no decrease in the measured concentration of ice nuclei per unit volume as the volume of air sampled increases; however, for larger volumes there is a decrease. We have compared the ice crystal count of pairs of filters which had each sampled simultaneously 100 l. and found that more than half the counts were within 5 per cent of the average. This is some improvement on Bigg's experiments in which nearly half were within 10 per cent of the mean. With our method we found that unexposed filters gave a background count of nil to six, with a mean of one, in the observed area, whereas over the whole filter the background count was one to six, with a mean of three. These background counts are insignificant compared with the counts of exposed filters.

From October 1965 to March 1966 more than forty 100 l. samples of air were taken outside the Meteorological Office at Bracknell and these show that the concentration of ice nuclei varied between 0·25 and 3·0/l. with 75 per cent between 0·6 and 1·8/l. at a temperature of about $-18°$ C. The results show none of the great variability from hour to hour and day to day that has previously been reported[2], although as yet the number of samples is not large.

We are continuing our experiments at ground level and hope shortly to obtain samples at higher levels from aircraft.

Radiocarbon Dated Postglacial Land Uplift in Northern Ungava, Canada

LATE Quaternary glacio-isostatic uplift curves based on radiocarbon dates of material from raised marine formations have been constructed for several parts of the Canadian Arctic[1–3]. So far, none has been published for areas bordering the Hudson Strait and in particular for the north-western part of the Labrador–Ungava Peninsula.

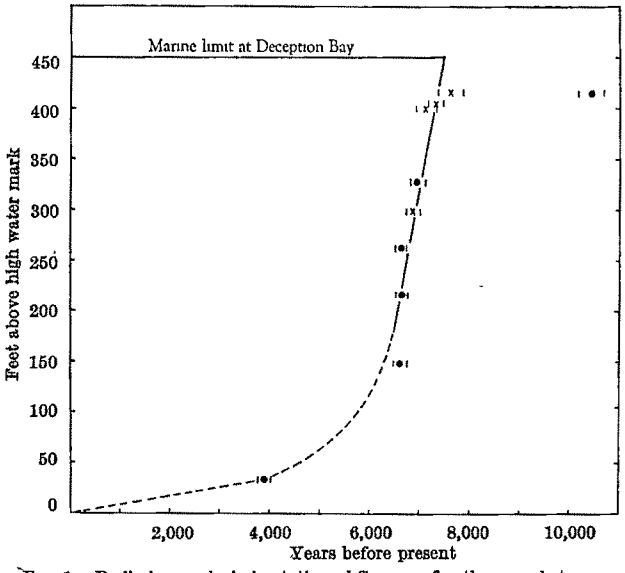

Fig. 1. Preliminary glacio-isostatic uplift curve for the area between Deception Bay–Cape Wolstenholme, Northern Ungava. |●| and |×|, Carbon-14 dates with limits of statistical errors; ●, Deception Bay; ×, other localities (see Table 1). All altitudes have been corrected for eustatic rise of sea-level before 6,000 years B.P. (that is, 3 ft./100 years).

Ten radiocarbon dates[4,5] of molluscs from raised marine terraces between Deception Bay (62° 7′ N., 74° 35′ W.) and Cape Wolstenholme (62° 35′ N., 77° 30′ W.) in Northern Ungava, Quebec, are now available. The dates provide sufficient data for construction of a provisional uplift curve (Fig. 1) in which ages are plotted against altitude.

I collected nine of the samples of dated shells during field work in 1961 and 1962. The tenth sample (*GSC*-327) was obtained by D. A. Nichols of the Department of Mines, Canada, in 1935. The molluscs were dated by Isotopes Incorporated, the National Physical Laboratory and the Geological Survey of Canada. Details of localities, shell identifications and radiocarbon ages are summarized in Table 1.

Before discussing the significance of the curve several points deserve comment:

(1) In constructing the curve it is assumed that the sites, despite the fact that Erik Cove is 96 miles west-north-west of Deception Bay, lie along rather than across the local trend of isobases. This assumption is based on my detailed studies[6–8] of the pattern of glaciation and deglaciation of the area. In support of this theory is the fact that marine shells from approximately the same altitudes (360–365 ft.), but at widely spaced locations

Table 1. RADIOCARBON-DATED SHELLS FROM NORTHERN UNGAVA

* *H.a.*, *Hiatella arctica* Linné; *M.t.*, *Mya truncata* Linné; *M.a.*, *Mya arenaria* Linné; *M.c.*, *Macoma calcarea* Gmelin; *B.b.*, *Balanus balanus* Linné; *B.*, *Balanus* sp.; *B.c.*, *Balanus crenatus* (Bruguière); *M.b.*, *Macoma balthica* Linné; *C.c.*, *Clinocardium ciliatum* O. Fabricus; *S.g.*, *Serripes groenlandicus* Bruguière.

along the coast, have similar radiocarbon ages, if the statistical errors inherent in dating the samples are taken into account (compare *I*-729, *I*-726 and *GSC*-327, Table 1): this suggests that west-north-west–east-south-east tilting of the land did not occur during uplift.

(2) As with all shell dates there is uncertainty as to the depth at which the molluscs lived or have been transported and the sea level related to any date was higher than the actual level of the molluscs. Because of this, the true uplift curve must always lie above the graphed position of the molluscs. Nevertheless, in the case of samples *I*-729, *I*-726, *NPL*-84 and *NPL*-71, the error will be slight, as the molluscs were obtained from shoreline deposits rather than fiord-bottom material; they were collected from topset beds of deltaic material and were associated with intertidal species of mollusca, such as *Mytilus edulis* Linné, and in one instance (*NPL*-71) thin peat layers and brackish-water ostracods.

(3) It should be noted that the dates *I*-729, *I*-726, *NPL*-84 and *NPL*-71 were obtained for bivalved mollusc shells which were found in living positions with their periostracum and, in some cases, siphons still attached, which suggests that they had not been disturbed since death.

(4) As can be seen from Fig. 1, it was possible to draw an uplift curve near nine of the dates. The oldest date of 10,450 years B.P. cannot be fitted into the scheme and it is possible that the sample dated was a mixture of old shells moved by ice and postglacial shells.

(5) Allowance has been made in Fig. 1 for eustatic rise of sea level of 3 ft. per century before 6,000 years B.P. (ref. 9).

Like all other uplift curves drawn, the pattern of uplift with respect to time is that of a strongly exponential decrease from approximately the time of ice removal to the present day. The graph indicates that the rate of uplift was initially rapid between about 7,700 and 6,700 years ago, that is to say, of the order of about 20 ft. per century: this compares favourably with that of 19·5 ft. per century calculated by Lee[1] for the coast of Hudson Bay.

From about 6,700 years ago to the present, the rate of emergence of the land gradually decreased and for the past 4,000 years would appear to have been just less than 1 ft. per century—a rate slightly less than those of 1–3 ft. suggested for other parts of Arctic Canada[1,3,10]. If, however, a marine transgression took place during the formation of the lowest marine terraces, as indicated by the sequence of thin peat layers and fossiliferous marine sediments in the "*Gemma* beaches"[8], then the rate of uplift would have been much higher and probably between 1·5 ft. and 3 ft. per century—a rate similar to that postulated for the historic rate of uplift of the Hudson Bay area[11,12].

Although the general form of this provisional curve is very similar to those constructed for other parts of Canada and Greenland[1,2,13], it is somewhat displaced in time; deglaciation took place at a later period than in most other areas but earlier than in the Foxe Basin area[3]. It appears that, even if sections of the south coast of Hudson Strait were open to the sea and, therefore, deglaciated in part by 10,450 years ago, as suggested by date *I*-488, the general deglaciation of Northern Ungava was delayed until 8,000 years ago in coastal areas and possibly as late as 6,700 years ago in inland areas, as suggested by date (*NPL*-82) of shells from the highest fossiliferous marine deposit 8 miles inland from Deception Bay. Thus local ice caps, or at least large valley glaciers, seem to have existed in Northern Ungava during the equivalent of the early part of the hypsithermal interval, preventing the incursion of the sea; a theory in keeping with that recently proposed for central and eastern Arctic Canada[14].

The field work was supported by grants from McGill Sub-Arctic Research Laboratory, and the U.S. Air Force Cambridge Laboratory (sub-contract *AF*-1, administered by the Arctic Institute of North America). I thank the

Geological Survey of Canada for permission to use date *GSC*-327 and the National Physical Laboratory and the Geographical Branch, Ottawa, for supplying the rest of the radiocarbon dates. I also thank Prof. J. B. Bird, McGill University, and Dr. W. Blake, jun., Geological Survey of Canada, for advice.

Trace Element Concentrations in the Sea off South Africa

A PRELIMINARY investigation of the distribution of the trace metals copper, iron and manganese, with special emphasis on copper, was recently undertaken in the ocean area south-west of the Cape of Good Hope. Oceanographic information collected concurrently with the samples was used in a provisional interpretation of the results.

Samples of sea-water were taken with a polypropylene sampler and stored frozen (−18° C) in polythene until analysed. Copper and iron were concentrated from the unfiltered samples by solvent extraction; manganese was concentrated by co-precipitation. The concentrated metals were determined spectrophotometrically. The chemical procedures will be described elsewhere[1].

Copper was estimated in seventy samples of surface water taken from an area up to 600 miles south and west of Cape Town (Fig. 1). Both coastal and deep-sea areas were sampled. The results indicate a marked relation between the copper concentrations and the water masses present (determined by analysis of temperature/salinity diagrams).

Copper concentration is at a minimum (2 μg/l.) in the Agulhas current and reaches a maximum (17 μg/l.) in vigorously upwelling water off the Cape of Good Hope. Off-shore water away from upwelling zones, in the south-east Atlantic Ocean, shows moderate concentrations (9–12 μg/l.) of copper as does also the sub-antarctic surface water just south of the sub-tropical convergence. Intrusion of Agulhas current water into the Atlantic Ocean could, in general, be followed by observing the change in copper content.

The low surface concentration of copper observed in the Agulhas current is possibly explained by its tropical origin. In equatorial regions, nutrients and trace metals are taken up by zoo- and phyto-plankton, which later die and sink. The strongly developed thermocline in tropical regions inhibits vertical mixing, and a net loss of trace metals from the surface layer is to be expected. Similarly, Morita[2] found low copper concentrations (0·5–0·7 μg/l.) in the tropical water of the Kuroshio current off Japan.

An apparent seasonal variation of copper content in surface waters off the Cape of Good Hope may be linked with upwelling processes. The maximum concentrations of copper (15–17 μg/l.) coincided with the season of maximum upwelling (summer) while, during the winter season of minimum upwelling, minimum concentrations were found (6–11 μg/l.). Because river discharge is negligible in this region, and indeed the season of maximum run-off is in the winter, it appears that the copper content must be controlled almost entirely by movements of water masses associated with upwelling.

In the mixing region south of Cape Agulhas, some Agulhas current water moves round to the north-west and penetrates some distance up the Cape west coast before its identity is lost by mixing with water of Atlantic Ocean origin in the Benguela current region. A steady variation in copper content could be linked to the extent of penetration of this current.

One set of samples was obtained from sub-surface depths in the upwelling region south-west of the Cape of Good Hope. High concentrations (15–16 μg/l.) of copper were found to a depth of 400 m. This layer consists mainly of South Atlantic Central water welling up to the surface. At greater depths lower concentrations were found (10 and 7 μg/l. at 700 and 1,200 m respectively). It is interesting to note that the Antarctic Intermediate water mass was found to lie at about 800–1,000 m depth in this region.

The Central water has its source in the mixing region just to the north of the sub-tropical convergence and then sinks and moves northwards[3]. Copper concentrations at the source of this water were found to be moderately high (13–16 μg/l.) in good agreement with values (15–16 μg/l.) found in the upwelling water off the Cape of Good Hope.

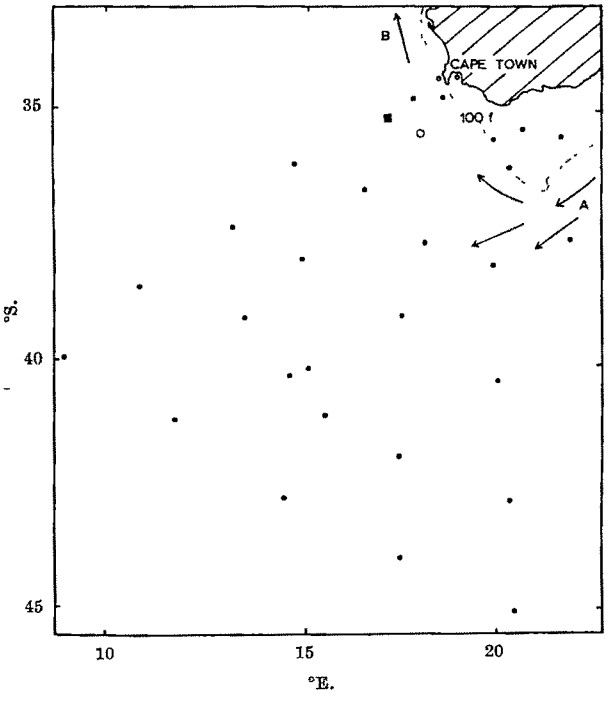

Fig. 1. Positions at which samples were obtained. *A*, Agulhas current; *B*, Benguela current. ●, Copper; ■, copper, iron; ○, copper, iron, manganese.

Ten samples of coastal water were collected for iron determination. It was concluded from the provisional results that upwelled inshore water off the Cape of Good Hope contained relatively high iron concentrations (10–13 μg/l.), whereas 60 miles offshore the iron content was much lower (1 μg/l.). Manganese was estimated in seven samples of coastal water. Little variation was noted and values ranged between 1 and 4 μg/l.

No previous data on these elements in the area studied were available for comparison, but our results are in general agreement with other data on copper, iron and manganese in the oceans[4].

This investigation was sponsored by the Sea Fisheries Division of the Government of South Africa, and samples

were collected aboard their research vessel *Africana II*. This support is gratefully acknowledged.

PHYSICS

Comparison of Electron Temperature with Thermosphere Probe Data

DURING the past few years evidence has been obtained for the existence of thermal non-equilibrium in the *F*-region of the ionosphere. A number of heat sources have been proposed to account for the observed selective heating of electrons in the ionosphere. The solar ultra-violet radiation from the Sun was shown to be the main heat source for the daytime heating of the lower- and mid-latitude ionosphere[1-3]. A comparison between measurements of electron temperature T_e, obtained from the *Dumbbell* rocket probe[4,5] and the atmospheric model values of neutral gas temperature T_g, has provided the first evidence for thermal non-equilibrium of the ionosphere. The simultaneous measurements of T_e and T_g with the modified "thermosphere probe" have now confirmed that the electron temperature in the ionosphere is considerably larger than the gas temperature. With the help of recent measurements of solar ultra-violet flux and absorption cross-section, we have calculated the heat input and electron temperature in the *F*-region of the ionosphere and have compared it with the thermosphere probe data[6].

The atmospheric model, ionizing solar ultra-violet flux and their absorption cross-section for various atmospheric constituents are taken from the values tabulated by Davies[7]. The total rate of ion production and electron density distributions in the ionosphere have been calculated from these data and various coefficients of production and loss rates. (Available coefficients of production and loss rates are adopted with reasonable changes to fit experimental ion and electron density profiles.)

Adopting the heating efficiency given by Hanson, the heat input of solar ultra-violet radiation, which is the product of heating efficiency and rate of ion production, is calculated for the *F*-region of the ionosphere. Fig. 1 shows a comparison of the calculated heat input of solar ultra-violet radiation with the values measured by the thermosphere probe. It is evident from Fig. 1 that the total heat input measured is an order of magnitude greater than the calculated heat input of solar ultra-violet radiation.

If Q is the energy of the solar ultra-violet radiation in ergs cm^{-3} given to the electron gas, N cm^{-3}, then in equilibrium

$$Q = -1{\cdot}30 \times 10^{-4} N \left[\left(\frac{dT_e}{dt}\right)_O + \left(\frac{dT_e}{dt}\right)_{O_2} + \left(\frac{dT_e}{dt}\right)_{N_2} + \left(\frac{dT_e}{dt}\right)_{O^+}\right] \text{ eV cm}^{-3}\,\text{sec}^{-1} \quad (1)$$

The cooling of fast photoelectrons owing to vibrational excitation of nitrogen molecules is ignored in the determination of electron temperature. The cooling rate of equation (1) is rather slow at higher temperatures and thus this omission may be justified in view of numerous uncertainties in the cooling rates and the heat sources.

The difference between electron and gas temperature is not linearly dependent on the heat input Q. The determination of electron temperature from equation (1) involves

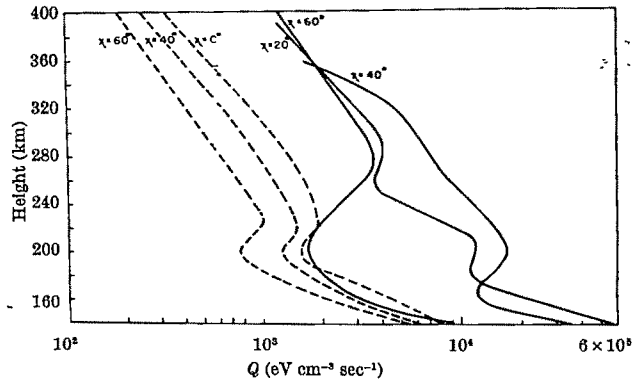

Fig. 1. Heat inputs calculated with data for solar ultra-violet radiation (– – – –) for $X=0$, 40 and 60, and with data from thermosphere probe (——) for $X=20$, 40 and 60.

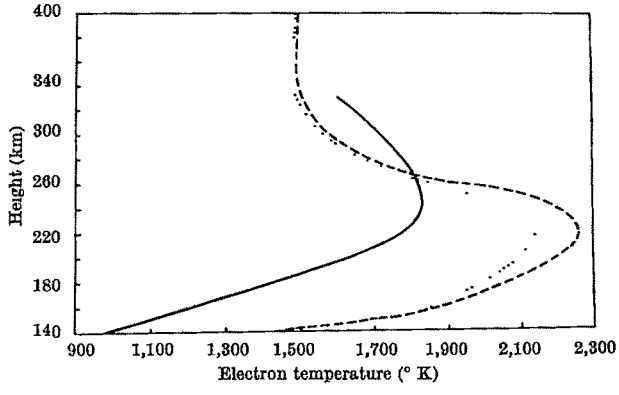

Fig. 2. Calculated electron temperature using solar ultra-violet flux data and collision frequencies for sun-spot maximum (. . . .) and minimum (– – – –), and electron temperature measured by thermosphere probe (—•—). Flight 6·07. Wallops Island, Virginia, April 1963, 1604 E.S.T.

solution of a seventh order equation in square root of T_e and is somewhat complicated. In the present communication the electron temperature corresponding to the heat input profile for solar ultra-violet (dotted curve Fig. 1) is obtained by graphical solution of equation (1). The electron temperature profiles thus obtained are compared with the data from the thermosphere probe as shown in Figs. 2 and 3.

The heat input of solar ultra-violet radiation to the ionosphere for three zenith angles is shown in Fig. 1 together with corresponding total heat input obtained from the thermosphere probe data. The calculated heat input of solar ultra-violet radiation is an order of magnitude less than the total heat input obtained from the thermosphere probe data. The electron temperature in the ionosphere resulting from heat input of solar ultra-violet is calculated using equation (1) and is compared with the electron temperature as measured by the thermosphere probe (Fig. 2). The absolute electron temperature of the solar ultra-violet depends very much on the atmospheric model used for calculation. The difference between electron and gas temperature ($T_e - T_g$) is better suited for comparative studies (Fig. 3). The electron temperature profile for solar ultra-violet shows a remarkable fit to the data obtained from the thermosphere probe. The data from the thermosphere probe gives a peak temperature at 240 km whereas calculated temperature profile gives a peak at 220 km and is about 100° K smaller than the peak temperature obtained by the thermosphere probe.

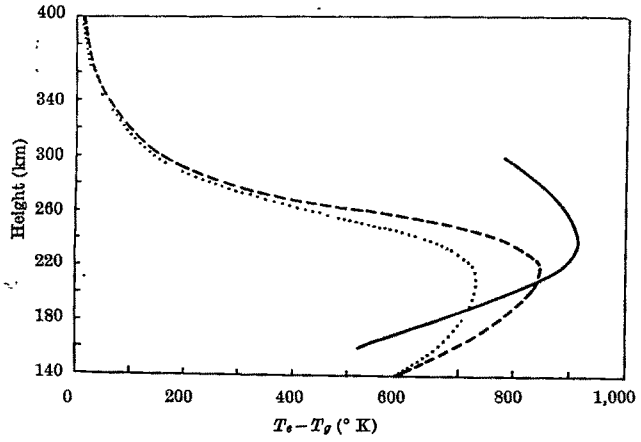

Fig. 3. Difference of electron-gas temperature calculated using solar ultra-violet flux data and collision frequencies for sun-spot maximum (. . . .) and minimum (– – – –), and values measured by thermosphere probe (——). Flight 6·07. Wallops Island, Virginia, April 1963, 1604 E.S.T.

There has been much controversy over the effect of magnetic disturbance on electron temperature. Jacchia and Slowey[8] have recently shown that during less disturbed periods ($k_p \leqslant 5$) there is a heat input which is best correlated with the k_p index. The rocket and satellite measurements of T_e (refs. 4, 5 and 9–11) have shown no increase in T_e correlated with the disturbed conditions. Maynard and Werstiuk[12] and Evans[13] have measured the electron temperature on the ground by means of radar observations of electron back-scatter and have shown that the electron and ion temperature increases at F-region heights during magnetically disturbed conditions. If our values for heat input are compared with the heat input measured on the magnetically disturbed days, the discrepancy in heat input, as already mentioned, is increased. The electron temperature profiles for disturbed days may not show a good fit as obtained here. This could be explained in terms of additional heat sources, namely, hydromagnetic[14] and corpulcular[15].

The calculated electron–gas temperature difference is found to fit well with the values measured with the thermosphere probe. The calculated heat input is, however, an order of magnitude smaller than the values measured with the thermosphere probe. The electron temperature below 200 km depends on Q/N and above this height it is controlled by Q/N^2. The higher values of electron temperature calculated may arise from an overestimate of the electron density, or from uncertainties in the electron cooling processes. It is evident from the present investigation, however, that the solar ultra-violet flux is the main source of selective heating of electrons in the ionosphere.

Suppression of Halo on Photographic Plates used in Mass Spectrometry

The halo effect is well known in mass spectrometry and consists of a large black spot on the photographic plate in the neighbourhood of high intensity isotope lines. It causes an undesirable rise in the limit of detection of impurities with adjacent isotope masses. It was suggested[1] in 1964 that this halation could be suppressed by applying a conductive layer between the emulsion and the glass of the photographic plate. The ions reflected by the silver bromide gelatin layer have lost a great deal of their energy, for example from 20 keV down to 2–4 keV. Some of these ions are brought back into the magnetic field

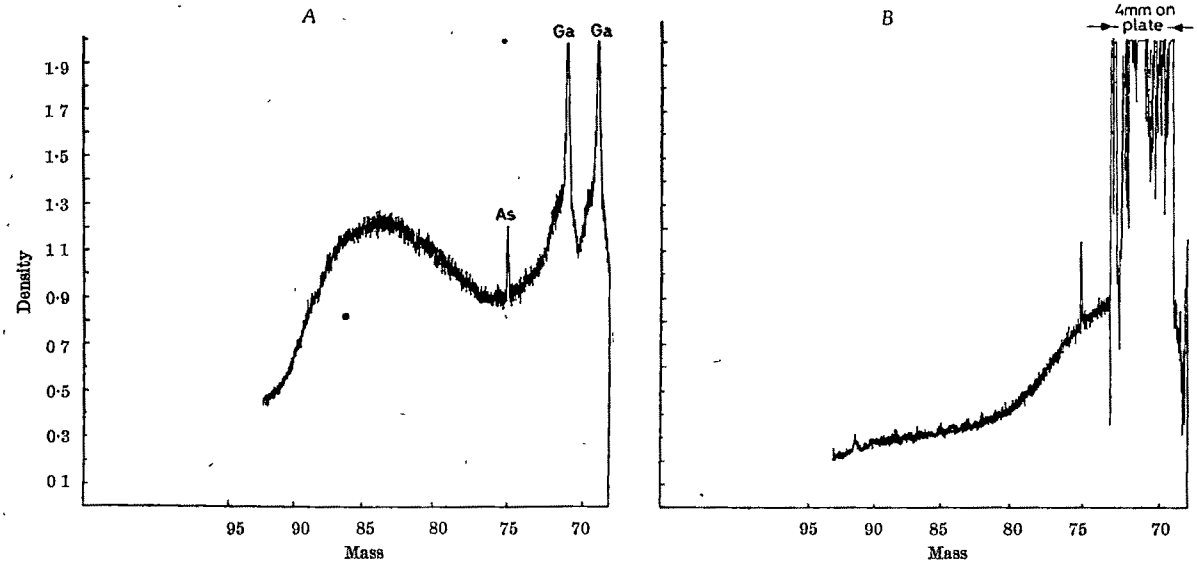

Fig. 1. Joyce Loebl recordings of part of a mass spectrogram of gallium obtained on an A.E.I.–*M.S.*7 mass spectrometer without (*A*) and with (*B*) the use of a small strip of graphite containing paint at the point of impact of the main isotope lines of gallium.

which returns them to regions of the photographic emulsion corresponding to masses higher than those of the main isotopes.

If, however, ions lose their charges more rapidly during passage through the emulsion, fewer of them are reflected. Swift[2] confirmed this view experimentally.

Mai[3] has shown that if the photographic plate is cut into parts in such a way that the ions of the main component do not strike the emulsion at all, no halo is produced.

All these precautions are fairly complicated. An easy and simple method of eliminating halation consists of painting a small conducting strip on the spot at which the main isotope line(s) will appear. This can easily be done in the dark room before the plate is placed in its hold using a rule and a small brush. This painted strip can be earthed by applying a second strip at the bottom of the plate so as to make contact with one of the pins on which the plate rests. If the strip is not earthed the effect is very poor.

The paint consists of a mixture of 300 mg graphite powder, 100 mg cellulose nitrate and polyvinyl acetate, and 180 mg ethyl acetate. After drying, the layer has a thickness of about 0·1 mm. Graphite has been chosen because of its low mass, which gives greater depth of penetration[4] and more chance of the ions losing their charge.

Figs. 1 *A* and *B* show Joyce Loebl densitometer recordings without and with the use of the strip of graphite paint mentioned above. This strip has a width of 4 mm on the plate. The mass spectrogram (obtained with an A.E.I. *M.S.*7 instrument) is of gallium with arsenic present as an impurity.

This work was carried out with the assistance of Miss H. Savenije, Mr. H. Kraay and Mr. A. Witmer.

THE SOLID STATE

Fast Domain Wall Motion in Double Nickel–Iron Films

Recently, Humphrey and Clow[1] found that flux reversal in multilayer films[2], consisting of 200 Å thick nickel–iron films interleaved with silicon monoxide layers each about 100 Å thick, was much faster than that observed in normal single films. A possible explanation for this fast flux reversal might be that domain wall motion is much faster in multilayer than in single films. To verify this assumption, Patton and Humphrey[3] have measured wall velocities in double films. For small driving fields, the wall velocity obeys the relation

$$V = m(H - H_c)$$

in which H is the applied field, H_c the wall motion coercive force and m the so-called wall mobility. Patton and Humphrey found that—contrary to expectation—the wall mobilities in double and in single films were about the same.

This communication reports the results of wall velocity measurements in double nickel–iron films (81/19) which show that wall mobilities in double films are much larger than those measured in single nickel–iron films. The measuring technique used has already been described[4] and is similar to that used by Patton and Humphrey[3].

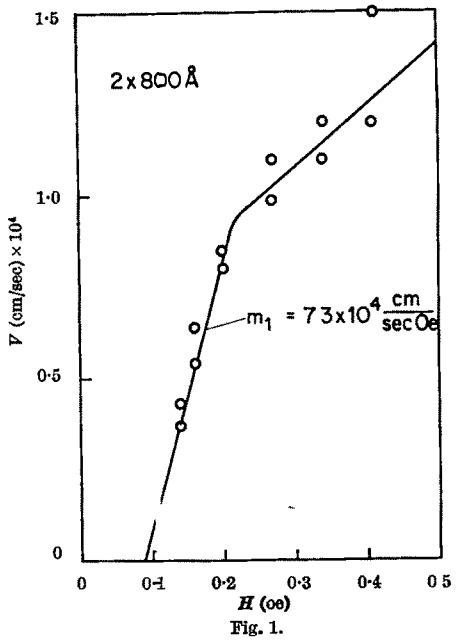

Fig. 1.

Fig. 1 shows the wall velocity measured in a double film (2 × 800 Å nickel-iron, 100 Å SiO, H_c = 0·09 oe, H_k = 5·4 oe) as a function of the applied field. The wall mobility as obtained from the straight line relationship for small driving fields is 7·3 × 10^4 cm/sec oe, which is much larger than that measured both in 800 Å and in 1600 Å single nickel–iron films. It is interesting to note that in double films the wall mobility decreases for higher fields, just as is observed in single films[4].

Table 1

Single films		Double films D_{SiO} = 100 Å	
D (Å)	m_1 (10^4 cm/sec oe)	D (Å)	m_1 (10^4 cm/sec oe)
90[1]	1·39	2 × 135[6]	9·1
260[2]	0·91	2 × 210[7]	5·4
450[3]	0·29	2 × 440[8]	4·1
880[4]	0·71	2 × 870[9]	7·3
1,650[5]	0·96		

Table 2

Film	H_c (oe)	H_k* (oe)
1	1·3	5·0
2	1·9	5·0
3	1·5	4·2
4	3·0	7·0
5	1·8	7·4
6	0·52	4·8
7	0·48	5·0
8	0·43	5·4
9	0·09	5·4

* Anisotropy field.

In Table 1, wall mobilities measured in double and in single films are compared; Table 2 gives the H_c and H_k values of the films. That walls in double films move much faster than those in single films can easily be observed, which is clearly in contradiction to the results of Patton and Humphrey.

E–X Band System of the Copper Iodide Molecule

THE coarse spectrum of copper iodide in the visible region was investigated by Mulliken[1] in 1925 and Ritschl[2] in 1927. Ritschl recorded five extensive band systems in absorption, all degraded to red in the region 3750–5500 Å. From a study of their vibrational analysis he concluded that all systems have a common lower state which is the ground state of the molecule. This communication reports the results of the rotational analysis of the *E–X* bands of $^{63}Cu^{127}I$.

The molecule was excited in an electrodeless discharge tube by a 2,450 Mc/s 'Raytheon' microwave oscillator and the rotational structure was photographed in the second order of a 10 m concave grating spectrograph[3] (dispersion 0·33 Å/mm). The overlapping structure due to the less abundant species $^{65}Cu^{127}I$ has been avoided by adjusting the time of exposures. Exposures of 1·5 h duration on 'Kodak II-O' plates were found to be suitable for recording the structure of the main bands. The iron arc spectrum was used as the comparison spectrum. The probable error of the measurements is estimated to be 0·04 cm^{-1}.

The seven bands (4,0), (3,0), (2,0), (1,0), (1,1), (0,1) and (0,2) which were found suitable for measurement have been analysed. Each of these bands shows the existence of only two branches *P* and *R*. The *J* numbering was fixed in the usual way by comparing the combination differences and the various rotational constants were determined by the graphical procedures described by Herzberg[4]. Results are given in Tables 1 and 2.

Table 1. ROTATIONAL CONSTANTS

Band	$B_{v'}$ (cm^{-1})	$B_{v''}$ (cm^{-1})	γ_0 (cm^{-1}
4,0	0·0642	0·0732	24,882·06
3,0	0 0645	0 0732	24,660·62
2,0	0 0649	0 0732	24,436·90
1,0	0·0652	0·0732	24,211·30
1,1	0·0652	0·0730	23,948·00
0 ,1	0 0656	0·0730	23,720·50
0,2	0·0656	0 0726	23,458 37

Table 2. MOLECULAR CONSTANTS

State	B_e (cm^{-1})	D_e (cm^{-1})	α_e (cm^{-1})	r_e (Å)	$I_e \times 10^{-40}$ (g cm^2)
E	0·0660	$2·2 \times 10^{-8}$	0·0004	2·463	423·64
X	0 0735	$1·6 \times 10^{-8}$	0·0003	2·334	380·41

From the fact that a single *P* and a single *R* branch are observed, it is concluded that the bands arise from a transition of the type $^1\Sigma - {}^1\Sigma$. A recent rotational analysis of the analogous *E–X* system of copper chloride by Rao, Asundi and Brody[5] lends support to this assignment. Rotational analyses of the other band systems are in progress

We thank Prof. N. L. Singh for his interest in the work and Shri D. K. Rai and R. B. Singh for helpful discussion during analyses of the bands.

Effect of Temperature on the Triplet–Triplet Annihilation Rate in Anthracene Crystals

Jortner, Rice, Katz and Choi have recently shown that triplet–triplet annihilation leading to delayed fluorescence in crystalline anthracene can be adequately described in terms of a random walk diffusion model when the effects of charge transfer interactions are included[1]. This model is valid if the scattering of the triplet excitation wave by lattice phonons is so strong that the mean free path of the triplet exciton is of the same order of magnitude as the crystal lattice spacing. On the basis of the random walk model the triplet–triplet interaction rate constant (γ) is given by

$$\gamma = 8\pi DR \qquad (1)$$

where *D* is the triplet excitation diffusion constant and *R* is the triplet–triplet interaction distance, taken to be 10^{-7} cm for crystalline anthracene[2]. The value of γ calculated by Jortner *et al.* for anthracene is 4×10^{-11}/cm^3/sec, and is in good agreement with the experimental values[2] which range from 1×10^{-11} to 5×10^{-11}/cm^3/sec. (Moore and Munro[3] have recently reported $\gamma = 2·1 \times 10^{-11}$/cm^3/sec for a carefully purified anthracene crystal.) The value of *D* calculated using equation (1) is 30×10^{-6}/cm^2/sec which shows quite good agreement with the value of 6×10^{-6}/cm^2/sec obtained by King and Voltz[2]. (In calculating the value of *D*, Jortner *et al.*[1] assume a pure anthracene crystal; King and Voltz[2], however, analysed the slow scintillation component obtained from anthracene crystals of commercial grade. They suggest that the ionizing radiation may perturb the crystal lattice, thus giving a value of *D* which may be different from diffusion in the perfect lattice.)

The diffusion length (*L*) of a triplet exciton is given by[1]

$$L = (2D\,T_0)^{\frac{1}{2}} \qquad (2)$$

where $T_0 = 10^{-2}$ sec is the approximate value of the lifetime of the anthracene triplet[4]. This gives $L = 3·5 \times 10^{-4}$ cm which is in quite good agreement with the experimental value of $10 \pm 5 \times 10^{-4}$ cm reported by Avakian and Merrifield[5].

Jortner *et al.*[1] have also considered the effect of temperature on the triplet diffusion constant (*D*) and the bimolecular annihilation rate constant (γ) as predicted by the strong scattering model. Considering the effect of thermal expansion of anthracene crystals, Jortner *et al.* expect the diffusion constant to increase by about 20–50 per cent on cooling the crystal from 300° K to 77° K. They suggest that investigations of the temperature dependence of the triplet–triplet annihilation process will provide an important test of the applicability of their theory[1].

In the present work the triplet–triplet annihilation rate constant (γ) has been determined as a function of temperature for a pure anthracene crystal 4 mm thick. For times short compared with the triplet lifetime (T_0) the fluorescence signal (*F*) is given by[3]

$$F = \tfrac{1}{4}A\gamma\,[N_0/(1+\gamma\,N_0\,t)]^2 \qquad (3)$$

where *A* is an instrumental factor and N_0 is the initial density of triplet states. From a plot of $F^{-1/2}$ against *t* the ratio of the slope/intercept gives the quantity γN_0. For excitation times (t_x) short compared with the triplet lifetime the initial density of triplet states is

$$N_0 \doteq Q_T\,t_x\,\varepsilon\,I_0 \qquad (4)$$

Q_T is the triplet quantum yield, equal to unity minus the prompt fluorescence quantum yield[6]. This gives $Q_T = 0·35$ for thick anthracene crystals[7]. ε is the absorption coefficient of the light and I_0 is the exciting light intensity measured using a thermopile. N_0, and hence γ, can therefore be determined[3].

Moore and Munro have used this technique to determine γ for several crystalline anthracene samples using exciting radiation at 434 nm to produce volume excitation of the crystals. The average value of γ obtained from four commercial grade crystals was $1·4 \times 10^{-11}$/cm^3/sec, this value being correct to within an order of magnitude[3].

Decay curves were obtained at various temperatures for a pure anthracene crystal using 434 nm exciting radiation, and the linear plots of $F^{-\frac{1}{2}}$ against *t* obtained at each temperature are shown in Fig. 1. I_0 and t_x are

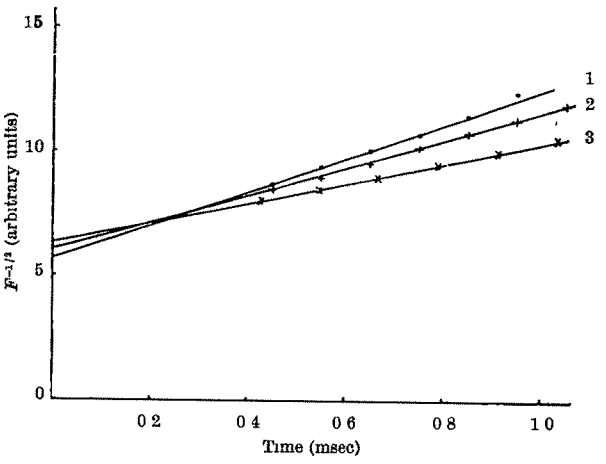

Fig. 1. Plots of $F^{-1/3}$ against t for a pure anthracene crystal at various temperatures. (1) 77° K, (2) 196° K, (3) 293° K.

independent of temperature and Q_T decreases by about 20 per cent when the temperature is reduced to 77° K. Although the variation of ε with temperature is not known it is considered probable that reducing the temperature to 77° K produces no significant change in this parameter. It was therefore assumed that N_0 did not change appreciably with temperature and, from the values of γN_0 estimated graphically, the values of γ at each temperature were calculated. The values of T_0 and γ are listed in Table 1 together with the corresponding values of D and L calculated using equations (1) and (2) respectively.

Table 1

Temperature	T_0 (sec)	γ (cm³/sec)	D (cm²/sec)	L (cm)
293° K	$4\,0\times10^{-3}$	$2\,1\times10^{-11}$	8×10^{-6}	3×10^{-4}
196° K	$5\,4\times10^{-3}$	$3{\cdot}0\times10^{-11}$	11×10^{-6}	4×10^{-4}
77° K	80×10^{-3}	$3{\cdot}7\times10^{-11}$	15×10^{-6}	15×10^{-4}

The results in Table 1 show that as the crystal temperature is reduced from 300° K to 77° K the diffusion constant (D) increases by nearly 100 per cent which shows good agreement with the increase of about 50 per cent calculated by Jortner *et al.* and therefore provides further evidence in support of the random walk diffusion model proposed to explain delayed fluorescence from anthracene and other organic crystals[1].

The rate determining process in the triplet–triplet annihilation mechanism is the formation of adjacent excited molecules. For reasons of spin conservation, however, only one-ninth of the triplet–triplet collisions produce a singlet exciton, and Singh *et al.*[8] suggest that the conclusion of Jortner *et al.* that triplet–triplet annihilation is controlled by diffusion is possibly premature. Kepler and Switerdick report that the diffusion constant calculated by Jortner *et al.* for anthracene may be several orders of magnitude too small and suggest that a band model may be more appropriate to describe triplet exciton motion in anthracene. The band model also predicts an increase in D and γ as the temperature of the crystal is reduced and so the results in Table 1 also may possibly fit into this model.

CHEMISTRY

Oxidation of Sulphur Dioxide in Air at 950° C: Co-operative Influence of Carbon Monoxide and Nitric Oxide

The oxidation of sulphur compounds in fuel to form sulphur dioxide, and the further oxidation of a small proportion of this to sulphur trioxide, give rise to problems of atmospheric pollution and of corrosion. The severe corrosion frequently experienced in those zones of boilers where the combustion products have become relatively cool is related to the sulphur trioxide of the flue gases, and the formation of sulphur trioxide in boilers has therefore been subjected to extensive investigations. The mechanisms generally held to be responsible for the production of the greater part of the sulphur trioxide detected in boiler flue gases are: (1) oxidation of sulphur dioxide by oxygen atoms in the flame; and (2) catalytic oxidation of sulphur dioxide at surfaces in the post-flame region.

Our recent investigations have directed attention to the possibility that other mechanisms may be important at temperatures below 1,000° C. In particular, attention has been directed to the part played by oxides of nitrogen and carbon, both of which occur in flue gases from normal fuels, and their influence on the oxidation of sulphur dioxide in a clean system has been investigated. A marked effect on sulphur trioxide production was found when nitric oxide and carbon monoxide were present together. The reactions

$$2NO + O_2 \rightarrow 2NO_2 \qquad (1)$$

$$NO_2 + SO_2 \rightarrow NO + SO_3 \qquad (2)$$

might be expected to lead to the production of sulphur trioxide in suitably designed experiments. In a flow system, when a mixture containing 0·2 per cent volume/volume of sulphur dioxide, and about 0·1 per cent v/v of nitric oxide, in air, was made to react at 950° C in a tube of the purest available silica to minimize heterogeneously catalysed reactions, practically no sulphur trioxide could be detected in the quenched products. The residence time at 950° C was about 1·5 sec. Similarly, when the nitric oxide was replaced by carbon monoxide (the combustion of which would give rise to oxygen atoms) no sulphur trioxide could be detected amongst the quenched products. When nitric oxide and carbon monoxide were present together, however, significantly large amounts of sulphur trioxide were found. Typical results are given in Table 1.

Table 1

0·2 per cent v/v of sulphur dioxide in air in the presence of certain additives

Temp. (°C)	Concentration of additives (p.p.m. v/v) NO	CO	CO_2	N_2 (carrier gas for CO)	Concentration of SO_3 found in products (p.p.m. v/v)
960	930	0	0	0	0
1,000	0	1,000	0	10^5	4
975	930	500	0	10^4	14
970	930	250	0	$2{\cdot}5\times10^4$	76
960	930	1,000	0	10^5	100
950	600	500	10^5	10^4	14
945	600	1,000	10^5	10^5	88

As can be seen from the last two lines of Table 1, in comparison with earlier ones, the addition of a considerable quantity of carbon dioxide did not substantially affect the amount of sulphur trioxide detected. The determinations of sulphur trioxide in the products were all made by the barium chloranilate colorimetric method, using the continuous analyser described by Laxton and Jackson[1].

The results are tentatively interpreted as follows. Because the air was not dried, we are concerned with the water-catalysed combustion of carbon monoxide. The reactions involved give rise to oxygen atoms capable of oxidizing nitric oxide, if this is present, to nitrogen dioxide. Nitrogen dioxide, it is known, sensitizes the water-catalysed (and incidentally the dry) combustion of

carbon monoxide[2], thus probably giving rise to an increased supply of oxygen atoms. These may directly oxidize sulphur dioxide, but on the basis of published rate data for the reactions

$$SO_2 + O + M = SO_3 + M \quad (3)$$
$$NO + O + M = NO_2 + M \quad (4)$$

where M denotes a third body it seems more likely that most of the sulphur trioxide detected in the experiments reported here arises through reaction (4), followed by reaction (2); extrapolation to 950° C of the data of Boreshov and Illarionov[3] suggests that reaction (2) is very fast at this temperature[4]. Data on reaction (3) can be found in reports by Kaufman[5], Levy and Merryman[6], and Webster and Walsh[7]; those on reaction (4) can be found in Kaufman's review[8].

Thermochemistry of Lanthanide Complexes

VALUES are now available for ΔH_1, the heat content change in the reaction

$$Ln^{3+}(aq) + aY^{n-}(aq) \rightarrow LnY^{(an-3)-}(aq) \quad (1)$$

where Ln represents a lanthanide element and Y a complexing agent such as the ethylenediaminetetraacetate (EDTA) or nitrilo-triacetate (NTA) ion. The measurements usually refer to dilute solutions of molar concentrations of ~ 0·01 or less. The dependence of ΔH_1 on the atomic number of the lanthanide is often rather complicated, a plot of one quantity against the other showing both a maximum and a minimum. This is true, for example, of the EDTA[1] and 1 : 1 NTA complexes[2,3] and the 1 : 1 and 1 : 2 diglycollate and dipicolinate complexes[4]. There are, however, grounds for believing that a complicating factor may be a change somewhere in the middle of the series in the effective hydration number of the uncomplexed lanthanide ion, consequent on the lanthanide contraction. This factor can be eliminated by measuring the integral heats of solution of a series of isomorphous lanthanide salts to give suitably dilute solutions. Such series of salts covering all the lanthanides are not numerous, but two well known ones are the bromates and the ethylsulphates, both of which crystallize as enneahydrates. If, for example, ΔH_2 is measured for the process

$$Ln(C_2H_5SO_4)_3 \cdot 9H_2O(c) \rightarrow Ln^{3+}_{\infty}(aq) + 3C_2H_5SO_4^-(aq) + 9H_2O(aq) \quad (2)$$

then $\Delta H_1 + \Delta H_2 = \Delta H_3$, where ΔH_3 is the heat content, increase for the process

$$Ln(C_2H_5SO_4)_3 \cdot 9H_2O(c) + aY^{n-}(aq) \rightarrow LnY^{(an-3)-}(aq) + 3C_2H_5SO_4^-(aq) + 9H_2O(aq) \quad (3)$$

from which the simple hydrated lanthanide ion has been eliminated.

We briefly report here the outcome of an investigation of this kind. We have measured the integral heats of solutions of lanthanide bromates and ethylsulphates in water at 25° C to give solutions of concentration ~ 0·01 M. The differential calorimeter used is capable of a precision of ~ 0·1 per cent in favourable circumstances, but the factor limiting the accuracy of our measurements is not the calorimetry, but departures of the solid hydrated salts from an exact stoichiometric composition. The bromates, which we studied first and which tend to crystallize rather rapidly from their supersaturated solutions, were found on analysis to tend towards a ratio of moles of water to gram ions of lanthanide somewhat more than nine, probably owing to the occlusion of other liquor in the crystals. The ethylsulphates appeared to crystallize rather more favourably, and all of them gave identical powder photographs. Nevertheless, while some of them analysed exactly as the enneahydrate within experimental error, others proved, like the bromates, to have a somewhat higher water content. This could again have resulted from the occlusion of mother liquor, or perhaps to the interstitial trapping in the lattice of individual water molecules, or both. In principle, a correction can be applied for occluded mother liquor by combining the analytical results for the specimen used with determinations of the solubility of the salt at 25° C and of the heat of dilution of the saturated solution. It is less easy to correct for errors due to interstitial water. We shall describe our work more fully elsewhere, but meanwhile we present in Table 1 values of the best estimates we can make at present of the heats of solution of the lanthanide ethylsulphates at 25° C. We do not believe that the main conclusions set out here are falsified by any corrections which we have had to apply.

Table 1. INTEGRAL HEATS OF SOLUTION IN CAL/MOLE OF THE LANTHANIDE ETHYLSULPHATE ENNEAHYDRATES AT 25° C

Concentration of solution ~0·01 M. 1 cal. = 4·184 abs. joules.

La	Ce	Pr	Nd	Sm	Eu	Gd
+11,260	11,620	11,870	11,790	12,490	12,350	12,130
Dy	**Ho**	**Er**	**Tm**	**Yb**	**Lu**	**Y**
10,890	10,520	10,010	9,170	8,720	8,590	9,970

When the values of ΔH_3 ($= \Delta H_1 + \Delta H_2$, ΔH_2 being the heat of solution of the ethylsulphate) are plotted against atomic number of the lanthanide, curves implying that the relation between the two quantities is still complicated are obtained for the following complexes: EDTA, 1 : 1 NTA, 1 : 1 and 1 : 2 diglycollate and dipicolinate. We think this is because these complexes are still partially hydrated and are subject to a change in co-ordination number about halfway along the series. For the EDTA complexes, crystallographic work supports this view[5]. So, although interference from a varying degree of hydration of the simple lanthanide ions has been removed, that associated with partial hydration of the complex remains. Plots of ΔH_3 (incorporating Grenthe's[4] values of ΔH_1) against atomic number for the 1 : 3 diglycollate and 1 : 3 dipicolinate complexes, however, are strikingly and significantly different, as is shown in Fig. 1. It is probable that each of these ligand anions occupies two co-ordination centres, and trials with models suggest that in these 1 : 3 complexes the co-ordination number of the metal is probably six, the shape of the complexes being about octahedral with water molecules sterically excluded from direct contact with the metal ion. Removal of the complications caused by partial hydration of the complex then reveals an essentially monotonic trend in the heat of complex formation, ΔH_3. But of particular interest is the bearing of the plots of Fig. 1 on the question of whether ligand field effects involving the $4f$ electrons contribute significantly to the stability of lanthanide complexes other than those of lanthanum, gadolinium, and lutecium. Such effects have been invoked, for example, by Yatsimirskii and Kostromina[6] to explain observed trends in the properties of lanthanide complexes, where in fact we believe any underlying simplicity is obscured by the hydration of the simple, and usually also

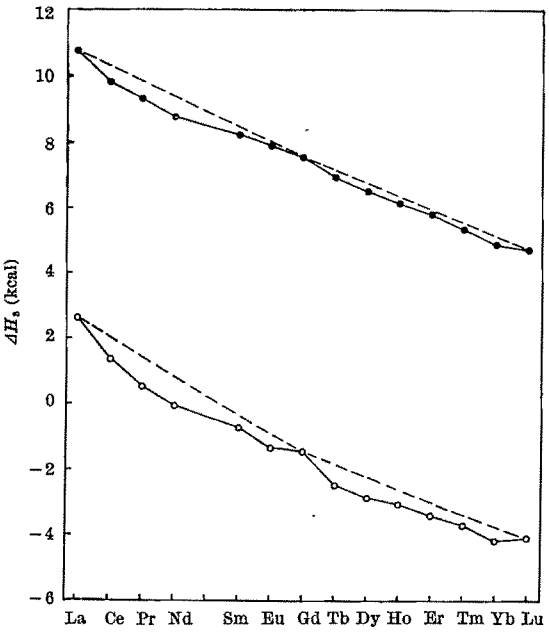

Fig. 1. Plot of ΔH_3 in cal/mole at 25° C against atomic number of the lanthanide for the 1 : 3 diglycollate and dipicolinate complexes. ΔH_3 is the heat content change for the process: $Ln(C_5H_5.SO_4)_3.9H_2O(c) + 3Y^{=}(aq) \rightarrow LnY^{3-}(aq)$. Full circles, diglycollate system; open circles, dipicolinate system.

of the complexed ions. It will be seen from Fig. 1 that the 1 : 3 complexes seem to be stabilized with reference to those of lanthanum, gadolinium and lutecium by an amount of the order of a few hundred calories, and it is significant that this effect is larger for the 1 : 3 dipicolinate than for the 1 : 3 diglycollate complexes, because the dipicolinate anion forms much the more stable complexes and presumably therefore exerts a stronger field on the metal ion. It is known that a plot of the ionic radii of the trivalent lanthanide ions against atomic number is made up of two crescents, and it might be asked how far this is therefore responsible for the shape of the curves in Fig. 1. If ΔH_3 for the two 1 : 3 complexes is plotted against ionic radius, the points, in fact, still tend to lie below a line through those for lanthanum, gadolinium, and lutecium, even though the deviations from this plot are smaller than those of Fig. 1.

The somewhat less complete results which we have obtained for the heats of solution of the bromates are consistent with these conclusions.

We therefore consider that this work shows that on eliminating the factors which normally complicate the thermochemistry of lanthanide complexes (namely, changes in the effective co-ordination numbers of both the simple and complexed ions) there is revealed a regular decrease of heats of formation with atomic number, superimposed on which there are ligand field stabilization effects which may contribute a few hundred calories to the heat of formation.

Chemical Reactions induced in Gases by means of a Laser

The induction of chemical reactions in condensed phases by means of a laser has been reviewed by Wiley[1]. During the course of studying the heating of gases by laser light pulses, we analysed the residual gases and found in some cases a significant change in composition. These results are preliminary in nature inasmuch as the experiments were not designed primarily for this purpose.

In our experiment, a typical *Q*-switched ruby laser pulse, of wavelength 694 mμ, had an energy of 5 J and a duration of 30 nsec, corresponding to an average power of $1{\cdot}7 \times 10^8$ W. This was focused to a "point" inside the target gas by a simple plano-convex lens, 23 mm in diameter and 37 mm focal length. Measurements of the focal volume showed that in the region of maximum intensity about 50 per cent of the light intensity fell within a circle of 200μ diameter, corresponding to the maximum power density of $\approx 2{\cdot}7 \times 10^{11}$ W/cm². The cone of gas within which the power density was at least 1×10^{11} W/cm² has a volume of about $4{\cdot}2 \times 10^{-5}$ cm³. Complete absorption of the light within this region would correspond to the delivery of about 3×10^4 eV of energy to each molecule, corresponding to a temperature over 10^7 °K. From our other work with hydrogen, however, we believe that the temperatures were below 2×10^6 °K.

The laser output was monitored by reflecting a small portion of the incident beam from a plastic pellicle into a rat's nest calorimeter. The exit beam was similarly monitored for each shot including shots through the evacuated cell. The percentage of absorption was determined by comparing the exit energy from the gas-filled cell to that from the evacuated cell. These measurements were qualitatively substantiated by observations of the energy-time trace of the exit beam, illustrated by Figs. 1*a* and *b*.

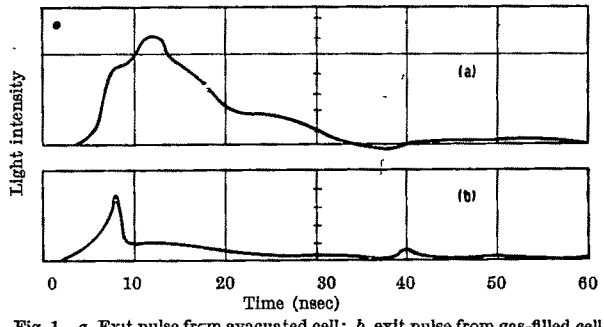

Fig. 1. *a*, Exit pulse from evacuated cell; *b*, exit pulse from gas-filled cell showing breakdown.

The gas mixtures which were irradiated are listed in Table 1. The cell volume was 4·5 cm³ for experiments (1)–(7) and 114 cm³ for experiment (8). The large percentage of light absorbed indicates that breakdown occurred in all cases. The mass spectrographic analyses of the gas samples are listed in Table 2. Some impurities were present in the starting materials and it is evident also that some air was incorporated in the course of filling, irradiating, and sampling.

With methane, the fraction decomposed was calculated from the analyses, taking into consideration the error which results from the presence of air and also the increase

in total volume which results from decomposition of methane, and the energy consumption was found to be 11 eV/molecule decomposed for experiment (1), 14 eV/molecule for experiment (2), and 49 eV/molecule for experiment (3). The ratio of hydrogen formed to methane decomposed was slightly greater than 1·5 which applies to the reaction

$$2CH_4 \rightarrow C_2H_2 + 3H_2$$

For CO_2, in a similar fashion, the energy consumption was found to be 34 eV/molecule in experiment (4) and 11 eV/molecule in experiment (5). The oxygen yield was as expected in experiment (4), but was very low in experiment (5), probably having been converted to deuterium oxide which at these concentrations and sample size was lost by adsorption during analysis.

Search for ammonia, nitrogen oxides and hydrocarbons in experiments (6)–(8) gave negative results.

Although the temperature within the directly irradiated volume was sufficient to cause complete dissociation and ionization, the low overall energy requirements imply that the number of molecules decomposed far exceeded the number originally ionized, and that most of the molecules decomposed received their energy indirectly. The pattern of product formation is what would be expected from high temperature reactions rather than from ionizing radiation. This is clearly shown in the methane results by the small yield of ethane or other derivatives of methyl radicals and, in general, by the lack of any product molecules more complex than the starting materials. Thus there cannot be a large contribution resulting from any mechanism which involves irradiation of the cold gas with ions or hot atoms from the plasma.

Those reactions which did occur proceeded with 10–20 per cent energy efficiency. The yields, expressed in radiation chemistry terms, correspond to G values of 2–9 molecules/100 eV, a value of 9 being considered quite large for endothermic radiolysis. For a reaction such as methane decomposition, wherein there is no appreciable back reaction to form methane again, higher yields might be anticipated if quenching were by the surrounding gas exclusively and not by the walls of the vessel. The nearest wall in our cell was only 3 mm from the focal "point". Further experiments in larger vessels and at various pressures are likely to be of considerable interest. Geometrical factors might also be important in the decomposition of carbon dioxide, and yields of nitrogen–oxygen synthesis.

The present work indicates that the giant pulse laser can be conveniently used to study very high temperature chemical reactions. Studies to establish the dependence of yield on intensity and configuration of focal spot would also determine the usefulness of the method as an absolute dosimeter or calorimeter for laser shots. Such a dosimeter would be useful in laser plasma studies.

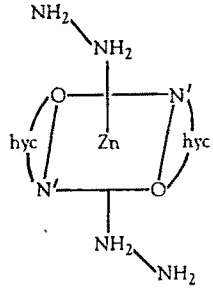
Transition-metal Chelates of Hydrazincarboxylic Acid

THE structural and chemical properties of compounds formed by hydrazincarboxylic acid, H_2N'-NH.COOH, with transition metals are being investigated in this laboratory, and this communication presents a brief account of the present stage of the structural researches. Three sets of compounds have been prepared (hyc = H_2N'-NH.COO)

(*a*) $M(II)(N_2H_4)_2$ hyc_2, where $M(II)$ = Mn, Co, Ni, Zn;

(*b*) $(N_2H_5)[M(II)\,hyc_3].H_2O$, where $M(II)$ = Fe, Co, Ni, Zn;

(*c*) $K[M(II)\,hyc_3]$, where $M(II)$ = Fe, Co, Ni, Zn.



It has been found from X-ray diffraction patterns that the crystals of each set are isostructural. The crystal structure of some of them has been determined, and results indicate that the compounds are chelates of hydrazincarboxylic acid.

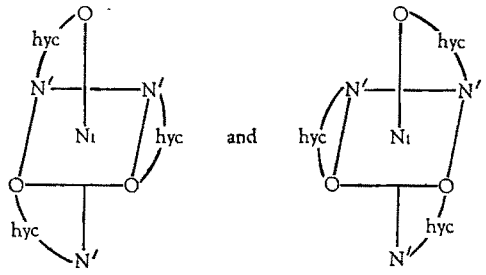
Compounds belonging to group (*a*) were prepared[1,2] from aqueous solutions containing a salt of the metal and hydrazine hydrate. When the solutions were left in open vessels, carbon dioxide was slowly absorbed from the air and crystals separated out. While the crystals of the zinc and the manganese compounds are colourless, those of the cobalt compound are orange-red, and those of the nickel compound blue-violet. Crystals are monoclinic and have space groups of the type $P2_1/c$. The crystal data for the zinc compound are

$a = 8{\cdot}412$ $b = 7{\cdot}384$ $c = 8\,270$ Å
$\beta = 109°\ 53'$ $D_m = 1\,936$ $D_c = 1\,926$ g.cm^{-3}

Two formula units are contained in the unit cell.

The crystal structure of the zinc compound, *bis*(hydrazine)–zinc *bis*(hydrazincarboxylato-N′,O), was determined[3] and found to consist of chelates of the type

where the hydrazine molecules, which act as monodentate ligands, and the hydrazincarboxylato anions, which act as bidentate ligands, are bound in the *trans* position. The co-ordination around the metal is of the octahedral type.



Compounds belonging to group (*b*) were prepared by bubbling carbon dioxide into a solution containing a salt of the metal and hydrazine hydrate. Crystals of the nickel compound are blue, those of the cobalt compound orange-red, those of the iron compound pale green, and

those of the zinc compound colourless. The crystals, which are piezoelectric, are monoclinic. From the systematic absences of the reflexions and from the piezoelectric properties exhibited, the compounds can be uniquely assigned to the space group *Cc*. The unit cell constants of the nickel compound are

$a = 12\,129$ $b = 10\,858$ $c = 10\,255$ Å
$\beta = 121° 06'$ $D_m = 1\,889$ $D_c = 1{\cdot}868$ g.cm^{-3}

Four formula units are contained in the unit cell.

The structure of the nickel compound was determined and found to consist of anionic chelates of the type

with cations $N_2H_5^+$ and water molecules. The co-ordination around the metal is again of the octahedral type. The hydrazincarboxylato groups are bound in the *cis*-position, that is to say, all oxygen atoms lie on the same face of the co-ordination octahedron and N′ atoms on the opposite face. The crystals are racemic, and both enantiomorphous forms coexist in the structure. The compound can thus be called hydrazinium *cis-trans*(hydrazin-carboxylato-N′,O)niccolate hydrate; the other metals form similar compounds. Before structural determinations were undertaken the formula M(II) $hyc_2.(N_2H_5)_2CO_3$ had been assigned to this class of compounds[4–6].

Compounds belonging to group (*c*) were prepared by evaporating mother liquors of type (*b*) compounds and treating them with potassium hydroxide. The colour of the crystals is the same as the corresponding salts of group *b*. The crystals, which are also piezoelectric, are trigonal; from systematic absences of reflexions and from piezoelectric properties it is possible to assign them to the space group $R\bar{3}c$. Crystal data for the zinc compound are (hexagonal cell)

$a = 10\,325$ $c = 17\,024$ Å
$D_m = 2{\cdot}123$ $D_c = 2{\cdot}088$ g.cm^{-3}

Six formula units are contained in the unit cell. The M(II) atoms lie on the trigonal axes. Chelate anions of the type $[M(II)\ hyc_3]^-$ are also present in these compounds and have trigonal symmetry; the ternary axis is normal to both the plane formed by three oxygen atoms and the plane formed by three N′ atoms. These crystals are also racemic.

Transition-metal chelates of hydrazincarboxylic acid exhibit similar properties to those of glycine[7].

Evidence for the Pyridine.2I_2 Complex in the Gas Phase

Some recent spectroscopic studies[1] have led to the identification of charge-transfer complexes in the gas phase, for the diethyl ether–iodine and the benzene–iodine systems. This was made possible by investigations of the charge-transfer ultra-violet band, and it was deduced, from the shift of the maximum of absorption, compared with that of the liquid-state system, that there is considerable interaction between the complex and the solvent molecules. To our knowledge, no direct evidence has previously been obtained by mass spectrometry of a charge-transfer molecular complex; this communication reports some preliminary results using this technique.

We have investigated the pyridine.2I_2 crystalline complex, prepared according to the method of Prescott and Trowbridge[2]; the structure of this compound, in the solid state, has been established by Hassel and Hope[3]. Crystals were directly introduced on the high vacuum side of the introduction system of an AEI-*MS*9 double focusing mass spectrometer, and the mass spectrum was recorded of the vapour in equilibrium with the crystal at about 35° C.

The mass spectrum consists mainly of the free pyridine and free iodine peaks. Additional peaks[4], however, were observed at many masses. The most important ones are given in Table 1, and it is probable that they correspond to the formulae indicated. The contributions of pyridine are also given for comparison. All figures are for electron energies of 50 V. The contributions of the complex to masses lower than 79 are minimum values; these were obtained by deducting the contribution of pyridine, assuming that all ions at *m/e* 79 result from pyridine itself. The sum of ion abundances below *m/e* 79, ascribed to the complex, represent 15 per cent of the pyridine contribution as evaluated; obviously this cannot be ascribed to possible variation of the cracking pattern of pyridine itself. The masses below *m/e* 79 have very different relative abundances from those of pyridine—the 51 peak is the principal ion, instead of the 52 peak in pyridine. Also noticeable are the abundances of the peaks

* (*a*) Contribution of complex; (*b*) contribution of pyridine or iodine.

at masses 26, 28 and 50. A small peak is observed at mass 128, corresponding to HI^+. Most important for our purpose, however, are the peaks observed at mass 460 ($Py.I_3$) and 587—the latter corresponds to the parent molecular ion of the complex $Py.2I_2^+$. As would be expected, its abundance is low (0·006 per cent total ionization); however, it indicates the presence of the charge-transfer complex in the gas phase. It is difficult to estimate the composition of the gas phase; however, a rough calculation, assuming as a first approximation a square root relation between molecular weights and total ionization cross-sections, would lead to about 2 per cent of complex and, assuming a pressure of 10^{-4} mm in the ionization chamber, the stability constant, K_c, could be calculated: $K_c = p_{\text{compl.}} (RT)^2/p^2_{I_2} \times p_{Py}$, which would have a value of the order of $7 \cdot 10^{14}$ mole^2 l.$^{-2}$.

Table 2. APPEARANCE POTENTIALS (A.P.) IN $Py.2I_2$ (IN eV)

m/e	Ion	A.P.	Literature (free molecules)
79	C_5H_5N	10·08	10·04 (electron impact) (ref. 7), 9·23 (photo-ionization) (ref. 6)
127	I^+	(1) 8·81	8·62 (ref. 8) (ion pair formation from I_2) 8·83 (calculated for ion pair formation from I_2)
		(2) 11·28	11·96 (calculated for $I_2 + e \rightarrow I^+ + I + 2e$)
254	I_2^+	9·37	9·35 (ref. 8)
587	$Py.2I_2^+$	8·9–9·1	No values

Appearance potentials have been determined using Warren's method and the vanishing current method of interpreting the data[5]. The results are summarized in Table 2 (mean values are given).

It can be seen from Table 2 that, owing to the high proportion of free pyridine and iodine at equilibrium, the appearance potentials for the $C_5H_5M^+$ and I_2^+ ions are practically the ionization potentials of these molecules, as determined by electron impact. For the same reason, the two distinct appearance potentials measured for I^+ certainly are related to the dissociation processes from a free iodine molecule, the lowest appearance potential corresponding to the ion pair process, the highest appearance potential corresponding to the normal dissociative process, without formation of a negative ion.

As can be seen, a value for the ionization potential of the $Py.2I_2$ molecular complex itself is obtained. It is somewhat lower than the ionization potentials of both iodine and pyridine, but the difference is not important if one takes into account the difficulty of such a measurement for a very low intensity ion. Because the electron impact value for pyridine is considerably higher than the photon impact value, our results, obtained by electron impact, suggest that in the complex the ionization might refer to an iodine $\pi_g 5p$ orbital, as in the iodine molecule itself[8], rather than to the π orbital of the pyridine ring.

Radiothermoluminescence of 4,4′-Dimethylbenzophenone

THE formation of radiation-induced colour centres in inorganic crystals is a well-known phenomenon[1,2]; however, such colour centres have been previously reported for only a limited number of simple organic compounds[3]. Colour formation in irradiated organic crystals probably results either from the unpairing of electron spins to give free radicals or triplet states or by the transfer of an electron into a lattice defect[4]. The latter would be the more probable explanation for stable colour formation. On heating the irradiated organic crystal to the melting point, emission of light and disappearance of colour would be expected as the electrons become released from lattice defects or free radicals combine.

We have now found that when solid 4,4′-dimethylbenzophenone (melting point 91° C) is irradiated with 2 MeV electrons from a Van de Graaff accelerator, the compound acquires a light pink to a deep red colour depending on both the dose and the particle size of the compound. At 2·0 Mrads the first visible coloration is obtained and the intensity of the colour increases progressively up to 20 Mrads. On melting, the colour of the irradiated 4,4′-dimethylbenzophenone was found to disappear with the emission of light. The amount of light emitted—that is, the "radiothermoluminescence"—was calculated as a function of a number of variables.

The effect of radiation dose on 4,4′-dimethylbenzophenone was tested as follows: 1·00 ± 0·01 g of the compound were placed in a 40 mm diameter aluminium pill box with a cover and was melted at 105° C. It was then allowed to crystallize slowly to give large crystals. Samples were then irradiated with 2 MeV at doses of 5–20 Mrads. To avoid overheating the samples, the dose was delivered in 1·0 Mrad pulses at 3 min intervals. Six hours after irradiation, the samples were placed on a thermostatically controlled hot plate in a dark box. The light emitted was measured by a phototube and the results were printed out directly[5]. The area proportional to the light emission was determined by a planimeter with the chart scaled so that 1 cm in width was equal to 24 sec of recorded time and 1 cm in height was equal to 0·003 μamp from the phototube. A plot of the results for radiothermoluminescence area against the dose of radiation used (Fig. 1) reveals a linear relationship for samples irradiated and stored in the dark.

To determine the effect of storage time between irradiation and the radiothermoluminescence measurements, individual samples were prepared and then irradiated as before. Fig. 2 shows the results of radiothermoluminescence after various periods of time. Substantial decreases were noted during the first few hours of storage after irradiation and a less noticeable decrease after 5 h. The same pattern of radiothermoluminescence decrease was found for both large and small crystals.

To test the effect of storage conditions—in the light as opposed to in the dark—radiothermoluminescence measurements were made both on small crystal samples both irradiated in the dark and stored in the dark and on similar samples irradiated in the dark but stored in the light. As shown in Fig. 3, the radiothermoluminescence decays more rapidly in the light than in the dark. In subsequent experiments, it was also shown that the red colour induced in 4,4′-dimethylbenzophenone by electron irradiation is bleached by light.

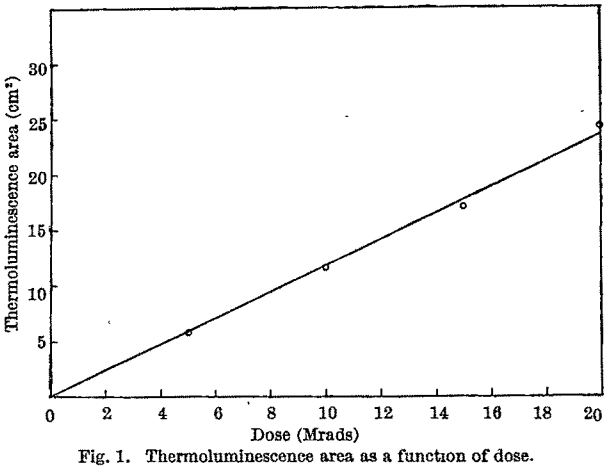

Fig. 1. Thermoluminescence area as a function of dose.

The luminescence after irradiation observed in these experiments could have been caused either by radiothermoluminescence or by oxyluminescence. (The latter phenomenon is the continuing luminescence which arises when an irradiated sample is continuously heated in oxygen[6,7].)

To eliminate the possibility that oxyluminescence was responsible for the luminescence obtained on heating an irradiated sample of 4,4′-dimethylbenzophenone, we melted the irradiated sample, allowed it to solidify, and then observed whether any additional luminescence resulted when it was further heated. The absence of any

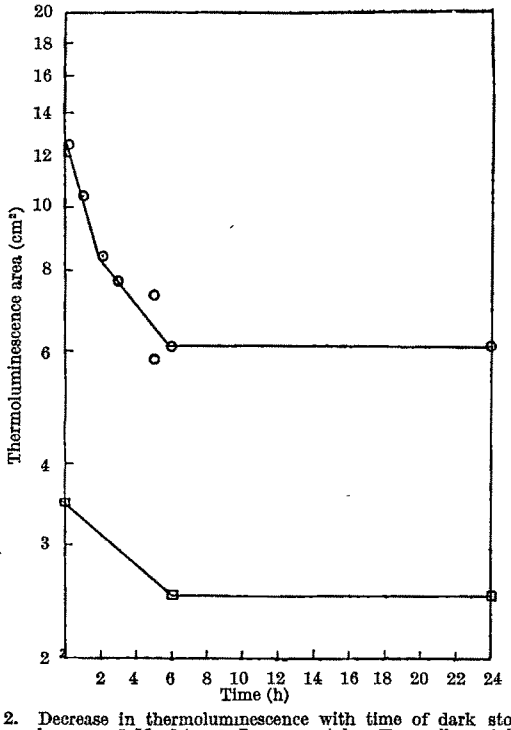

Fig. 2. Decrease in thermoluminescence with time of dark storage (samples given 5 Mrads). ○, Large crystals; □, small crystals.

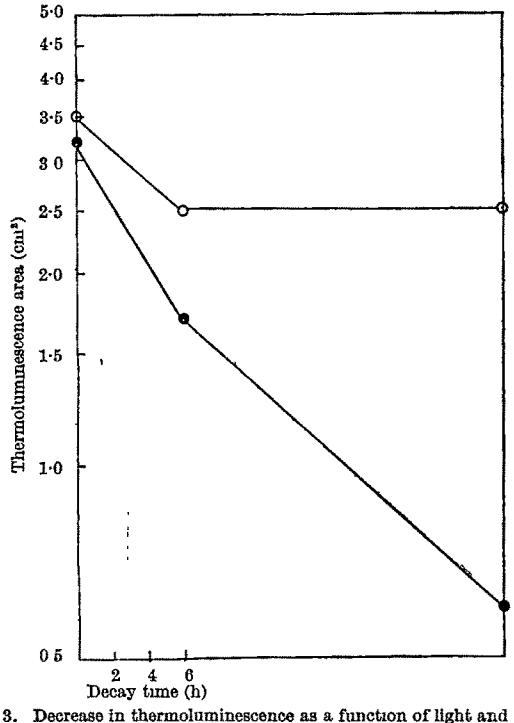

Fig. 3. Decrease in thermoluminescence as a function of light and dark decay time for small crystals. ○, Dark; ●, light.

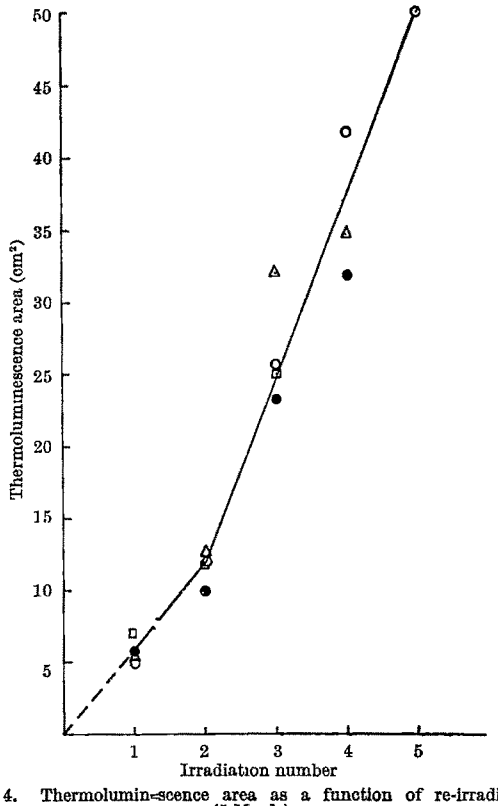

Fig. 4. Thermoluminescence area as a function of re-irradiation (5 Mrads).

such luminescence indicated that oxyluminescence played no part in the present findings.

Although 4,4′-dimethylbenzophenone could be recoloured by taking it through twenty cycles of irradiation, melting, resolidification and re-irradiation, the radiothermoluminescence did not remain constant with each re-irradiation. Instead, as can be seen from Fig. 4, measurement of the radiothermoluminescence for a series of cycles indicated that the response to the same irradiation dose increased as a function of the number of exposures to radiation.

Determination of the Sodium bound by Poly-acids

The fact is now widely accepted[1–3] that some part of the sodium in animal tissues occurs not in the form of free sodium ion but, rather, in an osmotically inactive form. The structures on which the binding occurs, as well as the amount of the sodium so bound, remain to be determined. A number of substances are capable of binding the sodium ion and some of them, such as the acid mucopolysaccharides and nucleic acids, belong to the group of polyacids—polymers with at least one acidic group in the monomer unit. Sodium as well as other positively charged ions are attracted into the neighbourhood of the fixed

negatively charged acidic groups by the strong electrostatic fields present, and their apparent activity coefficient is thus considerably lowered in comparison with that in corresponding solutions of sodium salts of simple mineral acids. This type of binding is called "site-binding"[4].

The binding of the sodium ion can be estimated by comparing the value of the apparent activity of this ion in the poly-acid solution with that in a standard solution of sodium chloride containing the same concentration of sodium. The apparent activity of the sodium can be determined by means of a glass electrode sensitive to sodium[5]. While there are no special difficulties in using this electrode in solutions of simple electrolytes, there are possible sources of interference with measurements in solutions of macromolecules. The unknown value of the liquid junction potential, which may differ significantly from that in standard solutions of sodium chloride, must be considered one of the most important. In order to prove that the low value of the apparent activity of the sodium ion in solutions of the sodium salts of the poly-acids results entirely from site-binding, an attempt has been made to demonstrate the binding indirectly.

Because the site-binding is purely electrostatic, it might be expected that a polyvalent cation having a much higher charge density would replace that of sodium bound in the neighbourhood of the charged groups of the poly-acid. As all the bound sodium could thus be liberated, it would be possible to infer the amount of it from the difference between the apparent activity of the sodium ion in the original solution and that in a solution in which all the sodium ions had been liberated by the addition of an excess of a polyvalent cation.

The sodium salt of heparin ('Heparin Spofa', twice recrystallized) was used. To determine this concentration of the acidic groups, solutions of the sodium salt were passed through a column of 'Dowex 50' in the hydrogen form. Completeness of the ion exchange was confirmed by flame photometry. Solutions of the free acid thus obtained were titrated with sodium hydroxide solutions free from carbon dioxide. The apparent activity of the sodium ion was measured with a glass semi-microelectrode sensitive to sodium and a saturated calomel electrode. The e.m.f. of the cell thus formed was standardized over the range 0·01–0·2 M with solutions of sodium chloride, and found to be reproducible to within 0·3 mV. The trivalent ion of lanthanum in the form of a 0·4 M chloride solution was used as the polyvalent cation. The glass electrode was insensitive towards the lanthanum ion in the range of concentrations used.

Because the potential of the glass electrode becomes dependent on *p*H at *p*H below 6, care had to be taken that the poly-acid solution was completely neutralized; otherwise, the lanthanum ion would have liberated not only the sodium ion, but also that of hydrogen. For the same reason, an atmosphere of nitrogen was used to guard against contamination by carbon dioxide.

The concentration of free sodium ions in a solution of the sodium salt of heparin is plotted in Fig. 1 as a function of the concentration of lanthanum chloride. The measurements have been corrected for the change of volume and for variations of ionic strength. It will be noted that an excess of lanthanum is necessary to liberate all the bound sodium. An identical curve would have been obtained if the solution of the sodium salt had been prepared by neutralizing the free heparin. The values found for binding of the sodium ion by heparin are comparable with those obtained by Ascoli *et al.*[6] by a different technique.

If the sodium salts of hyaluronic acid and deoxyribonucleic acid are used with the cation exchange resin 'Dowex 50*W*–*X*8' (200–400 mesh) in the sodium form instead of heparin, similar curves are obtained. The resin had to be suspended in a 0·01 M solution of sodium chloride.

Applications of this method are not limited to binding of the sodium ion by the poly-acids. It can also be applied to systems in which binding other than site-binding is involved, as with ethylenediamine tetraacetic acid or adenosine triphosphate. Moreover, because of this high selectivity of the glass electrode, the determination can also be carried out if cations other than sodium are present. Preliminary results indicate that this method, slightly modified, could also be used to analyse this binding of the sodium ion in biological systems.

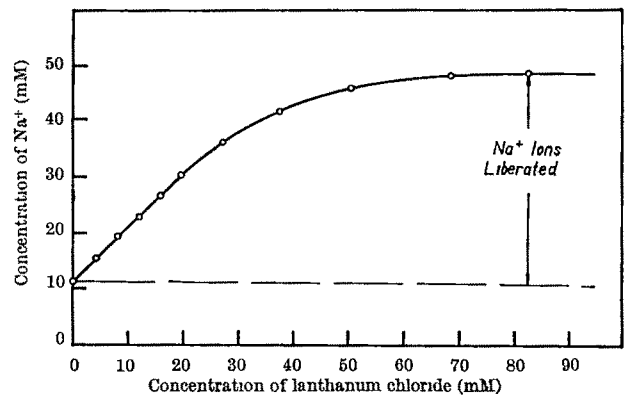

Fig. 1. Concentration of the free sodium ion in a solution of the sodium salt of heparin as a function of the concentration of lanthanum chloride. The concentration of the acidic groups of heparin as well as that of sodium was 48 mM.

Nomenclature of Elements

WOLFENDEN[1] has suggested changes in the names of the elements so as to ensure that the names of all the metals, but none of the non-metals, end in *ium*. For example, he proposes the new names platinium and helion. If this desirable proposal is to be adopted, a criterion is necessary to distinguish metals from non-metals.

An element can be defined as a metal if, at room temperature and pressure, it has a low electrical resistivity which increases with temperature. By this criterion there are twenty-two non-metals:

H	He					
		B	C	N	O	F	Ne
			Si	P	S	Cl	Ar
				Ge	Se	Br	Kr
					Te	I	Xe
						At	Rn

Changes in the names of elements in addition to those proposed by Wolfenden would be: germanon[2], arsenium[3], selenon[4] and telluron[5]. The references are to resistivity data for pure samples of these elements.

Least satisfactory is the choice of a name for tin, for below 13° C the stable phase is a non-metal[6,7].

RADIOBIOLOGY

Long-term *in vivo* Retention of Cerium-144 by Beagles

CERIUM-144 is a high yield (~ 5 per cent) product of nuclear fission that can be readily detected in debris from fission reactions. From about the first to the fourth year after fission, cerium-144 contributes most to total radioactivity[1]. Because each nuclear disintegration of cerium-144 and its daughter praseodymium-144 can result in deposition of the effective equivalent of more than 6 MeV in bone[2], cerium-144 ranks among the more hazardous fission products. Although cerium-144 is only poorly absorbed from the gut[2,3], it has been detected at low concentrations in foods, including clams and animal bone[4]. Liebscher *et al.*[5] detected it in both lung tissue and pulmonary lymph nodes from man. Other workers also identified cerium-144 in lung tissue ash[6]. A similar situation was observed for plutonium-239 by Bair[7]. To assess properly radiation protection guides, it is essential also to consider the bodily retention of the element in question. Virtually nothing is known about the retention of cerium-144 by mammals other than rodents. The purpose of this work was to study the long-term *in vivo* retention of cerium-144 following a single dose to adult beagles.

Four adult male beagles with an average weight of 13·4 kg (range 12·0–15·27 kg) were used. Ages ranged from 60 months to 76 months. Because the animals had been maintained in our colony since birth, they were known to be free from disease. Each dog was well acclimated to periods of confinement in metabolism cages. Immediately after a cage conditioning period of 2 weeks, each dog received about 28 μc. of carrier-free cerium-144 as cerium chloride in 1 ml. sterile solution by injection into an antecubital vein. The *p*H was adjusted to 3·5, because Aeberhardt *et al.*[8] have been able to demonstrate complete ionization and lack of colloid formation for *p*H values less than 4·5. Also, it has been demonstrated that both *p*H and carrier affect deposition patterns of lanthanons in the body[9]. Water and commercial dog food were always available. Within 30 min of injection, each dog was placed in a large volume radiation detector designed to measure the γ-ray activity of the entire animal[10]. The almost 4π steradian geometry of the detector virtually eliminates the effect of tracer redistribution. About 1 yr after injection the dogs were measured (whole-body counted) in an improved counting system[11]. Between day 369 and day 425 whole-body counts in both counters were made on each dog on five different occasions; after day 425, measurements were made only in the improved counter; the overlap period allowed for normalization of the counting data. A polyethylene bottle containing about 28 μc. of cerium-144 and tap water to make a total weight of 13 kg was used as a reference standard. Each dog was counted for 200 sec for each measurement, and appropriate corrections were made for pre-experimental γ-ray activities (caesium-137 and potassium-40). The percentage of biological retention (PBR) was calculated from the following relation:

$$(\mathrm{PBR})_n = 100 \cdot A_n/S_n \cdot S_i/A_i$$

where (PBR) is the percentage of biological retention on day n, and A and S are count rates of an animal or standard at the nth or ith (initial) measurement, respectively. All data processing was carried out on an IBM model 7094 computer; the data reduction and analysis techniques used have already been reported in detail[12].

Table 1 gives whole-body retention parameters for each dog. During the 1,050 day experiment each dog was measured 126 times. A simple exponential model was used because of the observed linear reduction of log retention as a function of time after injection. At least two power functions ($y = ax^b$) were needed to describe retention after day 1; one power function described the data reasonably well from days 100 to 1,050. Effective half-lives (T) approach the maximum value of 285 days, which is the physical half-life (T_r) of cerium-144 (that is, if no biological turnover occurred, the serial changes in body activity would result from physical decay of cerium-144 alone). That only two parameters are needed to describe retention over approximately four effective half-lives is of considerable interest, because cerium-144 is known to be deposited in tissues other than bone (for example, kidneys, liver and spleen) when injected into rodents at *p*H 3·5 (ref. 13). Probably the half-life observed is a reflexion of reasonably similar turnover rates from more than one site.

Table 1. COMPUTER-DERIVED WHOLE-BODY RETENTION PARAMETERS FOR CERIUM-144 INJECTED INTRAVENOUSLY INTO MALE BEAGLES

Dog. No.	a* (per cent)	$-k$* (day^{-1})	T_b (days)	T† (days)
19	97·7	$1\,789 \times 10^{-4}$	3,873 ± 623‡	265
21	97·8	$2\,032 \times 10^{-4}$	3,411 ± 263	263
24	99 1	$1\,861 \times 10^{-4}$	3,723 ± 501	265
31	99 3	$2{\cdot}141 \times 10^{-4}$	3,283 ± 378	262

* $R_t = a\,e^{-kt}$, for $t \geqslant 0 \leqslant 1{,}050$ days.

† $T = \frac{T_r \cdot T_b}{T_b + T_r}$, where T_r, the physical half-life for cerium-144, is 285 days.

‡ Best value ± one standard deviation. $T_b = 0{\cdot}693/k$; $\sigma T_b = \frac{0{\cdot}693\ \sigma_k}{(k)^2}$.

Biological turnover is extremely slow with an apparent biological half-life of about 10 yr. The biological half-life (T_b) of 1,500 days currently listed for bone by the International Commission on Radiological Protection[14] would seem to be too small. For cases involving internal deposition of cerium-144 in human beings, it would seem prudent and conservative to assume that physical decay alone would account for subsequent changes in the body burden of cerium-144. Furthermore, it is possible that following previous atmospheric nuclear weapon tests small quantities of fall-out cerium-144 might have been deposited in human bone. To our knowledge this conjecture has not been verified.

Recovery Effect of Heterologous Deoxyribonucleic Acid from Various Organs on Irradiated Mice

WE have previously shown that native homologous deoxyribonucleic acids (DNAs) can be used as therapeutic agents in irradiated animals. We showed that, for example, native homologous testes DNA significantly increases the percentage of survival of infantile rats and mice (8 and 17 days old), irradiated with a dose of 600 r.[1]. Furthermore, we obtained a positive therapeutic effect in infantile rats of the same age injected with liver DNA after irra-

diation with a dose of 600 r.[2]. Our results showed that other DNAs, such as those from thymus and spleen, can increase the survival from radiation disease[3]. We also showed that these homologous native DNAs from various organs not only increase the proportion surviving radiation disease, but also support the regeneration of function in the reproductive organs of irradiated immature male rats. The percentage of fertile rats is significantly higher (60–70 per cent) in animals treated with DNA (isolated from various organs) after irradiation, than in control animals (25–30 per cent)[3,4].

Histological investigations have shown that there is less damage to the spleen, bone-marrow, digestive tract and liver in the animals treated with DNA after irradiation than in the controls[5,6].

It has also been shown that the effects of lethal irradiation can be modified in different animals by other treatments applied after irradiation, for example, with bone-marrow cells[7,8] or spleen homogenates[9].

In view of the importance of this problem from both the theoretical and the practical point of view, we investigated the possibility of curing lethally irradiated animals with heterologous DNA. A greater effect was achieved if the donors were of the same species. Nucleic acids of rabbits injected into irradiated rats failed to give any protection[10].

Paoletti examined the restorative effect of calf thymus DNA in lethally irradiated mice[11], and found that the percentage of survival was at the limit of statistical significance. When he applied 2-β-aminoethylisothiourea (AET) before irradiation and then injected heterologous DNA, however, eleven animals out of forty survived.

In our experiments we irradiated 2-month-old *C57* male mice with 600 r. X-rays (approximately the 100 per cent lethal dose). The animals were irradiated under the following conditions: 200 kV, 14 m.amp, aluminium 3, distance 46 cm. Immediately after irradiation the animals were injected intraperitoneally with DNA extracted, according to the method devised by Zamenhoff[12], from various organs of rats of comparable age. Standard curves for the extracts are shown in Table 1.

Table 1

Extract	DNA : RNA	E_{260}/E_{230}
Liver	0 51	2 4
Testes	0 52	2 2
Spleen	0·52	2·3
Thymus	0 53	2·1
Kidney	0·50	2·1

The survival rates were determined over a period of 30 days for 288 adult male mice, 236 of which had received post-irradiation injections of DNA (see Table 2).

Table 2. DOSAGE OF DNA EXTRACT AND NO. OF MICE INJECTED AFTER IRRADIATION WITH 600 R. X-RAYS

Extract and dosage (mg)	No. of mice
Liver, 1 6–1 8	49
Testes, 1·3–2·0	48
Spleen, 1·0–1·4	53
Thymus, 2 0	51
Kidney, 1·2–1 4	35
(Controls)	52

The results obtained are shown in Fig. 1. They indicate that 4 per cent of male mice irradiated with a dose of 600 r. were able to survive (controls). Mice irradiated with the same dose and treated with DNAs show increased survival. Thus, liver DNA increases the percentage of survival to 53 per cent, kidney DNA to 54 per cent, thymus DNA to 37 per cent (above), spleen DNA to 37 per cent and testes DNA to 31 per cent (below).

Our results show that DNAs reduce the effects of irradiation by a factor of 9–13. Statistically the differences are highly significant ($P < 0{\cdot}001$).

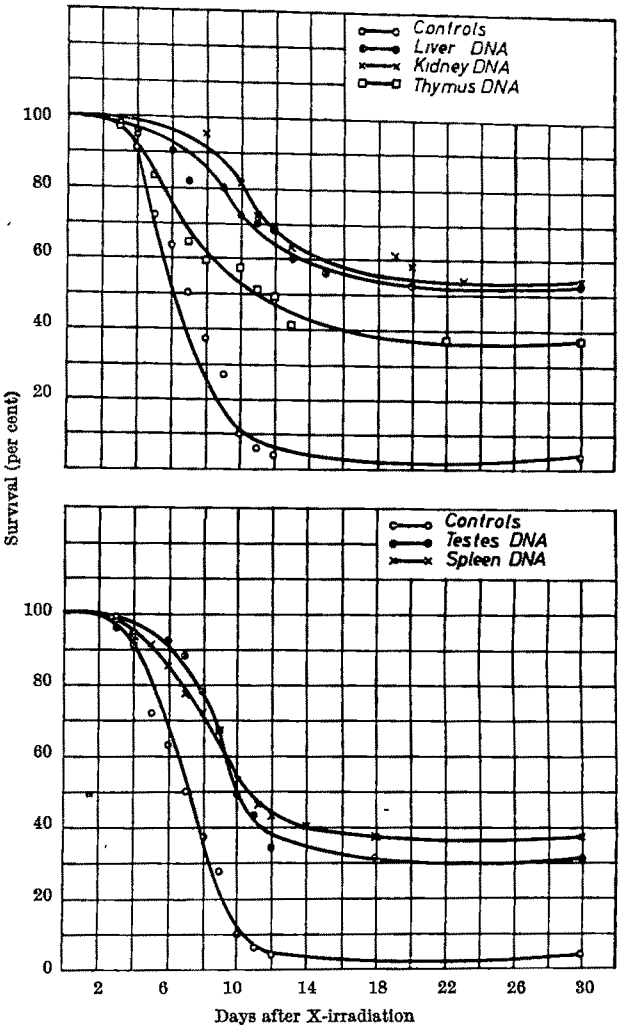

Fig. 1. Restorative effect of DNA isolated from different organs on the survival of adult male mice.

From these data, we conclude that heterologous native DNAs extracted from various organs of adult rats enable a high percentage of mice to survive the effects of irradiation. The exact nature of the mechanism involved has not as yet been established, but it is possible that DNA which has been damaged during irradiation can be replaced or restored by the injection of either homologous or heterologous deoxyribonucleic acids.

PHYSIOLOGY

Photoreceptive Features of Vesicles associated with the Nervous System of Cephalopods

FROM the results of an investigation using both the light and the electron microscope Nishioka, Hagadorn and Bern[1] concluded that the epistellar body of *Octopus bimaculatus*(?) found off the coast of California was probably a photoreceptive organ. Present within the lumen of the epistellar body are processes equipped with microvilli; these are often organized into rhabdomes as in the eyes of many protostome invertebrates[2]. In this species of *Octopus*, as well as in others studied, the epistellar body is only barely discernible as a pale orange spot at the base of the posterior stellar nerves of the stellate ganglion. In *Eledone*, however, the similarly located epistellar body is much larger and more intensely orange than in *Octopus*. Even with light microscopy the reticular pattern suggestive of rhabdomeric organization was apparent at the periphery of the lumen. The morphology indicative of a photoreceptive function and the large amount of pigment observed provided the basis for the present investigation of the biochemical nature of the pigment of the epistellar body of *Eledone moschata*. The details of this study and related information on vesicles associated with the nervous system of cephalopod molluscs will be reported elsewhere[3].

Sixty-three *E. moschata* were dark-adapted for at least 16 h before killing them. The stellate ganglia and eyes were then removed under red light. Both tissues were immediately frozen in beakers suspended over dry ice in acetone. After thawing and further dissection, the portion of the stellate ganglia which contained the epistellar bodies and the remainder of the stellate ganglia were homogenized separately and centrifuged in a sucrose gradient. The eyes were also homogenized and centrifuged in a similar sucrose gradient after an initial crude separation of cellular material from pigment granules. Material floating in the 0·5 M sucrose concentration was then removed and mixed with 1 M disodium acid phosphate and centrifuged. The precipitate was dissolved in digitonin and transferred to a Beckman cuvette, and the absorption spectrum characteristic of rhodopsin was obtained on the eye material using a Beckman ratio recording spectrophotometer. A similar spectrum was obtained with material from the epistellar body. The *p*H of the solution was then raised slightly above 9·0 with sodium carbonate, and the solutions containing rhodopsin were exposed to room light for about 1 h before a second absorption spectrum was obtained; this recorded the shift to metarhodopsin in both instances (Table 1). The λ_{max} of rhodopsin in the eye[4] was slightly higher than in the epistellar body, whereas the λ_{max} of alkaline metarhodopsin was identical for both organs. These curves were obtained on three separate batches of material, and the data for one run are given in Table 1. No evidence for the presence of rhodopsin–metarhodopsin was obtained from the stellate ganglion (control tissue preparations).

In their earlier paper, Nishioka *et al.*[1] concluded that the epistellar body could not be a neuroendocrine structure[5–7] or the homologue of the third-order giant fibre system of squids[5]. We have suggested that the parolfactory vesicles in decapod cephalopods[7] were more likely homologues of the octopod epistellar body. Ac... factory vesicles of the squid *L.* ... investigated. Histological ...

those of the octopod epistellar body[7]. These vesicles vary in number from four to fifteen on each side and lie superficially in connective tissue adjacent to the olfactory lobes—thus the name "parolfactory". Because of their minute size, we initially expected that they would be extremely difficult to find in fresh material; however, here again the intense orange pigmentation facilitated their collection.

Parolfactory vesicles from ninety-two *Loligo vulgaris* were used. Except for a shorter duration of dark adaptation (about 6 h)—because of the higher mortality of squids in captivity—the experimental procedure was identical with that used on *Eledone* material. Pieces of optic lobe approximately equal in volume to the parolfactory vesicles in their enveloping connective tissue were taken as control tissue, and the eyes[8] were again used for comparison. The λ_{max} of rhodopsin and of metarhodopsin from one of two determinations are given in Table 1. The optic lobes showed no evidence of visual pigment.

To substantiate further the specificity of the biochemical features of these photoreceptive structures, the antimony chloride method for determination of vitamin A_1 (see refs. 8 and 9) was used on extracts. Vitamin A_1 (ref. 9) was detected in both organs, but none was found in the control tissues (the remainder of the stellate ganglion in the octopus and parts of the optic lobe in the squid).

Because of the small size of both epistellar and parolfactory structures, no weights were taken. Nevertheless, we are impressed by the appreciable amounts of visual pigment isolated from these organs. Gross comparison with the eye leads us to believe that the concentration of visual pigment in the epistellar body and parolfactory vesicles is probably greater than in the eye.

We conclude from the biochemical information presented here that the epistellar body and the parolfactory vesicles contain considerable amounts of visual pigments very similar to those present in the eyes of the same animals. Our initial belief that the epistellar body was a vestigial organ in the adult organism[1] (conceivably important only in larval life) may now be untenable. It seems more likely that these organs are of importance in photoperiodic regulation in the adult, despite their cryptic locations. The vesicles are not to be viewed as "3rd and 4th eyes"[10], inasmuch as they would scarcely seem responsible for vision (that is to say, image perception). Photoreceptive function can extend to physiological regulations and include much more than vision *per se*. It is to this more general aspect that comparative physiologists need now address themselves.

This study was aided by a U.S. National Science Foundation grant. We thank Dr. Peter Dohrn, Dr. Andrew Packard and Dr. Luisa Tosi for their help in this research.

A Descending Pathway which is Monosynaptically Excitatory to Motoneurones

NEARLY twenty-five years ago, Lloyd[1] described a pathway descending in the ventral part of the spinal cord of the cat which ended directly on lumbosacral motoneurones and which facilitated the monosynaptic reflex. The pathway was shown by Lloyd to originate from neurones of the brain stem and from spinal proprioneurones. He named the pathway the "bulbospinal correlation system". Since Lloyd's original description, there has been some physiological work which suggests that the brain stem neurones from which this pathway originates may belong either to the reticular formation[2] or to the vestibular nuclei[3] or to both. Recent studies of the mode of termination of the reticulospinal and vestibulospinal tracts, however, offer little support for the presence of more than a few monosynaptic endings on lumbosacral motoneurones from fibres descending in these tracts[4]. The experiments to be described confirm the presence of long descending axons in the ventral part of the spinal cord which monosynaptically excite motoneurones.

Activity in what is presumed to be the bulbospinal correlation system of Lloyd has been investigated in the following manner. Cats were anaesthetized with pentobarbital sodium and their cords transected at the first lumbar level. The dorsal columns were removed for about a segment below the transection, and the dorsal halves of the lateral columns severed. The ventral part of the cord was placed on a pair of stimulating electrodes. Motoneurones of the lumbosacral enlargement were impaled by glass microelectrodes filled with 2·7 M potassium chloride or 4 M sodium chloride (resistances of 3–10 megohms). Because the roots were generally left intact, a motoneurone could be identified by the antidromic action potential that resulted from stimulation of the appropriate muscle nerve[5].

Motoneurones belonging both to extensor and to flexor muscles were frequently observed to receive short latency excitatory postsynaptic potentials from volleys descending in the ventral part of the spinal cord. Furthermore, when the ventral cord was separated into left and right halves, motoneurones often received comparable excitatory potentials from the two sides of the cord. For example, Fig. 1 illustrates the effects of stimulation of the left and right ventral cord quadrants on an extensor and a flexor motoneurone. The neurones were identified by their receiving antidromic action potentials from the flexor digitorum and hallucis longus (Fig. 1*A*) and the peronei-deep peroneal (Fig. 1*D*) nerves. Both these action potentials are shown at threshold stimulation of the motor axon; when no action potential was produced, the monosynaptic excitatory potential produced by the afferent volley in the same nerve could be seen. Each of the motoneurones received a small excitatory potential from volleys descending in either of the two halves of the ventral cord (Fig. 1*B–C* and *E–F*). The descending volley was recorded from the cord dorsum by a ball-tipped electrode placed near the entry point of the microelectrode. The interval between the arrival of the fastest component of the descending volley and the excitatory postsynaptic potential was less than 1 msec in each case, and so the potentials were monosynaptic.

The fact that the monosynaptic excitatory potentials which result from descending ventral cord volleys are rather small explains Lloyd's observation[1] that such volleys facilitate reflex transmission but do not discharge motoneurones. Lloyd also noted that repetitive stimulation of the bulbospinal correlation system greatly enhanced the facilitation. Fig. 2 illustrates the effect of brief repetitive stimulation of the ventral cord on the excitatory potentials recorded from motoneurones. The antidromic action potentials in Fig. 2*A* and *D* identify the motoneurones as belonging to the gastrocnemius-soleus and the posterior biceps-semitendinosus muscles, respectively. The monosynaptic excitatory postsynaptic potentials that were produced by single stimuli applied to the ventral cord are shown in Fig. 2*B* and *E*. The records in Fig. 2*C* and *F* were the result of brief tetanic stimulation of the ventral cord (four volleys at about 300/sec). The individual excitatory potentials not only merge with the residual depolarization of the previous potentials, but in addition they grow larger. The potential of Fig. 2*C* resembles the augmenting excitatory potentials produced by repetitive stimulation of the corticospinal and corticobulbar tracts and recorded from cervical motoneurones[6] or reticular formation neurones[7]. A difference may be seen, however, especially in Fig. 2*F*, in that the rising phases of the excitatory potentials from the ventral cord pathway are often double. The second component of the excitatory potentials evoked by repetitive stimulation begins too late to be monosynaptically evoked by the earliest component of the appropriate descending volley. Lloyd[1] pointed out that the ding volley has two peaks, which he to a directly conducted volley relayed through a set of

ation begins within 1 msec of the second component of the preceding descending volley. Thus, the simplest hypothesis to explain the augmentation of the excitatory potential with repetitive stimulation would be the adding together, with time, of the descending excitation of ventral horn interneurones, increasing their contribution to the relayed descending volley as more interneurones discharge. This would increase the second excitatory potential, adding to the peak of that produced monosynaptically by the direct volley. There may be in addition a growth of the initial excitatory potential, however, owing to a form of postactivation potentiation.

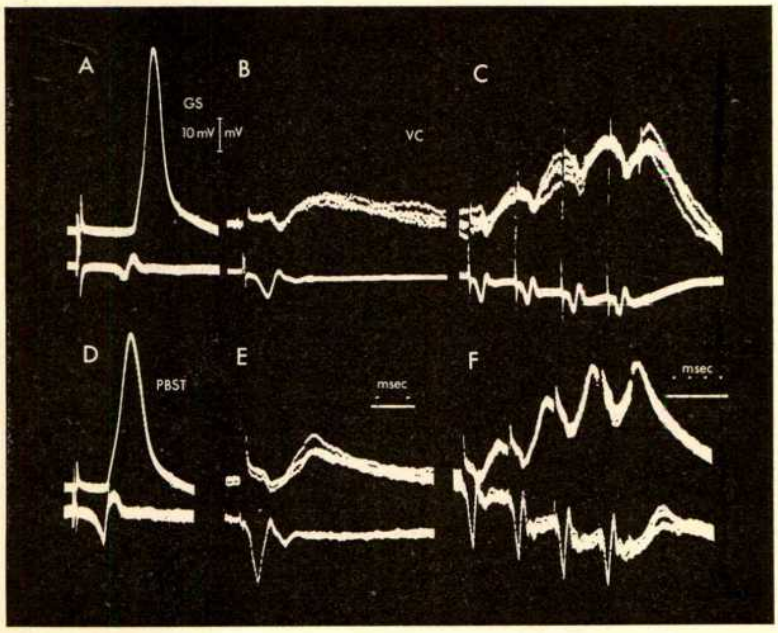

Fig. 2. *A–C* are potentials recorded from a gastrocnemius-soleus motoneurone. *A* is the antidromic action potential. *B* is the monosynaptic EPSP that was produced by stimulation of the ventral half of the spinal cord at the first lumbar level. *C* is also from ventral cord stimulation, but from four volleys at 300/sec. *D–F* are similar records from a posterior biceps-semitendinosus motoneurone. The potential scale is 10 mV for *A* and *D*; it is 1 mV for the other records. The time scale above *E* is for *A*, *B*, *D* and *E*; that above *F* is for *C* and *F*.

Further work is in progress to determine the site of origin of the descending ventral cord pathway. Assuming that it is identical to Lloyd's bulbospinal correlation system, this pathway should be of considerable importance both as a mechanism used by supraspinal control systems and as a part of the system for interlimb reflexes.

This work was supported by a U.S. Public Health Service research grant from the National Institute of Neurological Diseases and Blindness.

Note added in proof. Since this report was submitted for publication, two similar findings have been reported of descending monosynaptic excitatory fibres ending on spinal motoneurones (Lund, S., and Pompeiano, O., *Experientia*, **21**, 602; 1965; and Grillner, S., and Lund, S., *Experientia*, **22**, 390; 1966).

Sensory Discharges from Lactating Mammary Glands

Afferent nervous impulses from mammary glands are known to play a part in the reflex release of oxytocin during suckling[1]. They may also be implicated in the subjective sensation accompanying milk-ejection in women[2], in nervous reflex arcs controlling intramammary muscle tone[3] and milk secretion[4] postulated by Russian workers, and in the control of secretion from the anterior pituitary[5]. This communication describes preliminary findings from electrophysiological investigations of action potential discharges in mammary afferent nerves.

Lactating female rabbits were anaesthetized with urethane. A teat duct was cannulated for recording intramammary pressure changes. The abdominal segmental nerves were exposed, transected dorsally and filaments of the peripheral end were placed on silver–silver chloride recording electrodes under a pool of warmed liquid paraffin. Nerve fibre activity was recorded by means of a push-pull input to a high-gain oscilloscope and also monitored on a loudspeaker. Permanent records were made by photographing the stationary cathode-ray oscilloscope spot on a moving film. Selected nerve filaments were stained in osmic acid and sectioned transversely at 5μ.

The effects of various mammary stimuli were examined. These included: (*a*) pressure applied with a finger or a Von Frey hair; (*b*) the teat grasped with blunt forceps and light pressure applied; (*c*) suckling by a pup from the doe's litter; (*d*) cold, produced by spraying the area with ethyl chloride; (*e*) oxytocin injected intravenously to elicit milk-ejection; (*f*) distension of a mammary lobule by introduction of saline into the cannulated teat duct; (*g*) traction on an interlobular septum. Stimuli *a*, *b*, *e*, *f* and *g* were used after the skin over the gland under observation had been removed except over the teat itself, and the exposed surface sprayed with 2 per cent lignocaine to prevent injury discharges from cut or damaged nerve fibres.

With the skin over the gland intact, receptors have been detected which respond to pressure, including many of the low threshold, slowly adapting, type described by Frankenhauser[6]. Many teat pressure receptors adapting rapidly and a few adapting slowly were demonstrated, and these were activated in a characteristically rhythmic and vigorous manner by suckling (Fig. 1*A*). Most fibres activated by mechanical stimuli were also excited by cold. Injection of oxytocin caused excitation of many receptors coincident with the rise in intramammary pressure, though the pressure rise considerably outlasted the receptor discharge. Similar adaptation of pressure receptor discharge was seen when saline was introduced into the teat duct.

After removal of the skin, the number of units participating in a response recorded from any given nerve filament was greatly reduced. The response of remaining active fibres to finger pressure, distension of a mammary lobule and oxytocin injection (Fig. 1*B*) was retained. The number of responding fibres was reduced by infiltrating lignocaine around the base of the teat. Active fibres still present (Fig. 1*C*) were most sensitive to finger pressure when this was applied in an area at some distance from the nipple, indicating that they were situated within the parenchyma of the gland; such fibres were often excited by traction on the interlobular septum in this area.

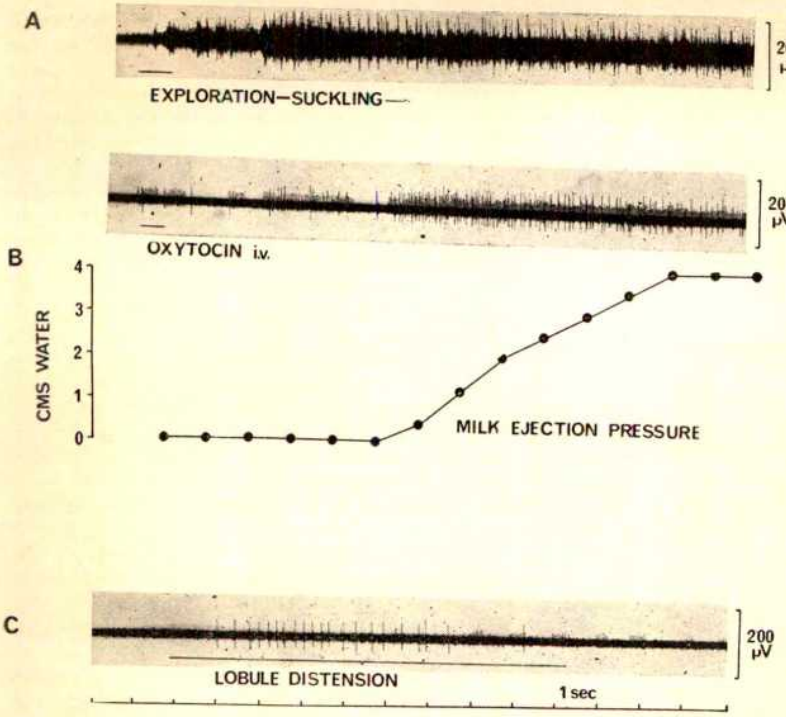

Fig. 1. Action potentials from mammary nerves. The bursts of small spikes in *B* and *C* can be correlated with respiratory rhythm. *A*, Skin intact. Short exploratory period followed by rhythmic suckling. *B*, Skin removed. Effect of intravenous oxytocin (250 mU) on milk-ejection pressure and nerve activity. *C*, Skin removed. Anaesthesia of base of teat. Effect of lobule distension.

Histological examination of the nerve filaments revealed the presence of both myelinated and unmyelinated fibres; it has not yet proved possible to assign modalities of sensation to particular fibre groups.

The data so far obtained confirm histological evidence of the profusion of teat receptors and provide physiological evidence for the existence of receptors within the gland itself. An understanding of their role in normal sensory and reflex phenomena must await a more detailed study of their thresholds and adaptation properties.

I thank Dr. B. A. Cross for much useful advice. The work was supported by grants from the Agricultural Research Council and by the U.S. Public Health Service.

Influence of Sex Hormones on Frequency of Micturition

THE frequency of micturition during pregnancy is regarded as a normal reaction to this physiological state. The mechanism which is responsible for this action, however, remains a matter of conjecture. It was once assumed that, during pregnancy, frequent micturition resulted from the impingement of the enlarging uterus on the urinary bladder. It has since been recognized that this is not the complete answer to the problem[1,2].

Although a neural component has been suggested[3], other factors in addition to neural stimuli should be considered as influencing vesicle activity. It is possible that the vesicle muscle is influenced not only by nerve supply but also by chemical substances carried in the blood, urine, or both. There is no evidence, however, to substantiate the suggestion that sex hormones have a direct influence on bladder motor activity[4]. Furthermore, studies have alluded to the fact that, in the pregnant state, the vesicle muscle is attended by a marked increase of hormones not only in the blood but also in the urine. The effective action site of these agents in influencing bladder motility to stimuli has not been ascertained. In an attempt to obtain information on this, *in vitro* studies were undertaken with rat urinary bladder according to the classical tissue-bath technique.

Thirty-two female Wistar rats were followed through three consecutive oestral cycles by the vaginal smear technique. During the fourth cycle, they were killed in the oestrus and dioestrus stages. These stages were selected because of their relative dominance of oestrogen or progesterone. Additional bladder preparations were used from thirteen full term pregnant rats.

The entire bladder was placed in an organ bath of 250 c.c. capacity containing oxygenated Tyrode's solution which was kept at constant temperature and *p*H. Following normal suspension, the bladder was everted, re-suspended in the bath of Tyrode's solution, and subjected to similar procedures. The following drugs were added directly to the bath: acetylcholine chloride, 5-hydroxytryptamine creatinine sulphate (serotonin), histamine dihydrochloride, pilocarpine hydrochloride, progesterone aqueous suspension, and polyoestradiolphosphate ('Premarin').

From our results, *in vitro* bladder muscle showed no spontaneous activity nor could it be activated by increased tension alone. In all preparations, acetylcholine always increased the tonus and force of contractions. This response occurred after a very brief latent period and was sustained for several minutes. No evidence of tachyphylaxis was obtained. In all cases, the dioestrus bladder responded to acetylcholine with a marked increase in tone, and contractions of greater magnitude and duration than those exhibited in the oestrus stage. Contractions of the pregnant bladder were similar to those of a bladder from an animal in dioestrus. No significant effects were obtained with pilocarpine, histamine, or serotonin.

The reactivity of the bladder was also followed after oestrogen and/or progesterone had been added to the bath. Irrespective of the stage, these hormones did not affect bladder motility. There was a distinct influence, however, on the responsiveness to acetylcholine which was the same whether oestradiol and progesterone were used alone or in combination. We found that pretreatment of the *in vitro* bladder with relatively large doses of oestrogen and/or progesterone (2 μg/ml.) made the muscle sensitive to acetylcholine (Fig. 1). This increased responsiveness to acetylcholine was not seen when the respective bladder was everted. It is interesting to note that administration of these hormones to serosal or mucosal preparations did not affect the bladder responsiveness to other parasympathomimetic agents.

Earlier investigations suggested a hormonal factor in the modification of bladder responses observed during pregnancy[5,6]. In the present investigation, *in vitro* evidence has been obtained suggesting (1) that hormones in the urine have no apparent effect on bladder contractility; (2) that circulating oestrogen and progesterone may exert a permissive effect on bladder contractility to cholinergic stimuli. It is, of course, recognized that the

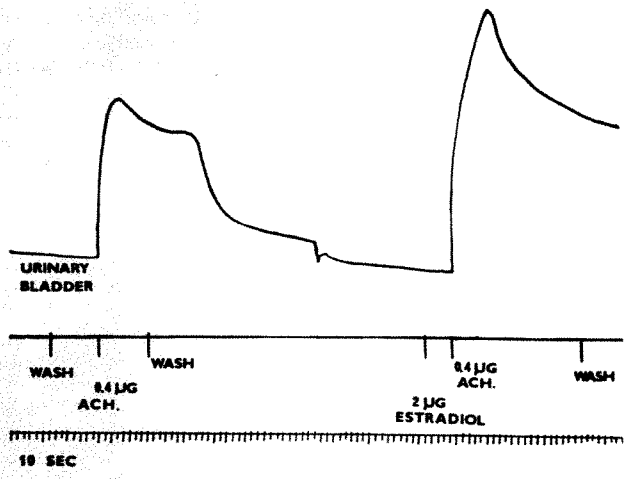

Fig. 1. Record showing the increased response of the excised dioestrus bladder to acetylcholine after treatment with oestradiol.

oestrogen and progesterone substances used may have exerted actions as chemical agents rather than as hormones. This is all the more true in view of the relatively high concentrations used in our *in vitro* studies. Experiments with doses of these substances in a lower concentration range are now in progress.

Anaphylactic Shock and the Secretion of Adrenal 17-Hydroxycorticosteroid in the Dog

IN earlier investigations we evaluated directly the adrenal 17-hydroxycorticosteroid (17-OHCS) secreted in response to histamine by unanaesthetized dogs[1]. Marked increase in 17-OHCS secretion was observed after injection of histamine. It has been suggested by some authors that histamine is released from mammalian cells in anaphylactic shock. Very little experimental information is available, however, on the effect of anaphylactic shock on the adrenal cortical secretion. In the present investigations we attempted to evaluate directly the adrenal 17-OHCS secretion in response to anaphylactic shock in unanaesthetized and anaesthetized dogs.

Mongrel dogs weighing 10–17 kg were used. In unanaesthetized dogs the adrenal venous blood was collected by a modification of the method of Satake, Sugawara and Watanabe[2] just as in our previous studies[1,3–6]. The dorsal spinal roots of T_{11}–L_3 were cut bilaterally under sodium pentobarbital anaesthesia. The experiments were performed more than 3 weeks after the spinal cord sections. The lumboadrenal vein was exposed by way of the lumbar route and its small branches were doubly ligated and cut. A small glass cannula, connected with a short rubber tube, was inserted into the vein on the side of the adrenal gland. The cannula and the rubber tube were filled with heparin–saline solution. A loop of silk thread was placed around the adrenal vein between the posterior vena cava and the adrenal gland. The actual experiments were performed without anaesthetizing the animals about 18 h after the cannulation of the adrenal vein. Adrenal venous blood samples were taken 30 and 10 min before anaphylactic shock was induced. At the time of collecting the adrenal venous blood the silk thread around the adrenal vein between the adrenal gland and the posterior vena cava was gently tightened so as to direct adrenal venous blood flow to the exterior through the cannula and the rubber tube.

In anaesthetized dogs the adrenal venous blood samples were withdrawn by almost the same procedure as in unanaesthetized dogs. No dorsal spinal root sections, however, were performed in this group. On the day before the experiments were performed the adrenal vein cannulation was performed under sodium pentobarbital anaesthesia. Actual experiments were started about 18 h after the cannulation. One hour before the start of observation the animals were anaesthetized with an intravenous injection of sodium pentobarbital (25 mg/kg).

Anaphylactic shock was induced in both groups of animals by the method used by Sato, Ohguri and Wada[7]. About 4 weeks before the experiments were performed 0·5 ml. horse serum/kg body-weight was injected subcutaneously. On the following day the same amount of serum was injected intravenously. On the day of the actual experiments, horse serum diluted 1 : 1 with isotonic saline solution was injected intravenously at a speed of 2ml./min until the femoral artery pulse became feeble.

In advance of the experiments described here, some experiments were undertaken on anaesthetized dogs in which the measurements of blood pressure were made by a mercury manometer connected with the femoral artery; horse serum was injected intravenously until the blood pressure began to fall. In those experiments, before injection of horse serum the blood pressure was 90–94 mm mercury. It fell to 20–34 mm mercury within 2 min after the end of injection. This low blood pressure level continued for a few minutes and then slow recovery occurred. About 40 min after injection the blood pressure resumed the pre-anaphylactic level. In those experiments, however, the 17-OHCS secretion before anaphylactic shock was induced was sometimes so high that it was far outside the range of physiological variations of 17-OHCS secretion rate. Thus in the experiments described here the blood pressure was not registered. In actual experiments horse serum was injected in volumes of 0·18–0·46 ml./kg. The adrenal venous blood samples were also taken at 10, 20, 40 60, 90 and 120 min after the horse serum was injected. The volume of adrenal venous blood collected at each period before and after inducing anaphylactic shock was 2·5–4 ml. Isotonic saline solution was injected intravenously to replace all blood loss. The blood samples were immediately centrifuged and adrenal venous plasma was analysed for 17-OHCS according to the method devised by Nelson and Samuels[8].

Experiments were performed on four unanaesthetized and three anaesthetized dogs. In all cases the femoral artery pulse became definitely feeble after the injection of horse serum. In addition to this hypotension, a variety of symptoms of anaphylactic shock was observed in unanaesthetized dogs. Just before the end of the period during which the horse serum was injected, the dogs became restless. Salivation, dilatation of the pupils and retraction of the nictitating membranes were observed. Respiration became irregular and laboured, and its frequency exhibited a definite increase. Within a few minutes a marked paralysis developed. The animals were unable to stand, and lay on their side. In this condition they did not respond to various painful stimulations, and myasthenia was observed. These symptoms lasted for about 20 min, after which the animals slowly recovered. In four dogs (dogs 4, 5, 6 and 7) defaecation occurred about 10 min after the injection of serum. Table 1 shows the results of the adrenal 17-OHCS secretion rate before and after anaphylactic shock was induced. The 17-OHCS secretion rate markedly increased after anaphylactic

shock was induced in anaesthetized as well as in unanaesthetized dogs. There seemed to be a possibility that in unanaesthetized dogs psychical excitation as a result of anaphylactic shock could be responsible for the increase in adrenal cortical secretion. We were able to show that this was not the case, however, because a marked response of adrenal cortical activity to anaphylactic shock was also observed in anaesthetized dogs.

Antagonistic and Synergistic Actions of Thyrocalcitonin and Parathyroid Hormone on the Levels of Calcium and Phosphate in the Rat

THE discovery of the existence of a hypocalcaemic hormone in the thyroid gland[1] raises the question of the respective roles of thyrocalcitonin and parathyroid hormone on plasma calcium and phosphate homeostasis. As the kidney is a target organ for parathyroid hormone and is involved in plasma phosphate homeostasis, it was thought important to investigate the effects of thyrocalcitonin on calcium and phosphate levels in plasma, and on their excretion in the urine, both in the presence and absence of parathyroid hormone.

Male Wistar *CF* rats, 60 days old and weighing 150 g, were thyroparathyroidectomized. One day later, animals showing signs of incomplete operation (plasma calcium level above 8·0 mg/100 ml.) were discarded. At the "beginning" of the experiment (time 0), forty fasted rats received 1 ml. of isotonic glucose intravenously; the urethra was then ligated. The animals were divided into four equal groups: controls; animals treated with thyrocalcitonin; animals treated with parathyroid hormone; and animals treated with both thyrocalcitonin and parathyroid hormone. The hormones were given as follows: 20 U of purified thyrocalcitonin[2,3] was injected intravenously at time 0, and 100 IU of parathyroid hormone (Lilly) subcutaneously at time "−5 h" (that is, 5 h before the "beginning" of the experiment). At +1 h, blood was collected, the rats were killed and the contents of the bladder quantitatively collected. Calcium was estimated by flame photometry and phosphate by the technique of Fiske and Subbarow[4]. Creatinine was measured colorimetrically[5].

The results presented in Fig. 1 are expressed as differences between the rats treated with hormone and the control rats. The expected changes in plasma calcium levels that are produced by parathyroid hormone and thyrocalcitonin are abolished by the combined administration of the hormones; 20 U of thyrocalcitonin can counteract the effect of 100 IU of parathyroid hormone. This antagonism is consistent with a dual hormonal control to ensure blood calcium homeostasis. Both thyrocalcitonin and parathyroid hormone lower plasma phosphate, and their action is additive when administered simultaneously. This finding raises the question of plasma phosphate homeostasis since the interplay of thyrocalcitonin and parathyroid hormone cannot possibly explain the maintenance of a constant phosphate plasma level, as they are synergistic in lowering phosphate.

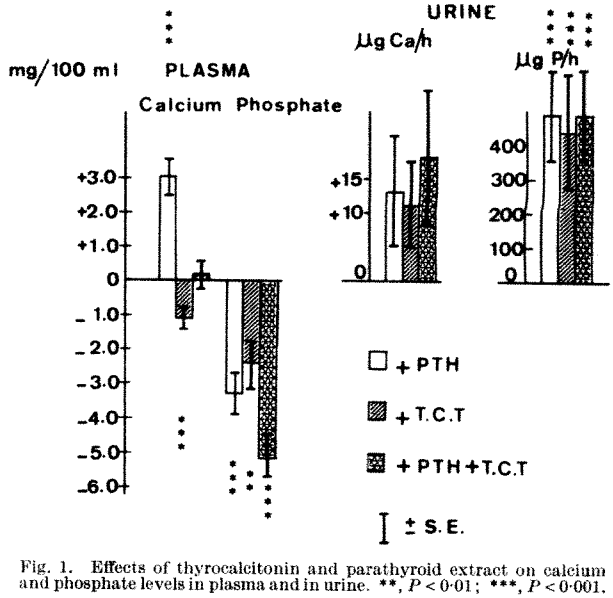

Fig. 1. Effects of thyrocalcitonin and parathyroid extract on calcium and phosphate levels in plasma and in urine. **, $P < 0.01$; ***, $P < 0.001$.

As to the urine composition (Fig. 1), parathyroid hormone elicits the expected phosphaturic response. Thyrocalcitonin has the same phosphaturic effect[6]. The combined administration of both hormones does not increase the phosphate excreted, which would indicate that the maximal response was obtained for each hormone at the dose used. That the phosphaturic effect is present with unchanged glomerular filtration rate is obvious because creatinine excretion rates do not vary significantly in any groups: control = 231·4 ± 46·4 μg/h; parathyroid hormone-treated animals, 261·0 ± 22·55 μg/h; thyrocalcitonin-treated animals, 252·0 ± 26·15 μg/h; and animals treated with both hormones, 262·0 ± 37·76 μg/h. This is consistent with a diminished tubular reabsorption for phosphate, even though the experimental condition used cannot distinguish between a competitive and a non-competitive mechanism for phosphate excretion or reabsorption.

Phosphate clearance should not be used to demonstrate hypersecretion of parathyroid hormone without adequate controls because thyrocalcitonin has the same effect, which cannot be mediated in our experiments by a secondary response of parathyroid hormone in thyroparathyroidectomized animals. In the normal rat, a phosphaturic effect was observed after injection of a crude thyroid extract[7]. Urinary calcium is increased in the three treated groups, but this increase is not statistically significant. For this reason, renal excretion of calcium is not likely to contribute to the effect of lowering the calcium in plasma brought about by thyrocalcitonin.

In summary, thyrocalcitonin and parathyroid extract are effective in the control of the calcium level of plasma and act antagonistically. The two hormones lower plasma phosphate synergistically; thus it is not possible to account for the mechanism responsible for raising the phosphate level in plasma. Thyrocalcitonin possesses an important phosphaturic effect.

We thank J. F. Staub for his technical assistance.

Aorticopulmonary Glomus Tissue in the Cat

HUGHES has recently reported a portal blood supply to aorticopulmonary glomus tissue in the cat[1]. The pulmonary arterial vasa vasorum, arising from the coronary arteries, form an intramural capillary network in which it is suggested the blood may come into gaseous equilibrium with that in the lumen of the pulmonary artery itself. This network is said to drain into venae vasorum which supply the aortic bodies.

Although a schematic representation of the hypothetical portal system is depicted, there is nothing in the histological figures or elsewhere to suggest that this is more than a speculation. In fact, we have recently re-examined the blood supply of the aorticopulmonary bodies, and careful scrutiny of serial sections of cat pulmonary artery with its associated glomus tissue has failed to reveal any such portal vessels. Hughes also states that the large arteries—said by previous workers to supply the aortic bodies—are not in fact end arteries but pass straight through the glomus tissue, the glomus being supplied instead by the portal system he has described. In our experience this is not the case. In several of our experiments we found an aortic body which had a single (relatively large) artery which was traced in continuity from a systemic source. On histological examination, the vessel could be traced through many sections as it divided into the small vessels of the body.

In a series of new-born kittens the systemic and pulmonary arteries of which were injected with masses of contrasting colour, some aortic bodies were supplied by a single branch of the pulmonary artery. The vasculature of these bodies contained the pulmonary injection mass but none of the systemic injection material that would have been present if the portal system described by Hughes had existed. As post-natal development proceeds, anastomoses develop between this pulmonary vessel and certain systemic arteries; finally, the pulmonary connexion is obliterated, leaving the glomus supplied solely by the systemic vessels. All these arterial connexions could be traced in continuity under the dissecting microscope or through serial histological sections. At no stage in development was there any sign of the intramural vasculature described by Hughes. Our investigation into the post-natal changes in the blood supply of aorticopulmonary bodies confirms and extends the findings of several earlier workers (for review, see Comroe[2]).

Physiological evidence for the existence of pulmonary arterial chemoreceptors was obtained by Duke *et al.*[3]. With the help of his portal system, Hughes avers, it is possible to reconcile the findings of Duke *et al.* with the absence of a direct blood supply from the pulmonary artery to glomus tissue in the adult animal. On the contrary, this could not possibly explain the results of Duke *et al.* In one set of experiments these investigators recorded action potentials while perfusing the isolated pulmonary artery alone. Because there was no circulation of blood in the systemic vessels, there can have been no flow through the coronary arteries nor through the vasa vasorum of the pulmonary artery. It is true that Duke *et al.* did perfuse the systemic circulation in a second series of experiments in which reflex effects were examined, but, as the blood was usually pumped into the rostral end of the brachiocephalic artery, there can again have been no flow through the coronary arteries, nor through the hypothetical portal system.

A number of other points in Hughes's article merit some comment.

(1) Contrary to Hughes's interpretation, the existence of a pulmonary arterial blood supply to a particular group of aortic body tissue in the foetus, while interesting, is not evidence of its function as a chemoreceptor.

(2) No evidence is advanced to substantiate the report of chemoreceptors in the retroperitoneal tissues.

(3) The analogy drawn between aortic bodies (vascular chemoreceptors) and adrenal medullary (endocrine) tissue is erroneous. The term "glomus", which is generally well understood in the context of chemoreceptor tissues, should not be used for the endocrine system and such usage only serves to reintroduce confusion into a nomenclature which had been reasonably clarified[4,5].

Reflex Regulation of Gill Water Flow (Ventilation) in *Squalus acanthias*

THE factors regulating the volume flow of water through fish gills are obscure. This communication describes a mechanism which serves this function in the elasmobranch.

These studies were performed in the dogfish shark, *Squalus acanthias*. Three animals were studied. The animals were removed from water and plastic cannulae were inserted into their spiracles. These cannulae were connected to a sea water reservoir so that the rate of gill flow could be varied by appropriate manipulation of a valve controlling the flow from the reservoir. Effluent water from the gills was collected by means of a funnel and the volume measured directly in a graduated cylinder. Opercular rate was determined by direct observation.

The data are summarized in Fig. 1. The opercular rate (15–44/min) varied more or less directly with the rate of flow of water through the gills (0·09–2·00 l./min) over a wide range. This mechanism operates so that when a given volume (or pressure) is attained inside the respiratory chamber of the fish it results in a respiratory

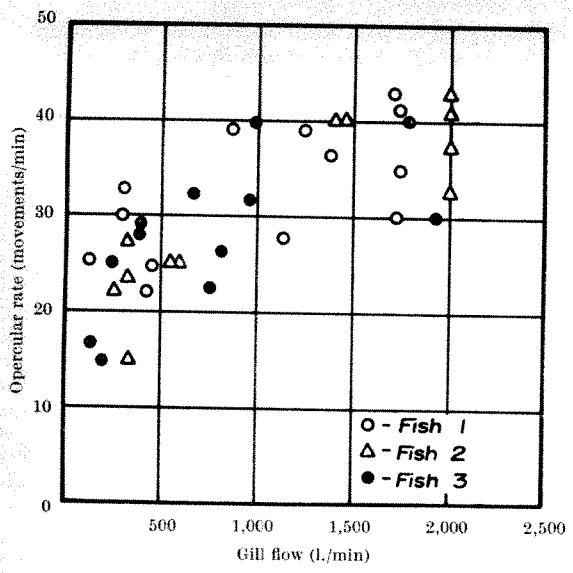

Fig. 1.

effort as shown by opercular movement. This suggests that the major adjustment of gill ventilation occurs by modification of the respiratory rate rather than by the volume of water flowing through. The nature of the stimulus for this reflex (pressure as compared with volume), the receptors and central connexions are not known. Its function, however, appears to be analogous to that of the Hering-Breuer reflex in mammals.

BIOCHEMISTRY

Chondromucoprotein-degrading Enzymes

THE chondroitin sulphate-protein complex of cartilage, chondromucoprotein[1], is normally unable to diffuse out of the tissue, but can be released in a soluble form by severe mechanical disruption of the tissue[1] or *in vivo* by chemical degradation, for example, by papain[2]. Other enzymes capable of degrading chondromucoprotein so that it may be lost from the intercellular matrix are present in lysosomes[3], and these enzymes may play an important part in the pathological deterioration of cartilage. It seems probable that the lysosomal enzyme activity involved is of the acid protease type[3,4], but hyaluronidase[5,6] or xylosidase[7] may also be implicated.

In the past the most widely used method for detecting and estimating the degradation of chondromucoprotein by enzymes has been viscometry[8], but this is unsatisfactory for crude protein mixtures owing to precipitation of chondromucoprotein by oppositely charged protein molecules at acid *p*H[9], and also because of spontaneous alterations in the viscosity of chondromucoprotein solutions[1]. Viscometry is also ill-suited to problems such as the localization of small quantities of enzyme after disk electrophoresis. A new method is described here.

A polyacrylamide gel containing 7 per cent (weight/volume) of polymer[10] was modified by the inclusion, before polymerization, of chondromucoprotein (0·05 per cent of light protein-polysaccharide—prepared from bovine nasal septum[11]). Gel columns 5 mm in diameter were cast in glass tubes and sliced transversely with a razor blade to form disks about 1·5 mm thick. The disks were stored under sodium acetate buffer (*p*H 4·0, 0·1 M containing 1 per cent *n*-butanol) at 4° C until required.

A preparation of particle-bound enzymes was made as follows: livers from freshly killed rabbits were passed through a cold mincer and mixed with iced 0·25 M sucrose solution. The tissue was then homogenized and a pellet of mitochondria and lysosomes was prepared by differential centrifugation[3]. The pellet was treated with a large volume of acetone at 4° C and the solid material was then filtered off and dried under reduced pressure. The acetone powder was stored at 4° C.

A crude enzyme preparation was obtained by extraction of the powder (10 mg/ml.) with acetate buffer (*p*H 4·0).

Groups of disks were shaken for 16 h at 37° C with acetate buffer (0·25 ml.; *p*H 4·0, 0·2 M) and enzyme preparation (0·25 ml.). Control groups were incubated with buffer in place of enzyme. The gels were then placed in the destaining tubes of a disk electrophoresis apparatus, and electrophoresis was carried out at 8 m.amp per tube (30 min) with acetic acid (7 per cent volume/volume) as electrolyte. The disks were then stained in alcian blue (1 per cent in 7 per cent volume/volume acetic acid) for 15 min, rinsed with water, and returned to the destaining tubes of the disk electrophoresis apparatus. Unbound dye was removed electrophoretically with acetic acid electrolyte.

Undegraded chondromucoprotein was completely immobile when trapped in the polyacrylamide gel, and intense staining was obtained in the absence of degrading enzymes (Fig. 1*a*). On the other hand, gels that had been incubated in the presence of the enzyme preparation showed only the faintest staining (Fig. 1*b*); this is attributed to the fact that free chondroitin sulphate is mobile in this gel.

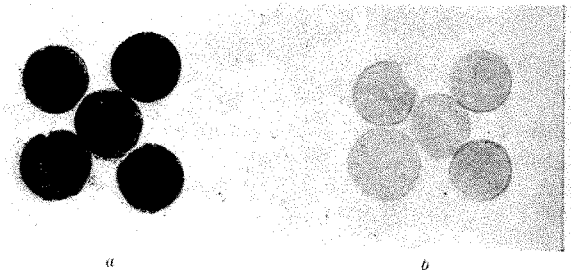

Fig. 1. Disks of polyacrylamide gel, containing chondromucoprotein, stained with alcian blue after incubation at *p*H 4·0 with (*a*) buffer alone, or (*b*) a buffered extract of particle-bound enzymes (see text).

The stained disks could be stored, at least for several months, without deterioration. The method has been used qualitatively to locate enzymes capable of degrading chondromucoprotein in effluent fractions from chromatographic columns, but experiments are in progress to modify the method for quantitation by spectrophotometry.

An adaptation of this method has made it possible to locate enzymes which are responsible for the degradation of chondromucoprotein after disk electrophoresis[10], in a manner analogous to that which has been applied to deoxyribonucleases[12]. Disk electrophoresis gels were prepared in the usual way[10], but with the inclusion of chondromucoprotein (0·05 per cent) in the small-pore gel. The enzyme sample (E 1 cm/280 mμ = 20) was obtained by concentration of the crude preparation described earlier, by means of ultrafiltration, followed by dialysis against a *tris* chloride buffer (*p*H 8·6, 0·01 M). A portion (0·04 ml.) of this preparation was applied to each gel.

After electrophoresis the gels were removed from the tubes and each was halved by a longitudinal cut (with an apparatus based on that of Fairbanks *et al.*[13]). Half of each gel was stained with naphthalene black to show the distribution of protein (Fig. 2*a*), while the other was placed in an ice-cold acetate buffer (*p*H 4·0, 0·1 M) for 30 min, and then in a fresh portion of the same buffer for 30 min at 45° C. After incubation the gels were equilibrated with ice-cold stock *tris*-glycine buffer[10] diluted 1 : 20 and then returned to the destaining tubes for electrophoresis at 8 m.amp per tube (30 min) with the buffer system of Boyd *et al.*[12]. They were then stained with alcian blue, and destained electrophoretically. Enzyme activity was visible as a rather broad, clear zone in the otherwise blue gel (Fig. 2*b*). The mobility of this zone was approximately equal to that of the transferrin band in a standard run simultaneously.

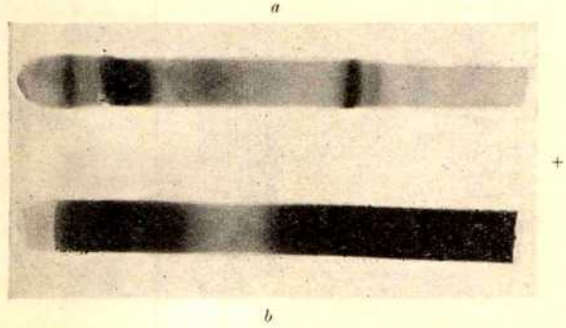

Fig. 2. Half gels showing the result of disk electrophoresis of a preparation of mitochondrial-lysosomal proteins. *a*, Stained with naphthalene black; *b*, stained with alcian blue, as described in the text, to demonstrate chondromucoprotein degrading activity.

Apart from its application to the study of enzymes responsible for the breakdown of chondromucoprotein, the method described here is of interest as a possible model for the way in which chondromucoprotein is held in cartilage. The large molecules of the complex may simply be trapped in a three dimensional network of collagen fibrils so that they cannot be released intact except by destruction of the network.

Previously work[3,4], indicating that chondromucoprotein-degrading activity is present in lysosomes, is supported by the results described here, and it is hoped that, by use of the new methods described, it will be possible to gain further knowledge of the enzymes involved.

I thank Dr. J. T. Dingle and Dame Honor Fell for advice and encouragement. This work was carried out during the tenure of a Medical Research Council junior research fellowship.

Collagen Levels in Tendon of Wounded and Unwounded Animals

IT was reported by Peacock[1] that the skin of rats bearing a 6 cm skin incision shows a small increase of collagen soluble in salt at sites distant from the lesion. Houck *et al.*[2] found, apparently in contrast, that skin distant from an area of necrosis mediated by croton oil lost salt-soluble collagen. Nevertheless, here the fall in dermal collagen was accompanied by a loss of collagen from the lesion itself, while in the former experiment both wound and distal skin collagen increased during the period of observation. Smith and Wogensen[3] could find no significant decrease of total collagen in the skin of rats distant from a croton oil injury. Adamsons *et al.*[4] found a sustained rise in skin collagen in rats distant from a large paramedian incision. Recently, Houck[5] has postulated that a previously observed rise in acid-soluble collagen in skin distant to a croton oil injury results from labilization of insoluble collagen by a collagenase, which itself shows a fall in concentration[6].

In connexion with a programme of research concerning the dynamics of chemical composition of various tissues in animals carrying lesions of connective tissue, we have measured the quantity of hydroxyproline in tail tendon of rats with a dorsal skin wound. The results are now reported.

Three experiments were performed. In each case, actively growing rats weighing 130–140 g were arranged in groups of four. The groups of four were matched in pairs having as nearly as possible the same average weight, one group of four in each pair being set aside for testing with the lesion, and the other as a control. A separate group of four rats was killed on the same day as the infliction of the wound on the test animals. (This was a 6 cm incision through the dorsal skin and panniculus along the line of the vertebral column. As an extra irritant, a polythene tube 3 cm long (external diameter 6 mm, internal diameter 4 mm) was buried in the cavity, which was then closed with five or six Michel clips.) One group of wounded animals and one group of controls were killed on selected days. In the second experiment only female rats were used, but in the first and third experiments, because of supply difficulties, each group of four rats was composed of two males and two females in the 130–140 g range. Growth rates were significantly lower in the wounded rats up to the fourth day after wounding. Thereafter no difference was apparent between test animals and the controls. After the animals had been killed, 0·2–0·3 g tendon was removed from the tails. Hydroxyproline was assayed by the Leach modification[7] of the Neumann–Logan method.

Table 1. HYDROXYPROLINE CONTENTS OF TAIL TENDON FROM WOUNDED AND CONTROL RATS*

Days after wounding	Experiment	Control animals	Wounded animals
0	1	28·41 ± 3·55	—
0	2	36·18 ± 2·79	—
0	3	99·5 ± 4·5	—
4	1	33·2 ± 1·6	35·2 ± 2·22
4	2	116·0 ± 4·3	122·2 ± 4·4
5	1	25·35 ± 3·6	31·3 ± 1·85†
7	1	37·7 ± 1·72	44·2 ± 1·94†
7	2	104·4 ± 3·1	120·0 ± 2·9†
10	1	28·1 ± 0·65	33·25 ± 1·75†
10	2	41·0 ± 1·63	39·0 ± 2·85
10	3	95·4 ± 3·9	108·3 ± 3·5†
15	1	31·5 ± 1·63	38·1 ± 3·07
15	2	43·5 ± 1·89	38·5 ± 2·02
15	3	106·1 ± 3·3	113·8 ± 1·2

* Results from three experiments, expressed as mean value ± standard error of the mean. For experiments 1 and 2, values are mg per g fresh tissue, and for experiment 3 mg per g dry weight.
† Significantly different from control ($P < 0·05$).

The results are presented in Table 1. There is a transitory but significant rise in tendon collagen in the wounded animals, apparent between the fifth and tenth days after wounding. The results for tendon therefore parallel those of Peacock[1] and Adamsons *et al.*[4] for skin.

The implications of a rise in collagen in connective tissues distinct from those bearing the actual lesion are of great interest. It appears that in the early stages of response to injury, the body proteins may be classified into three groups: (*a*) those which do not maintain their normal tissue concentration and are depleted; (*b*) those which maintain their normal concentration; and (*c*) those which exhibit an elevated concentration. In category (*a*) will fall muscle proteins[8], in (*b*) proteins from liver[8], and in (*c*) we can at the present moment place only collagen. The humoral or other factors controlling this multiple response must be quite complex.

I thank Mr. J. C. Lai for his technical assistance, and Dr. Y. E. Hsia for helpful discussions.

Effect of Dipicolinate on the Heat Denaturation of Proteins

DIPICOLINIC acid (DPA, pyridine-2,6-dicarboxylic acid) is synthesized during sporogenesis in spore-forming bacteria and excreted during germination as the calcium salt. Heat resistance of spores has long been thought to be associated with the presence of DPA. Church and Halvorson[1] reported a quantitative relationship between heat resistance and DPA content in spores. Black *et al.*[2] found that at a concentration of DPA greater than 50 μg/mg dry spores the heat susceptibility appears to remain constant and minimal.

This communication describes the results of experiments on the heat treatment of proteins in the presence of the sodium or calcium salts of DPA. Human serum albumin solution becomes turbid when heated at 60°–95° C. However, the occurrence of turbidity in 0·05 per cent solution is completely prevented by 10^{-3} M of sodium DPA. A similar effect of relatively small amounts of sodium DPA can also be seen in solutions of bovine serum albumin, ovalbumin and human serum γ-globulin. The following procedure was used for the precipitation test at the isoelectric point. Two ml. of 3×10^{-1} M sodium DPA was mixed with the same volume of 1 per cent bovine serum albumin. The mixture was heated at 65° C. Then 4 ml. of 0·2 M acetate buffer, *p*H 4·8, stored at the same temperature, was added and the solution was cooled for 5 min in water. After centrifugation (3,000 r.p.m., 15 min), the supernatant was filtered. Two ml. of the filtrate was mixed with 8 ml. of the biuret reagent. The mixture was maintained at 37° C for 30 min, and the optical density was measured at 530 mμ. The results are shown in Fig. 1.

Further experiments were carried out with the sulphydryl group of proteins. One ml. of 3×10^{-1} M sodium DPA was mixed with 1 ml. of 1 per cent bovine serum albumin, and then 0·5 ml. of 0·5 M phosphate buffer (*p*H 6·8) and 0·5 ml. of 0·01 M potassium ferricyanide were added. After heating at 90° C, the solution was cooled for 5 min in water, and mixed again with 5 ml. of the phosphate buffer. The optical density of the filtrate was measured at 420 mμ. The results are shown in Fig. 2.

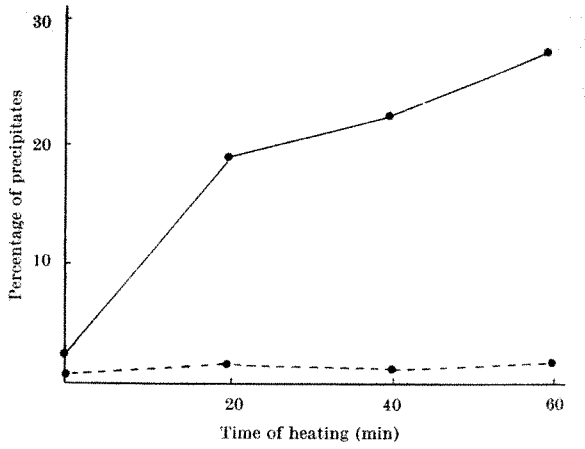

Fig. 1. Precipitation test. The ordinate indicates the percentage of the total amount of protein precipitated. Broken line, material with DPA; full line, control without DPA.

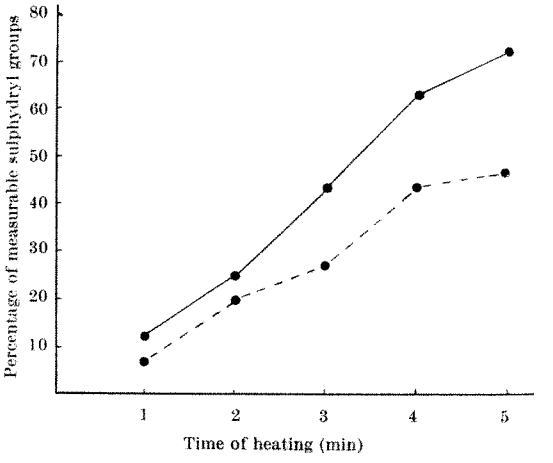

Fig. 2. Appearance of sulphydryl groups. The ordinate indicates the percentage of the total amount of sulphydryl revealed. Broken line, material with DPA; full line, control without DPA.

As shown in Figs. 1 and 2, both the precipitation of protein and the numbers of sulphydryl groups measured are decreased by the addition of sodium DPA. Similar results are obtained when calcium DPA is used. These experiments indicate that DPA has a preventive action on the heat denaturation of proteins. This effect seems likely to be connected with the heat resistance of spores.

Inhibition of Protein Synthesis by *Cyclo*heximide (Actidione) in *Chlorella*

*Cyclo*heximide is an antibiotic produced by *Streptomyces griseus*. It inhibits the growth of fungi[1,2], algae[3], protozoa[4] and higher plants[5], but has no effect on bacterial growth[1]. In yeast cells[6,7] and mammalian cells[8] *cyclo*heximide inhibits both protein and DNA synthesis simultaneously, whereas the inhibition of RNA synthesis is delayed. With intact cells, it was not possible to resolve the controversy over whether the primary effect of *cyclo*heximide was on the synthesis of deoxyribonucleic acid or on the synthesis of protein. Investigations with extracts free of cells[9,10],

however, showed that the primary effect of *cyclo*heximide was to inhibit synthesis of protein, and that it did this by preventing the transfer of the amino-acids from the *s*RNA–amino-acid complex to the polypeptide chain.

Although growth of algae is also sensitive to *cyclo*heximide, so far as I am aware there have been no investigations of the mechanism of its action in these organisms. Features of *cyclo*heximide inhibition in the green alga *Chlorella pyrenoidosa* have therefore been examined and the results show that the primary effect is an inhibition of protein synthesis and that inhibition of both DNA and RNA synthesis is delayed.

Chlorella pyrenoidosa, strain 211/8 *p* (the name of this organism has recently been changed from *C. vulgaris*[11]), was grown under conditions described previously[12] with ammonium sulphate as the source of nitrogen. After 4 days growth (by which time the cultures had reached the stationary phase of growth) the cells were collected by centrifugation, washed once, resuspended in medium free of nitrogen and the cell density adjusted to 5 mg dry wt. per ml.

The experiments were carried out in darkness at 25° C with ammonium sulphate (0·003 M) as the source of nitrogen and glucose (1 per cent) as the source of carbon. Protein synthesis was measured by following the incorporation of ^{14}C-phenylalanine into the protein fraction, and nucleic acid synthesis was measured by following incorporation of ^{14}C-adenine into the DNA and RNA fractions.

Fractionation of the cells in experiments which involved phenylalanine was achieved by suspending the cells successively in 75 per cent ethanol, absolute ethanol (100° C for 2 min), trichloroacetic acid, ether, and then hydrolysing with N sulphuric acid at 100° C for 3 h. After centrifugation, the residue (that is, the protein fraction) was resuspended in 50 per cent ethanol, 0·1 ml. was plated on to a ground glass disk and the radioactivity counted. Fractionation of the cells in those experiments utilizing radioactive adenine was carried out by the method of Smillie and Krotkov[13]. Preliminary experiments confirmed the validity of this method. Thus when ^{14}C-phenylalanine was supplied and the cells fractionated by the method of Smillie and Krotkov, less than 3 per cent of the radioactivity incorporated could be detected in the nucleic acids, which indicated that there was little contamination between the protein and nucleic acid fractions. Also, when ^{14}C-uracil was incorporated, no radioactivity could be detected in the DNA fraction.

Growth of *Chlorella* is inhibited by *cyclo*heximide at a concentration of 0·25 μg/ml. Protein synthesis in resting cell suspensions (as measured by the incorporation of ^{14}C-phenylalanine) is inhibited by about 70–80 per cent at a concentration of 2·5 μg per ml. (Fig. 1). Increasing the concentration of antibiotic up to 20 μg/ml. has no significant effect on the degree of inhibition. The inhibition of protein synthesis seems to be a primary effect because it can be detected within 15 min of adding the inhibitor, and there is no significant increase in the degree of inhibition with time.

Comparable inhibition of protein synthesis has been observed when $^{14}CO_2$ (under photosynthetic conditions) or ^{14}C-(U)-glucose is assimilated. These experiments also show that *cyclo*heximide has no inhibitory effect on the synthesis of polysaccharide or on the respiration of glucose.

Nucleic acid synthesis as measured by the incorporation of ^{14}C-adenine is also inhibited by *cyclo*heximide (there is no inhibition of incorporation into the cold-acid-soluble fraction). The inhibition is not immediate, however, and inhibition of RNA synthesis is more delayed than is that of DNA (Fig. 2). Thus if incorporation is measured after 30 min, *cyclo*heximide at a concentration of 3 μg/ml. does not inhibit RNA synthesis, whereas DNA synthesis is inhibited by about 30 per cent. The corresponding figures after 90 min are 20 and 50 per cent, and after 2 h RNA synthesis is inhibited by about 35 per cent and DNA synthesis by about 70 per cent. Inhibition of nucleic acid synthesis is also delayed when incorporation of ^{14}C-glycine is measured. In such experiments, however, the delay is shorter than when adenine incorporation is measured. This shorter delay presumably arises because purine biosynthesis is also sensitive to *cyclo*heximide. Although no direct evidence for this has yet been obtained with *Chlorella*, the idea of indirect inhibition of purine biosynthesis by *cyclo*heximide agrees with the results which Widuczynski and Stoppani[14] obtained with yeast cells.

Thus, the inhibitory effect of *cyclo*heximide in *Chlorella* appears to resemble that in yeast and mammalian cells. That is, the primary effect is an inhibition of protein

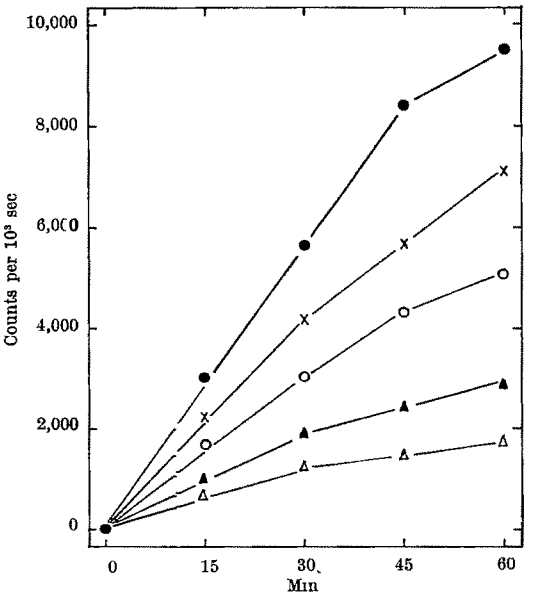

Fig 1. The effect of *cyclo*heximide on the incorporation of ^{14}C-phenylalanine into the protein fraction of *Chlorella* The cultures were shaken in the dark in the absence of *cyclo*heximide (●) or in the presence of the antibiotic at final concentrations of 0·5 (×), 1 0 (○), 1 5 (▲) and 2 5 (△) μg/ml ^{14}C-Phenylalanine (a final concentration of 4 0 mM and a specific activity of 0 3 μc./mmoles) was added at zero time and 3 ml. samples withdrawn at suitable time intervals.

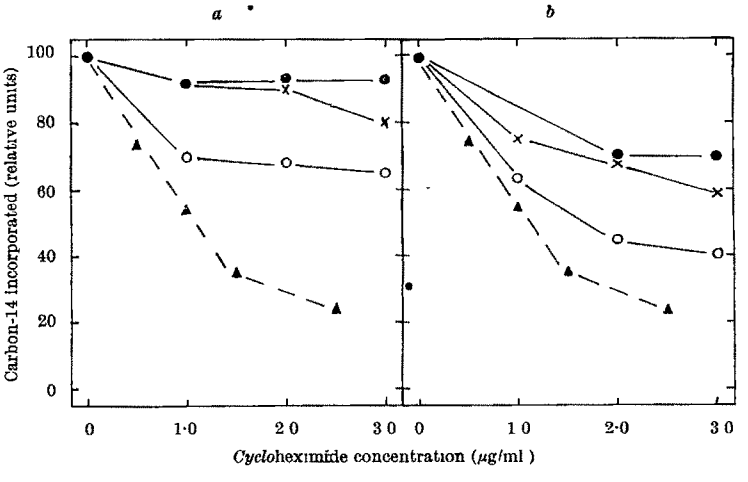

Fig. 2. The effect of *cyclo*heximide on the incorporation of ^{14}C-adenine into (*a*) the RNA and (*b*) the DNA fractions The cultures were shaken in the dark in the presence of various concentrations of *cyclo*heximide, ^{14}C-adenine (a final concentration of 10^{-7} M and a specific activity of 30 mc. mmole) added at zero time and 3 ml. samples were withdrawn after 30 (●), 90 (×) and 120 (○) min. – – ▲ – – , ^{14}C-Phenylalanine incorporation into protein after 30 min (for details see legend to Fig. 1).

synthesis, whereas inhibition of nucleic acid synthesis is indirect.

Role of Glucose 6-phosphate in the Synthesis of Glycogen by the Rat Liver *in vivo*

SINCE Leloir and Cardini[1] showed that glycogen was synthesized from uridine diphosphate–glucose (UDPG) by liver extracts, it has become commonly accepted[2,3] that the normal mechanism of glycogen synthesis in liver and muscle does not involve a reversal of the phosphorylase reaction but the following sequence of reactions:

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{hexokinase}} \text{Glucose 6-PO}_4 + \text{ADP}$$

$$\text{Glucose 6-PO}_4 \xrightarrow{\text{phosphoglucomutase}} \text{Glucose 1-PO}_4$$

$$\text{UTP} + \text{Glucose 1-PO}_4 \xrightarrow{\text{UDPG pyrophosphorylase}} \text{UDPG} + \text{pyrophosphate}$$

$$\text{UDPG} + \text{primer} \xrightarrow[\text{synthetase}]{\text{glycogen}} \text{Glycogen} + \text{UDP}$$

Figueroa *et al.*[4] (and others referred to in ref. 4) working with rat liver preparations have suggested that the hexokinase reaction is not an obligatory step in the synthesis of glycogen from glucose. Petrova[5] working with liver slices and Beloff-Chain *et al.*[6] studying the uptake of glucose by the rat diaphragm have reached similar conclusions. Experiments *in vivo* reported here lend support to these latter suggestions.

^{14}C-glucose was injected intravenously into rats and the livers rapidly removed into liquid nitrogen 10 min later. Fractionation of a perchloric acid extract of the liver on 'Dow 1'—formate resin[7] followed by paper chromatography enabled the specific activities of liver glucose, glucose 6-phosphate, UDPG glycerophosphate and lactic acid to be determined (Table 1).

Table 1. RATIO OF SPECIFIC ACTIVITY PER CARBON ATOM IN LIVER METABOLITES TO THAT IN LIVER GLUCOSE

	UDPG	Glucose 6-PO$_4$	Glycerophosphate	Lactic acid
Normal fed rats (5)†	0·646 ± 0·032*	0·291 ± 0·017	0·224 ± 0·012	0·244 ± 0·032
Fasted	0·597	0·392	—	—
Anaesthetized	0·770	0·371	—	—

* Results are means ± *S.E.*
† Number of rats in parenthesis.

If glucose 6-phosphate occupies the position in the sequence glucose→glycogen indicated above, then its specific activity should at least be equal to that of UDPG at this time. A conclusion in support of the claim made by the workers already mentioned that glucose 5-phosphate is not a direct intermediate in the synthetic route glucose to glycogen could be drawn from these data.

Other possibilities for consideration are:

(1) Glucose 6-phosphate compartmentation, that is, the glucose 6-phosphate initiating glycolysis, is separated from that involved in glycogen synthesis. This is pertinent because it has recently been shown[8] that two distinct enzymes are involved in the initial phosphorylation of glucose. The specific activities of α-glycerophosphate and lactic acid are only slightly lower than that of glucose 6-phosphate and it can be calculated from the data that 14 per cent of the glucose 6-phosphate pool should have a specific activity equal to that of UDPG and the remainder equal to that of the glycolytic intermediates, α-glycerophosphate and lactic acid. If phosphorylation of unlabelled glycerol from triglyceride degradation by liver glycerokinase were to occur, then the specific activity of α-glycerophosphate would be lowered relative to glucose 6-phosphate and the size of the glucose 6-phosphate pool involved in UDPG synthesis calculated here would be even lower.

(2) Breakdown of liver glycogen, when the animals are being killed, by phosphorylase to provide an unlabelled source of glucose 6-phosphate from glucose 1-phosphate by phosphoglucomutase. This possibility has been investigated in a rat fasted for 24 h the glycogen reserves of which are much lower than those in fed rats and by taking a liver sample from a rat in which the injection of ^{14}C-glucose and subsequent operations were performed under ether anaesthesia. The ratios of the specific activities of glucose 6-phosphate to UDPG were not grossly different in these rats from those in the fed unanaesthetized rats. Neither of these experiments suggested that glycogen provides unlabelled glucose 1-phosphate.

These results obtained from *in vivo* experiments lend some support to the suggestions based on evidence obtained *in vitro* that glucose 6-phosphate is not an obligatory intermediate in the direct pathway from glucose to UDPG in rat liver, and also that glucose 1-phosphate derived by the action of phosphoglucomutase on this glucose 6-phosphate is similarly not a precursor of UDPG. Because glucose 1-phosphate is the only known precursor of UDPG, at least two pools of glucose 1-phosphate should exist, the average specific activity of which is unpredictable because the contributions from the different sources are unknown.

The lability of glucose 1-phosphate prevented its isolation by the present technique; however, the relationship of the specific activity of glucose-1-phosphate to that of glucose 6-phosphate and UDPG requires investigation in order to resolve the problem of the initial reactions of glucose which occur before metabolic conversion to glycogen and carbon dioxide.

Use of Sudan Black as an Indicator of Vitamin D on Thin-layer Chromatograms

THE chief problems in the accurate analysis of vitamin D in natural products by physico-chemical methods are: (*a*) the elimination of large quantities of interfering sterols, vitamin A and other carotenoids; (*b*) the need to

measure minute amounts of vitamin D by a reproducible and specific technique.

The structural differences between vitamin D and other related sterols, such as cholesterol, 7-dehydrocholesterol or ergosterol consist only in the presence of one or two methyl groups in the side chain and an extra double-bond in the open ring B of the penteno-phenanthrene moiety. The resolution of these sterol mixtures by column adsorption chromatography is thus not easily effected[1]. Paper chromatography has been investigated extensively as a means of separating sterols and carotenoids present in animal tissues from minute quantities of vitamin D. Because conventional partition technique is generally unsuitable for these strongly lipophilic substances, a reverse-phase system using paraffin impregnated paper and an aqueous organic solvent is preferred[2]. The use of acetylated paper with benzene–methanol mixtures has not been fully explored[3]. Mayer *et al.*[4] have shown that the instability of vitamin D is accentuated on exposure to high alcoholic dilutions or in spots on paper impregnated with paraffin.

Our own recent attempts at the gas-chromatographic separation of vitamin D and cholesterol have not been successful. However, thin-layer chromatography (TLC) using 'Silicagel G' (Merck) and chloroform as solvent was found suitable. Vitamin D was found to be unstable if left in the dry state on the active layers. It was therefore necessary to place the "chromatoplate" in the solvent tank immediately after applying the solution containing vitamin D, and also to extract the vitamin from the plate immediately after chromatography. When this was done, quantitative recovery of 30 μg of vitamins D_2 and D_3 was obtained.

Table 1. MOVEMENT OF SUDAN BLACK, VITAMIN D AND CHOLESTEROL ON THIN-LAYER CHROMATOGRAMS AT DIFFERENT TEMPERATURES

Temperature in °C	Vitamin D R_F value	Vitamin D R_s value (mean)	Vitamin D Standard error of mean	Cholesterol R_F value	Cholesterol R_s value (mean)	Cholesterol Standard error of mean
4	0·45	0·94	0·0003	0 32	0·68	0 001
23	0·40	0 97	0·002	0·30	0 77	0 003
27	0·41	0 98	0·002	0·30	0·76	0·005

R_s value is distance run in relation to that of Sudan black.

During chromatography of colourless substances, such as vitamin D and other sterols on thin layers, we considered using reference dyes which have R_F values similar to that of vitamin D. A fat-soluble dye, Sudan black, was found to have several components, one of which behaved like vitamin D when run on TLC as shown in Table 1. Thus, by running a dye spot alongside the vitamin D, it was possible to predict its position on the plate without the application of locating reagent. The adsorbent on the plate containing vitamin D was collected in a "zone extractor"[5] constructed from a glass column (10 × 1 cm) incorporating a sintered glass filter disk (porosity 3). The vitamin was eluted with chloroform, and a modification of the method of Nield, Russell and Zimmerli[6] was used to detect it. It proved impossible by this procedure to locate less than 0·5 μg of the vitamin.

This work was carried out in the Department of Pathology, University of Manchester. I thank the Federal Nigerian Government for assistance during this period and Prof. O. Bassir of the University of Ibadan, Nigeria, for helping in the preparation of this manuscript.

Tritiated Angiotensin : Preparation and Purification

THE preparation of tritiated angiotensin with a specific activity of 300 μc./mg in 40 per cent yield was reported earlier[1]. This peptide was purified by chromatography on carboxymethyl cellulose followed by electrophoresis on paper at *p*H 2·1. While electrophoresis on paper gave a pure product, the procedure is tedious and time consuming, especially for the preparation of larger amounts. An improved method of purifying tritiated angiotensin substituting partition chromatography on 'Sephadex G–25' for paper electrophoresis permitting larger samples to be readily purified has been elaborated. A similar chromatographic procedure has been used by Yamashiro[2] for purification of oxytocin. The procedure is illustrated with angiotensin tritiated by the Wilzbach technique[3] rather than the spark discharge procedure used earlier[1].

The starting material, 50 mg of asparagine[1]–valine[5]–angiotensin II (supplied by Dr. R. Schwyzer), was placed under 3 c. of tritium gas at a pressure of 250 mm of mercury at 27° C. After exposure for 2 weeks, the peptide was dissolved in a few millilitres of 0·1 N acetic acid and evaporated to dryness under a stream of nitrogen. This was repeated three times to remove exchangeable tritium. The residue was then dissolved in 5 ml. of the upper phase of *n*-butanol–acetic acid–water (4 : 1 : 5) solvent system and applied to the 'Sephadex' column.

The column was prepared as follows: 'Sephadex G–25' (coarse) was mixed with the lower phase of the solvent system and was allowed to stand for about 4 h. To remove entrapped air, the flask was evacuated to about 20 mm of mercury pressure for 20 min. The slurry of adsorbent was poured into a glass chromatograph tube 22 mm in diameter partially filled with the upper phase of the solvent system. After the particles settled by gravity, the upper phase of the solvent was passed through the column until the excess water (lower phase) had been removed. The finished column was 700 mm high.

The column was developed with upper phase solvent and the effluent was collected in 6·3 ml. fractions. Fractions 85–115 contained the angiotensin and gave a single radioactive peak on paper chromatography using the same solvent system. It was shown to be heterogeneous, however, by paper electrophoresis at *p*H 2·1 (ref. 4). The peptides of these combined fractions were further separated on carboxymethyl cellulose as described previously[1] to yield 7·85 mg (15·7 per cent) of homogenous angiotensin with a specific biological activity of 12 pressor units (ref. 5) for each nanogram and a specific radioactivity of 104 mc./mg.

This partition column has been applied to samples tritiated by the spark discharge procedure used earlier[1], and the yield of peptide, biological activity and radioactivity of the final product was similar to results previously reported. A modified spark discharge procedure, in which the gas phase consisted of 3 c. of tritium at 10 mm of mercury pressure and 4 c.c. helium, gave a crude peptide sample containing less than 5 per cent of the radioactivity of a similar sample run without the helium (these tritiations were carried out by Dr. T. Sullivan). Thus, the spark discharge procedure previously reported remains the preferred method of introducing tritium into angiotensin II.

Radiolysis of tritiated angiotensin into several peptides has been observed when the peptide was stored in 0·1 N acetic acid at 3° C for more than a year. This destruction of peptide can be prevented by addition of 0·1 per cent ascorbic acid to a 0·1 M acetic acid solution of peptide. After 1·5 years of storage of such solutions only 5 per cent of the radioactivity was not contained in angiotensin as demonstrated by paper electrophoresis.

Glass Microelectrodes: the Origin and Elimination of Tip Potentials

ONE of the most important artefacts in electrophysiology is the microelectrode tip potential[1,2]. Its existence precludes accurate determination of cell membrane resting potentials, particularly with extracellular solutions of low ionic strength where the error may be as large as 50 mV. Adrian[1] found that the tip potential of electrodes filled with 3 M potassium chloride was logarithmically related to the external concentration of sodium chloride or potassium chloride (in an inverse way) and correlated with electrode resistance (correlation coefficient $\approx 0{\cdot}7$). It was concluded that tip potentials are junction potentials produced by some substance blocking the tip of the electrode, reducing the mobility of the chloride ion and exaggerating the difference of mobility of the sodium and potassium ions. This communication is primarily concerned with a simple method for eliminating tip potentials and with an extensive series of observations on the tip potential phenomenon.

The major group of observations was made with 3 M potassium chloride electrodes pulled from 'Pyrex 7740' tubing and filled by the alcohol–distilled-water–potassium chloride method. Measurements of tip potentials were made with a silver–silver chloride reference electrode system and either a Keithley 610*A* electrometer or a Grass *P6 DC* preamplifier. We define the tip potential as the difference between the total circuit electromotive force before and after breaking the tip of the microelectrode, with the sign of the tip potential taken as that of the inside of the electrode relative to that of the outside solution. The results for 558 electrodes are shown in Table 1. Because of the correlation of electrode resistance with tip potential, only electrodes of resistance 1–10 megohms in 100 mM external solution are included.

In the first place it is seen that the experiments of Adrian are confirmed, and in the second it is seen that appropriate trace concentrations of thorium chloride can eliminate the tip potential and that physiological concentrations of calcium chloride significantly reduce it. It is also seen that at certain concentrations of thorium chloride the sign of the tip potential may be reversed. We have observed that frog sartorius muscle fibres can be soaked for 1 h in Ringer's solution containing 100 μM thorium chloride without any observable effect on either resting or action potentials. This is about ten times the concentration needed to eliminate tip potentials.

Several other observations are pertinent to the interpretation of the results in Table 1. (1) If electrodes are filled with 10 mM salt solution and exposed to an identical solution, substantial tip potentials (for example, 10 mV) both positive and negative can be measured. The high electrode resistances (10^9 ohms or greater) prevented a quantitative analysis. (2) If electrodes are filled with 3 M potassium chloride containing 10 μM thorium chloride and no thorium chloride is present in the outside solution, the tip potentials are not affected. (3) If 'Pyrex' glass membranes approximately 0·1μ thick (as evidenced by the presence of interference colours) are exposed to water, they rapidly change their shape and become soft. We believe this is an indication of extensive hydration and swelling. It is known that 'Pyrex' can absorb 1·8 mg of water per c.c. of glass[3,4]. It is probable that the electrical resistance of such thin membranes falls by five to ten orders of magnitude on exposure to water.

Table 1. MEAN AND STANDARD ERROR OF MICROELECTRODE TIP POTENTIALS (IN mV) WITH OUTSIDE SOLUTIONS OF VARIOUS ELECTROLYTE COMPOSITIONS

Composition	Sodium or potassium concentration of outside solution: 1 mM	10 mM	100 mM	1 M
NaCl	−33·9±3·3	−22·2±2·0	−11·9±0·9	−5·5±0·5
NaCl+2 mM $CaCl_2$	−12·6±1·2	−13·8±1·1	−10·0±0·9	−6·0±0·5
NaCl+10 μM $ThCl_4$	+5·0±0·9	+2·3±1·0	+0·8±0·9	−5·4±0·4
KCl	−30·0±2·0	−20·3±1·8	−10·5±0·7	−5·0±0·3
KCl+2 mM $CaCl_2$	−15·3±1·1	−15·2±1·4	−10·3±0·8	−5·1±0·3
KCl+10 μM $ThCl_4$	+9·1±1·0	+6·4±0·9	−0·3±0·9	−4·9±0·2
NaCl+1 μM $ThCl_4$		−8·6±0·9		
NaCl+50 μM $ThCl_4$		+1·2±0·9		
NaCl+100 μM $ThCl_4$		−3·8±0·6		

Although there are several ways to interpret all these observations, we will here discuss only one of them. We believe that these results are most simply explained by considering the tip potential to have originated from an interfacial potential between glass and electrolyte solution and that the system can be approximately described by the equivalent circuit shown in Fig. 1. It is well known that glass-electrolyte interfacial potentials are greatly reduced in solutions of high ionic strength[5]. If electrodes contain 3 M potassium chloride, the internal interfacial potential is practically non-existent. The outside interfacial potential, however, can be substantial and will depend on the ionic strength and species of ions of the outside solution. With symmetrical solutions, differences between the inner and outer surfaces will cause a net potential difference in a manner similar to that presumed for asymmetry potentials in glass *p*H electrodes[6,7]. Near the tip of the electrode the glass wall should be about 0·1μ thick. The critical point in this interpretation is the magnitude of change in specific resistivity when glass this thin is exposed to water. As has already been indicated, our observations suggest to us that extensive hydration and swelling occur. The specific resistivity of 'Pyrex 7740' glass is 10^{14}–10^{15} ohm cm. Where the glass is 0·1μ thick the areal resistivity is 10^9–10^{10} ohm cm^2. If the wall is this thin over 25μ^2, the dry resistance of the wall near the tip would be of the order of 10^{16}–10^{17} ohm. If hydration, swelling and perhaps dissolution cause the resistance to decrease by ten orders of magnitude, the amplitude of the tip potential would be related to a voltage-divider network and the observed correlation of tip potential with electrode resistance would follow from

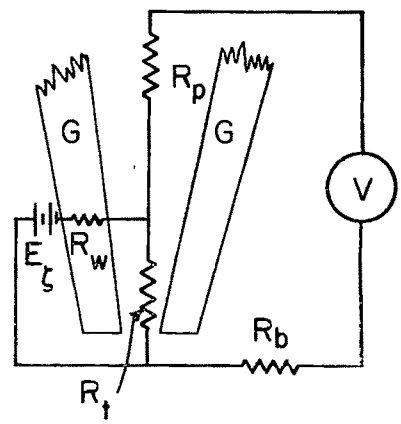

Fig. 1. Equivalent circuit illustrating origin of microelectrode tip potentials. *V*, Electrometer; *G*, wall of micropipette; R_w, resistance of wall near tip, R_p, resistance of bulk electrolyte; R_b, resistance of outside solution; R_t, resistance at tip; E_ζ, outside interfacial potential.

this. That the correlation is far from perfect is an indication that the equivalent circuit in Fig. 1 is at best an approximation.

So far as the action of thorium is concerned, it is well known that glass-electrolyte interfacial potentials can be eliminated by trace concentrations of heavy metal ions while electrochemical junction potential differences are not affected[5]. It should be noted in Table 1 that thorium chloride produces a reversal of sign.

We therefore suggest that tip potentials are related to interfacial potentials, perhaps according to the scheme shown in Fig. 1, but that in any case they can be controlled by appropriate concentrations of thorium chloride in the extracellular solution. A constant error still remains because of the tip potential associated with the intracellular solution, but for experiments involving variation of extracellular ion concentrations, this error is eliminated by treating differences rather than absolute magnitudes.

3,4-Dimethoxyphenylethylamine in Schizophrenia

Reports of the occurrence of 3,4-dimethoxyphenylethylamine (DMPE) in the urine of schizophrenic patients are attracting increasing attention[1,2], although some of the chromatographic procedures used to detect this amine have been criticized as being insufficiently definitive. This communication reports an investigation in which, using two-way thin-layer chromatography, we have failed to detect urinary DMPE in any of twenty-two schizophrenic patients. In seventeen of the patients the illness was of recent acute onset, the remaining five having been ill for several years. Of the seventeen acute cases, fourteen had received no previous medication at all for their condition, while the other three had been treated with barbiturates only. None of the five chronically ill patients had received drug therapy for at least 3 years. No dietary restrictions were imposed.

Twenty-four hour urine collections were made from each patient and a volume of 400–500 ml. was adjusted to *p*H 9 with sodium hydroxide solution and extracted with chloroform (2 × 200 ml.). The dried extract was shaken thoroughly with N/1 hydrochloric acid (2 × 10 ml.), which was then evaporated to dryness *in vacuo*. The solid residue was dissolved in a small volume of aqueous methanol and chromatographed in two dimensions (15 cm each way) on silica-gel plates, using the solvents described by Kuehl *et al.*[3]. Primary amines were located with ninhydrin reagent. As little as 3 μg of DMPE in each 400 ml. of urine could be detected by this method, as shown by adding appropriate amounts of authentic amine to urine.

Initially, in sixteen cases the presence of a purple spot in very close proximity to the position indicated for DMPE was interpreted as resulting from the latter. Subsequent work, in which two chromatograms were run (one with added DMPE) for each patient, however, indicated that this spot was not exactly coincident with DMPE, and in no case were we able to locate a pink spot corresponding to the DMPE on the duplicate chromatograms. Furthermore, overspraying the chromatograms with Ehrlich's reagent, as described by Friedhoff and Van Winkle[4], failed to demonstrate an orange spot in the DMPE position, except when this amine had been deliberately added. It would thus seem that, in the cases we have studied, either excretion of DMPE did not occur or that the amounts excreted were below the limit of detection of 10–15 μg/24 h.

This result is surprising in view of the large proportion of acute subjects in our sample, a fact which other workers have indicated as being favourable for detection of DMPE. We would tentatively suggest that our use of two-dimensional thin-layer chromatography, with its excellent resolution and thus reduced probability of detecting false positives, plus the definite absence of drug metabolites which are known to interfere with detection of DMPE, might be important factors in the results obtained in this study

Recoveries of Iocine-131-labelled Iodo-amino-acids in the Plasma Protein-bound Iodine Assay

It is the orthodox view that circulating thyroid hormone consists mainly of thyroxine (T_4), together with small amounts of triiodothyronine (T_3), while the iodotyrosines account for only 0–4 per cent of the total organic iodine[1–4]. There have been reports[5–8], however, that the iodotyrosines account for 30–50 per cent of the iodine in normal human blood. In the condition of thyrotoxicosis, quite large amounts of diiodotyrosine (DIT) are detected in the plasma, although the amount has not yet been precisely quantitated[3,4,9].

Most of the reports on the recovery of organic iodine compounds by means of the various protein-bound iodine (PBI) procedures refer only to the recovery of iodothyronines. However, there are two reports[10,11] which suggest that there are marked differences in the extents of recovery of the iodotyrosines by the two commonly used protein precipitation procedures, namely, the zinc sulphate-sodium hydroxide (Somogyi) system and the trichloroacetic acid (TCA) system.

In view of the increased attention which has been given to the possibility of finding greater amounts of iodotyrosines in the blood of normal people than were previously estimated, we decided to investigate the recovery of iodine-131-labelled monoiodotyrosine (MIT) and diiodotyrosine using both the Somogyi and trichloroacetic acid systems throughout the PBI procedure. At the same time, the opportunity was taken to re-investigate the recovery of iodine-131-labelled T_3 and T_4. The recovery of each iodo-amino-acid was studied after addition to plasma samples of diverse ability to bind thyroid hormone.

Blood was withdrawn from a healthy volunteer, heparinized and the plasma separated under conditions free of iodine. Plasma containing increased amounts of thyroid binding proteins (TBP) was obtained by pooling specimens from four euthyroid, pregnant patients.

Plasma containing a decreased amount of TBP was obtained from two patients with nephrosis and hypoalbuminaemia. The PBI values for the three plasma specimens—namely, for normal binding, for decreased binding and for increased binding—were, respectively, 4·7, 3·2 and 7·9 μg per 100 ml. of plasma (normal range 3·8–7·0 μg per 100 ml.). The values for resin uptake of T_3 were: for normal binding 100, for decreased binding 132, and for increased binding 55 per cent (normal range 70–112 per cent).

Iodine-131-labelled T_3 and T_4 were obtained from Abbott Laboratories at specific activities of approximately 40 μc./μg on receipt. Each was purified by chromatography on filter paper in *n*-butanol : ethanol : 2N ammonia (4 : 2 : 2). After the purified T_3 and T_4 had been located by autoradiography, each was eluted from the filter paper in 10 per cent (v/v) acetic acid, immediately before the plasma samples were enriched with the iodine-131-labelled amino-acids.

Iodine-131-labelled MIT and DIT were manufactured by the iodination of tyrosine with Na ^{131}I. Each was purified by two chromatographic separations on paper in *n*-butanol saturated with 2N acetic acid and eluted as for T_3 and T_4.

About 0·07 μc. in 10 μl. of each iodine-131-labelled amino-acid was then added separately to duplicate 1·0 ml. portions of each of the three samples of plasma, and the enriched specimens were equilibrated overnight at room temperature. The PBI was assayed using two methods for precipitation of protein, namely, the Somogyi method, and with trichloroacetic acid[12]. After precipitation and washing, the protein bound iodine was fired according to the alkaline incineration procedure of Acland[13].

Initial counts were made following precipitation and centrifugation of the protein but before washing the precipitate. Subsequent counts were made after each wash and after firing. Where necessary, counts were adjusted with the appropriate correction factors, including background, decay, dead time and for variation in scaler performance. All counts were made in a volume of 3 ml. of fluid in $\frac{5}{8}$ in. test-tubes, using a scintillator detector fitted with a well-type crystal with the scaler set to 30,000 counts.

The percentages of recovery of the iodoamino acids obtained using the two procedures are given in Tables 1 and 2.

The conclusions are that in the Somogyi system, an average of 94·0 per cent of T_4, 99·1 per cent of T_3, 93·3 per cent of DIT and 87·8 per cent of MIT can be precipitated from plasma of normal thyroid binding capacity (that is, are recoverable following precipitation and washing of the precipitate). There appears to be no alteration in the recovery of T_3 and T_4 when they are added to plasma samples of decreased or increased binding capacity. For both MIT and DIT there appears to be a reduced precipitability in the Somogyi system with plasma of increased T_4 binding capacity, but the number of observations are insufficient to allow statistical analysis.

In the TCA system, the recoveries of pooled results of T_4 and T_3, 93·8 per cent and 94·6 per cent respectively, are of the same order as in the Somogyi system. There are, however, marked reductions in the recoveries of DIT and MIT (8·2 and 3·7 per cent respectively). There are probably no differences in the TCA system between the recoveries with plasmas of differing binding capacity. Losses in firing were tested only for the iodothyronines. For both T_3 and T_4 the losses were negligible (Table 2), and amounted to less than 2 per cent of the activity after the final wash before firing.

The excellent recovery of T_4 and T_3 by Somogyi precipitation agrees with previous reports on this subject[12,13]. This investigation has made the useful observation that the precipitability of iodothyronines is not markedly affected by substituting a TCA for the Somogyi precipitating system. However, Malkin's observation[14] that T_3 is slightly more readily precipitated than T_4 when using the Somogyi system has been confirmed.

The absence of losses on firing, as noted in the present investigation, confirms the findings of Acland[12]. Malkin, however, encountered losses of iodine up to 50 per cent of the total amount during firing. These losses must, in some way, be associated with the ultramicro system used. Possibly the use of a carrier such as the glycine, recommended for the butanol extractable iodine (BEI) procedure[15], may minimize losses in an ultramicro system.

A further observation of practical importance is that the precipitability of the iodothyronines is not altered when studies are performed using plasmas of differing capacity to bind T_4. Conditions such as nephrosis and hypoalbuminaemia cause a decrease in binding of T_4 by the plasma and are associated with a low PBI, while the patient remains in euthyroid status[16]. Conversely, pregnancy and oestrogen treatment cause increased T_4 binding and an associated increase in PBI[17,18]. Our findings eliminate any possibility that the abnormal PBI values have a chemical basis.

A further interesting finding of this investigation was the striking discrepancy between the precipitability of the iodotyrosines by the TCA system and that by the Somogyi system. This discrepancy is more marked than those noted by Tong *et al.*[10] and Blizzard and Mosier[11]. These observations are relevant when considering the controversial claim of Werner *et al.*[6] and of Russell Fraser *et al.*[8] that the normal circulating thyroid hormone in man contains up to 2 or 3 μg per 100 ml. of iodotyrosines in addition to iodothyronines. In that event there should be a marked discrepancy between the PBI values obtained for normal plasma after the two types of precipitation; and this does not seem to occur.

Assuming that there is no iodotyrosine in normal plasma[1–4] it would seem justifiable to replace the widespread use of the TCA precipitation system with the Somogyi system, accounting as it does for at least 95 per cent of the iodothyronines and 85 per cent of the

Light-stimulated Oxygen Uptake and Glycolic Acid Oxidase in *Typha latifolia* L. Leaf Disks

The relationship between light and green plant respiration has been the subject of a considerable debate[1] which has been carried over into recent literature[2]. Investigations using simultaneous monitoring of water and oxygen-17 indicated that light-stimulated oxygen may occur in some species but not in others[3–6]. Similar results were obtained in experiments monitoring carbon dioxide absorption and evolution[7].

We have investigated the temperature dependence of photosynthesis and respiration in the broad-leaved cattail (*Typha latifolia* L.). We found light-stimulated oxygen uptake in leaf disks at high temperatures. Zelitch[2] has related such light-stimulated respiration to glycolic acid oxidase activity. The activity of this enzyme is resistant to inhibition by potassium cyanide[8] but is sensitive to inhibition by α-hydroxysulphonates[9]. Glycolic acid synthesis in *Chlorella* is inhibited by carbon dioxide concentrations exceeding 0·1–0·2 per cent[10,11].

In leaf disks of *T. latifolia*, the rate of oxygen consumption at 52° C in the light was more than 150 per cent of the rate in the dark (Table 1). This stimulation was not inhibited by potassium cyanide. Although the rates of oxygen consumption are higher in the lowest concentration of carbon dioxide, the proportionate stimulation by light is similar in the presence and absence of potassium cyanide. This shows that the same system is probably operating at both concentrations of carbon dioxide.

Table 1. Effect of Light and Potassium Cyanide on Oxygen Consumption by Leaf Disks of *T. latifolia* at Two Concentrations of Carbon Dioxide

Treatment	Oxygen consumption (μl./g/h)	
Carbon dioxide concentration:	0·2%	1·0%
Light	184	136
Dark	116	88
Dark + potassium cyanide	108	82
Light + potassium cyanide	198	139

Three to five leaf disks 10 mm in diameter weighing 200–300 mg were floated on 2·5 ml. 0·067 M phosphate buffer, *p*H 7·8, in each of ten Warburg flasks with 0·5 ml. diethanolamine-thiourea solution in centre well adjusted to maintain constant carbon dioxide concentration. A control flask lacking leaf disks was run at each treatment. Flasks were equilibrated with shaking in the dark before manometric determination of oxygen changes on a 'Gilson *GRP*-14' constant-pressure differential respirometer. ($T = 52°$ C.) Illumination from below at 900 ft.-candles. Five min equilibration periods allowed between treatments. Potassium cyanide tipped in from sidearm to make 0·02 M.

Table 2. Effect of a Glycolic Acid Oxidase Inhibitor (2-Pyridyl-hydroxymethanesulphonic Acid) on Light-stimulated Oxygen Uptake by *T. latifolia* Leaf Disks at Different Concentrations of Carbon Dioxide

Treatment	Oxygen consumption (μl./g/h)	
Carbon dioxide concentration:	0·2%	1·0%
Light	191	146
Dark	75	61
Light + inhibitor	134	97
Dark + inhibitor	52	36
Treatment $A \div$ treatment $B \times 100$		
Light ÷ dark	254	241
Light inhibitor ÷ light	70	66
Dark inhibitor ÷ dark	69	60
Light inhibitor ÷ dark inhibitor	256	266

Experimental technique identical to that for Table 1 except *tris*-buffered (*p*H 7·8) 2-pyridylhydroxymethanesulphonic acid added from sidearm to make 0·04 M.

Although insensitivity to potassium cyanide constitutes presumptive evidence that glycolic acid oxidase is the active component, more definitive evidence was provided by experiments with 2-pyridylhydroxymethanesulphonic acid (Aldrich Chemical Co., Milwaukee, Wisconsin), a specific inhibitor of glycolic acid oxidase[9]. Table 2 shows that the oxygen consumption by leaf disks of *T. latifolia* was inhibited 30–40 per cent by this inhibitor and the inhibition was similar in light and dark and at high or low carbon dioxide concentrations. Light and dark rates were equally inhibited, resulting in similar light stimulation in the presence and absence of inhibitor, indicating that glycolic acid oxidase is responsible for oxygen consumption in both illuminated and unilluminated leaf disks. As in the previous experiment, rates were greater in lower concentrations of carbon dioxide, but the proportionate values were similar.

Table 3. Effect of Alternating Light and Dark Periods on Photostimulated Oxygen Uptake in *T. latifolia*

Time (min)	Treatment	Oxygen consumption (μl./g/h)
0–5	Light	191
5–10	Light	176
10–15	Dark	143
15–20	Dark	88
20–25	Light (0·5 min) + dark (4·5 min)	110
25–30	Dark (4·5 min) + light (0·5 min)	77

Experimental technique identical to Table 1 except no equilibration period allowed between treatments. Carbon dioxide concentration was 0·2 per cent.

These data provide support for Zelitch's contention that glycolic acid is the substrate of photorespiration[2], but they also indicate that the same pathway is functional at high concentrations of carbon dioxide and in the dark. In an experiment in which no period was allowed for equilibration between treatments, the rate of oxygen consumption in the light was found to be higher if the light period followed a dark period and higher in the dark if the dark period followed a light period (Table 3). Although the effect on dark rates is undoubtedly due in part to equilibration overshoot, the light pattern cannot be explained on this basis. Instead, it shows a dependence of light reactions on substrates that can be generated in the dark. The ability of a 30-sec light flash to restore 25 per cent of the difference in activity between illuminated and unilluminated treatments substantiates this conclusion. It seems probable, on the basis of these data, that photostimulated respiration at high temperatures in *T. latifolia* leaves results from the oxidation of light-generated substrates in a reaction linked to glycolic acid oxidase.

This investigation was aided by grants from the Tektronix Foundation and Portland State College. I thank I. Zelitch for his comments on the early phases of the work.

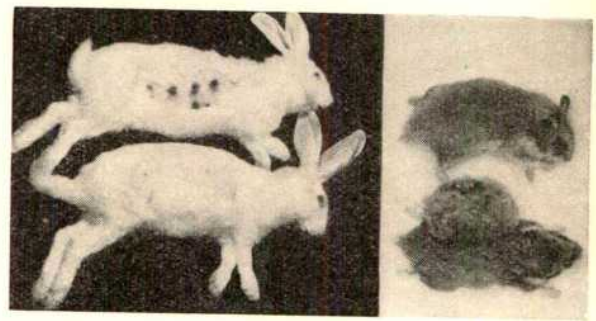
PHARMACOLOGY

Alanosine, a New Antiviral and Antitumour Agent isolated from a Streptomyces

DURING the course of a systematic screening for antibiotics with antiviral activity, *Streptomyces alanosinicus* nov. sp. (ATCC 15710) was isolated from a Brazilian soil sample. This culture produced, under submerged conditions, a new antibiotic with antiviral and antitumour activity to which the name "alanosine" was given.



The organism grew well on the standard culture media, forming a light brown to brown vegetative mycelium with a diffusible brown to dark brown pigment. The spores (oval to ellipsoidal) appear in monopodially branched sporophores with tightly coiled spirals. Cultures for antibiotic production were made in a medium containing (per cent w/v) 5·0 glucose, 1·0 dried whale meat, 0·5 calcium carbonate, 0·1 ammonium sulphate, 0·1 Epsom salt, and copper, iron, zinc and manganese in trace amounts. The fermentations were carried out in small fermentors containing 4 l. of this medium. After 72–96 h incubation at 28° C with constant aeration and agitation, spectrophotometric titres of 1,200 μg/ml. were obtained.

After centrifugation the fermentation broth was purified with carbon; the filtrate was concentrated under vacuum at 45° C, acidified with sulphuric acid to separate calcium sulphate and precipitated with an excess of methanol. The purification of the crude product was carried out by dissolving the active substance in acid methanol and reprecipitating by neutralization. The product obtained, with an ultra-violet titre of 40–45 per cent, can be crystallized from an aqueous concentrated solution containing acetic or sulphuric acid. Recrystallization from distilled water yielded a white crystalline powder with an ultra-violet titre of 100 per cent.

Alanosine is insoluble in organic solvents, slightly soluble in water at neutral *p*H, and very soluble in water at *p*Hs lower than 3·5 and higher than 7·0. It gave a positive ninhydrin reaction. An aqueous solution heated with sulphanilic acid and alphanaphthylamine developed a red-violet colour characteristic of a nitroso group. The ultra-violet absorption spectrum showed a maximum at 250 mμ ($E^{1\%}_{1cm} = 630$) at neutral *p*H and at 228 mμ at acidic *p*H. $[\alpha]^{25}_{D} = -37{\cdot}8°$ ($c = 0{\cdot}5$ per cent in water). Microanalytical data: carbon, 24·07; hydrogen, 4·86; nitrogen, 28·15; oxygen, by difference, 42·92. These results correspond to an empirical formula $C_3H_7N_3O_4$ giving a molecular weight of 149·1. The molecular weight determined by potentiometric titration was 155. The structural formula of alanosine as elucidated by ultra-violet, infrared, nuclear magnetic resonance and catalytic reduction studies proved to be L(−)2-amino, 3-nitroso hydroxylamino propionic acid. The antibiotic is very stable at neutral and unstable at acidic *p*H.

The *in vitro* antiviral activity was investigated using a human embryo epithelial cell line. Tubes containing a cell layer 72 h old were incubated for 24 h with various non-toxic dilutions of the compound and then inoculated with 100 $TCID_{50}$ of the virus suspension. When the control tubes showed 100 per cent cytopathic effect (CPE), the protection afforded by alanosine was estimated. Under these conditions CPE was inhibited at 8 γ/ml. for three strains of polio and Coe, and at 2 γ/ml. for a neurovaccinia, a sheep pox and two strains of cow pox viruses.

In the case of neurovaccinia, a significant protection was afforded even when treatment started as late as 24 h after virus infection. Rabbit skin infection through scarification using a neurovaccinia strain was used for the estimation of *in vivo* activity. Topical treatment with a 0·5 per cent ointment administered 18 h after infection, twice daily for 5 days, gave a significant protection. In the control animals the "take" was positive up to 10^{-5} dilution of the stock virus suspension and in the treated ones it was never more than 10^{-2} dilution. Administration of alanosine for 6 days *per os* at 5 mg/kg/day and intramuscularly at 0·5 mg/kg/day gave complete inhibition, even at the site where undiluted virus suspension was inoculated (Fig. 1*a*).

a *b*

Fig. 1. *a*, Antivaccinia activity: upper animal treated with buffer and lower one treated with alanosine *per os* at 5 mg/kg/day. *b*, Antitumour activity: lower animal treated with buffer and upper one with 20 mg/kg/day subcutaneously.

Alanosine has demonstrated a marked antitumour activity against a transplanted fibrosarcoma induced by *SV*-40 virus in newborn hamsters, although the antibiotic did not show any *in vitro* antiviral activity against the virus itself. Six- to eight-week old hamsters were transplanted with the tumour tissue and 24 h later alanosine at 20 mg/kg/day was administered subcutaneously at a site far removed from the zone of transplantation. Final results were taken 21 days after the appearance of a palpable tumour in the majority of the control animals. Although the transplantation efficiency checked over a 2-year period has always been 100 per cent, no tumour developed in any of the treated animals (Fig. 1*b*). A second transplantation was carried out using the treated animals from the previous experiment, and it was observed that the pre-treatment with alanosine did not affect either the period taken for the appearance of a palpable tumour or the further development of it. In another experiment, animals with a well developed tumour were treated subcutaneously once daily with 30 mg/kg, and the controls having tumours of similar size were treated with buffer solution. Weekly measurements of the tumours were taken for 7 weeks. In the control animals, the tumour size increased 400–500 per cent, and was occasionally of the same order as that of the host animal. In the treated group, however, any further development of the tumour was completely arrested. In some cases the size was reduced to such an extent that an accurate measurement was impossible.

Detailed reports on the chemical and biological properties of alanosine will be published elsewhere.

PATHOLOGY

Trauma and Melanoma Production

IT has long been held that malignant melanoma of man can arise as a result of trauma to a mole (naevus or benign melanoma) or even normal skin[1-4]. Other workers[5-8], however, do not accept this thesis. They believe that as yet there is no authenticated case of a mole having become malignant as a result of trauma and that the local appearance of a malignant melanoma after incomplete removal of a supposed benign naevus indicates that the lesion was already malignant before removal.

Hitherto, only one attempt has been made to investigate this problem in the experimental animal. My colleagues and I[9] traumatized about eighty carcinogen-induced benign melanotic tumours in the Syrian hamster but failed to induce malignant change or even a modest growth stimulation in any of these tumours. In fact many of the lesions regressed as a result of trauma.

This problem has now been investigated in another experimental animal, and forms the subject of this report.

It is now well established[10,11] that deeply infiltrating and destructive melanomata can be produced in various viviparous fishes by hybridization and that these tumours arise as a result of the genetic imbalance produced, which permits the proliferation of macromelanophores and melanocytes. In most instances this proliferation affects large areas of the skin which are thickened (a state referred to by Reed and Gordon[10] as melanosis) and it is from such genetically predisposed sites that the malignant melanoma ultimately arises.

In this respect the piscine model is similar to the human, for most human melanomata arise from pre-existing moles which are considered to be areas of melanocyte proliferation produced as the result of a developmental defect[4]. Therefore, it appeared worth while to investigate the effect of trauma to the skin of *Xiphophorus maculatus* × *X. helleri* hybrids showing various grades of melanosis to see if frank melanomata could be precipitated by this procedure.

With this in view 112 hybrids of both sexes, aged between 3 and 5 months, were divided into two equal groups. The skin of each experimental animal was traumatized in one of the three following ways: (1) Pricking with a needle over a selected area once a week for 3 months. (2) Excising a strip of skin measuring about 5 mm × 1 mm. (3) Excising portions of dorsal or caudal fin through hyperpigmented areas. The experimental and control animals were observed until they died, or for a period of 12 months. During this period three melanomata developed in the control group and four in the experimental group, but in no case did a melanoma arise from, or near, a traumatized site.

These observations indicate that single or repeated mechanical trauma does not induce melanomata to develop in the skin of these hybrid fishes genetically predisposed to melanoma formation. These observations are therefore in keeping with the observation that trauma does not induce malignant change in the benign melanomata of hamsters and also with current opinion that trauma does not precipitate malignant change in human moles.

It is extremely difficult to evaluate the role of trauma in tumour production or in the transformation of benign tumours into malignant ones. There is, however, fairly conclusive evidence that mechanical trauma can produce epithelial tumours from skin that has been pretreated with carcinogens. This has been shown to occur both in the rabbit and man[12]. The situation regarding melanocytes and melanomata, however, seems to be different, for neither recent clinical opinion nor experimental investigation supports the idea that melanomata arise as a result of trauma.

IMMUNOLOGY

Transfer of Experimental Nephritis in Rats by means of Lymphatic Duct Lymphocytes

THE successful transfer of nephrotoxic nephritis (Masugi's method) in rats to essentially healthy animals of the same inbred strain by parabiosis was described earlier[1,2]. In these experiments, transfer of rabbit antibody from the first into the second rat was excluded by the fluorescent antibody technique[3]. Recently, experiments were reported in which the so-called auto-immune nephrosis was also induced by parabiotic transfer[4]. Furthermore, this disease has been transferred by means of lymph node cells[5]. Nephrotoxic nephritis was "transferred" by peripheral white blood cells of nephritic donors[6]. It was assumed that blood lymphocytes were the immunologically responsible cells and caused the renal lesions in the recipient. It was considered that further investigations of the transfer of circulating lymphocytes obtained from a lymphatic vessel would prove whether or not this assumption was correct.

Sprague-Dawley rats of an inbred strain were injected with 0·5 ml. of nephrotoxic rabbit serum per 100 g body weight. Between twelve and sixteen days later, when the nephritic lesions were fully established, the lymphatic vessel accompanying the superior mesenteric artery was cannulated with a *PE* 50 polyethylene catheter using the Bollmann technique[7]. The animals so treated were kept in a special cage throughout the experiment which allowed forward and backward movement, but prevented the animals from turning around. The rats were fed an ordinary diet and received water *ad libitum*. The outflowing lymph was collected in tubes containing Hanks's solution with 100 units of heparin. Up to 15 ml. of lymph fluid was obtained from a single donor. The recipients of lymphatic material were divided into three groups. The first group of twenty-seven animals received the whole lymph containing 100–500 × 10^6 lymphocytes in 10–12 ml. lymphatic fluid. The material was injected intravenously in from four to thirteen portions. In the second group, twenty-two rats were given isolated lymphocytes in a total of 70–300 × 10^6 cells injected in between two and nine portions. When preparing the cell suspension, the whole lymph was centrifuged for 20 min at 1,000 r.p.m. The supernatant was discarded and the cells were resuspended in Hanks's solution. This procedure was

repeated three times. Microscopic observation using Schreck's method of eosin staining revealed that 80–90 per cent of the cells were alive after this washing procedure. The third group of twenty rats received 7–16 ml. of lymph fluid free of cells by way of between four and twelve injections. The lymph fluid was obtained by high speed centrifugation for 10–15 min. No cells were found on examination under the microscope.

All rats of the three groups were killed 10 days after the final injection. Their kidneys were removed and after decapsulation fixed in 10 per cent formol. After a careful imbedding procedure which lasted 6 days, 5μ paraffin sections were stained with haematoxylin–eosin and periodic acid-Schiff (PAS). Controls were performed by injection of lymphatic material from healthy donors prepared in the same way as in the experimental groups.

The results are summarized in Table 1. Six out of twenty-seven animals which received whole lymph developed nephritic lesions. Positive results were obtained only if lymphatic fluid containing more than a total of 200×10^6 lymphocytes was given. Similar relations were found in the second group. Four animals out of twelve developed renal disease when injected with more than 200×10^6 pure cells, whereas all ten rats receiving only $70–200 \times 10^6$ cells showed no lesions. In the third group only one rat out of twenty developed nephritis. This animal had been injected with a total amount of 16 ml. of lymph free of cells.

When investigated histologically, it was found that the kidney lesions were mainly confined to the glomerula. They consisted of enlargements of the tufts, thickening of the basement membrane, adhesions between the loops, and increases in the endothelial and epithelial cells both in number and in size. Occasionally, adhesions occurred between loops and the Bowman's capsule. Crescent formation was never observed. Epithelial cells of the proximal convoluted tubules contained hyalin droplets, but casts were seldom found. In the interstitial tissue of the external cortex some small perivascular infiltrates of lymphocytes were found. The alterations were the same as those found earlier during successful transfers of nephrotoxic nephritis by parabiosis or by peripheral white blood cells[8]. The severity of the kidney lesions is less than in nephrotoxic nephritis and can be compared with the membranous type of human glomerulonephritis despite certain typical differences. Sections stained with PAS showed PAS-positive material in the thickened basement membrane and around the cytoplasm of the mesangial cells. Studies with the fluorescent antibody technique showed that the lymphatic cells of the donors, whether suspended in the original lymph or washed with Hanks's solution, did not contain traces of the rabbit anti-rat kidney serum which might have been responsible for the nephritis induced in the recipients.

From their histological appearance the renal lesions observed in the recipients would be classified as nephritis. The morphological pattern is the same as that of renal changes produced by parabiotic transfer. There is considerable evidence for the existence of a secondary nephritis inducing factor, which is possibly part of an auto-immune mechanism. Attempts have failed to induce renal lesions by serum alone from donors with nephrotoxic nephritis or with auto-immune nephrosis. Likewise, in other experimental auto-immune diseases such as allergic encephalomyelitis[9], thyroiditis[10], and aspermatogenesis[11], serum, even if circulating antibodies were present, did not lead to successful transfers. On the other hand, it was possible to induce experimental thyroiditis[12] and experimental auto-immune nephrosis[5] with lymph node cells in an essentially healthy recipient. Reactions arising from histo-incompatibility were excluded by inducing immunological tolerance in the recipients or by using inbred strains. It should be emphasized that our experiments—in contrast to those of other authors working in this field—were performed without Freund's adjuvant. This seems to be of special importance so far as the induced renal lesions are concerned. In our experiments the possibility of alterations in the glomerula caused by Freund's adjuvant alone certainly can be excluded.

Table 1. Transfer of Renal Disease by Lymphocytes

Material injected	No. of recipients	Amount of cells (lymph) injected	No. of injections	Survival time after the final injection	Histological examination: Normal	Nephritis
Whole lymph	6	$100–200 \times 10^6$	4 to 13 ×	10 days	6	0
	12	$200–300 \times 10^6$		10 days	9	3
	9	$300–500 \times 10^6$		10 days	6	3
Washed lymphocytes	10	$70–200 \times 10^6$	2 to 9 ×	10 days	10	0
	12	$200–300 \times 10^6$		10 days	8	4
Cell-free lymph	7	7–10 ml.	4 to 12 ×	10 days	7	0
	13	10–16 ml.	4 to 12 ×	10 days	12	1

Further investigations should elucidate the part played by the injected cells and also their fate. With the fluorescent antibody technique no traces of the nephrotoxic rabbit antibody were found on the surface of the lymphocytes. Nevertheless, the transport of antigen-antibody complexes by the injected cells cannot be completely excluded because of the possibility that they were masked in the interior of the cells. It is, however, unlikely that those small amounts of transferred nephrotoxin would be sufficient to cause renal disease. It is more likely that the lymphocytes are effective by synthesizing antibodies systemically or locally in the target organ. On the other hand, they might only give information to the immunologically competent system of the recipient; in this case the mechanism responsible for kidney injury would represent a second step.

There is some evidence for the latter hypothesis. Experiments (as yet unpublished) with lymphocytes labelled with tritiated thymidine, which belong to the same series as those described here, indicate that the transferred cells do not adhere to the glomerular capillaries. Autoradiographs showed no special avidity for the lymphocytes for the renal tissue.

These findings support the suggestion that a transfer factor similar to the findings of Lawrence[13] in tuberculin hypersensitivity causes nephritis in the recipient animals.

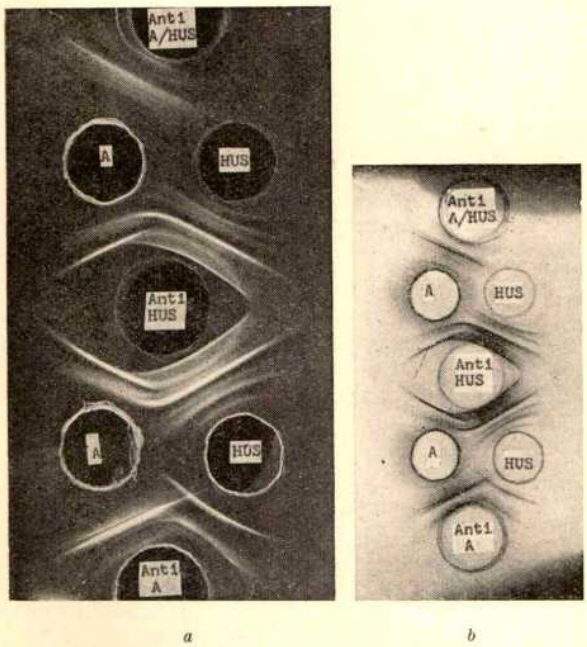
Antigenic Constituents of Human Cortical Grey Matter

Recent work in this laboratory has been directed towards the development of improved methods for the extraction of proteins of human brain, and their chemical and immunological characterization. Thus Bogoch, Rajam

and Belval[1] have demonstrated a large number of protein entities in an extract of low ionic strength of human cortical grey matter. This extract (*A*) was prepared by cold homogenization in 0·005 M phosphate buffer, *p*H 7, and ultracentrifugation at 80,000*g* to yield a clear supernate. Chromatography of concentrated *A* on DEAE cellulose, using a gradient increasing in ionic strength and decreasing in *p*H, indicated the presence of at least fifteen main protein groups; that these chromatographic groups were heterogeneous was suggested by the results of assays for hexose, hexosamine, neuraminic acid and protein in each tube of chromatographic effluent as well as by electrophoretic findings. The total number of distinct or partially related proteins appeared to exceed a hundred. Supporting evidence, obtained in work on animal brain material, has been adduced by others[2].

This communication is concerned with a preliminary assessment of the minimum number of distinct major antigens present in *A*. Rabbit antiserum against total extract *A* was prepared using complete Freund's adjuvant emulsified with 10–12 mg quantities of total *A* protein for each dose. Nine such doses were administered by the intramuscular route, over a 9 week period, and the rabbits were bled 14 days after the final dose. Serum was absorbed with whole human serum (anti-*A*/HUS) to minimize reactions with serum proteins present as contaminants in *A*, when the following experiments were run.

Macro double-diffusion reactions were performed in 1 per cent Noble agar, using saline–borate buffer *p*H 8 (ionic strength 0·16) as the equilibration medium. *A* was made to react against anti-*A*/HUS and, for comparison, with unabsorbed *A*. Original wet preparations were photographed, washed, dried and stained with amido-schwartz 10*B*. Samples of both types of preparation are presented in Fig. 1. Results indicate that *A* contains a minimum of nine distinct antigenic components, three of which are either identical with human serum proteins or are contaminants of serum protein. The *A* : anti-*A*/HUS interaction apparently indicates that the major precipitin arc was identical with serum protein on the basis of deflexion of that end of the arc approaching the human serum reservoir. That this was a physical deflexion which resulted from the length of the arc in relation to the periphery of the reservoir is suggested by the absence of deflexion of the same arc in the *A* : anti-*A* (unabsorbed) reaction, where it suffered no deflexion in the area of diffusing serum proteins. The wet preparation suggested that the arc nearest the *A* reservoir in the *A* : anti-*A* (unabsorbed) reaction could be identified with a major serum protein arc; however, the stained preparation clearly indicated that no such reaction occurred.



These results suggest that the antigenic heterogeneity of the component proteins of *A* does not parallel the molecular heterogeneity which we reported earlier; indeed, a unit relationship between variants of a given molecular type and individual antigenic species need not necessarily be expected. A similar situation was encountered in analogous experiments on chemical and antigenic properties of lens proteins[3]. In additional work, however, *A* has been chromatographically fractionated into two distinct complexes of basic (*B*) and progressively acidic (post-basic, *PB*) proteins. Immunoelectrophoretic examination of the separated, concentrated *B* and *PB* fractions indicated a minimum content of four and seven antigenic components respectively, one of which is a protein resistant to 100° C for 1 h, which can be precipitated with ethanol at a final concentration of 75 per cent. The total number of antigenic components so far detected is thirteen. Thus, further sub-fractionation and concentration of sub-fractions may result in the detection of a considerably larger number of antigenic components in dilute salt extracts of human grey matter.

This work was supported by a grant from the National Institute of Child Health and Development, the National Institutes of Health, and by a grant from the National Science Foundation.

Organ Specificity of Heat-stable Antigens from Human Brain

A PRELIMINARY assessment of a neutral aqueous extract of low ionic strength of human grey matter (extract *A*) has indicated that there are nine distinct major antigens, of which three are either human serum protein contaminants or species-specific antigens shared with serum[1].

This communication reports the presence in *A* of five or six tissue antigens of the class known as "*BE*" (ref. 2)—this nomenclature denotes that they are resistant to boiling for 1 h and can be precipitated at an ethanol concentration of 70–75 per cent. Milgrom *et al.*[2] demonstrated earlier that such an antigen can be extracted from human grey matter by methods somewhat different from those reported here.

Scheme I outlines the method of extraction of normal human cortical grey matter to yield extract *A*, and the preparation of both crude and purified heat-stable antigens (*HT*) from *A*. Heat-stable antigens were prepared in the same manner from whole normal human liver and kidney. Rabbit antiserum against purified brain *HT* (anti-*HT*) was prepared using complete Freund's adjuvant emulsified with 0·64 mg protein for each dose. Between three and five doses were administered to rabbits by the intramuscular route at intervals of 10 days, and the animals bled 10–15 days after the final dose.

Fig. 1 shows the antigenic inter-relationships of *HT* from human liver, kidney and brain when they were made to react in double-diffusion tests against anti-*HT*.

Scheme I. Outline of preparative method.

Two species-specific antigens were common to *HT* from all three sources; with the antiserum used, brain *HT* exhibited three immunoprecipitin arcs not shared by liver or kidney *HT*. The three preparations contained a species-specific component which was also present in human serum.

The fact that we were unable to detect three of the heat-stable antigens from the aqueous extracts of human brain in comparable extracts of tissues usually rich in species-specific antigens suggests that they are organ-specific. Our investigations are being extended to a larger number of representative human tissues in order to evaluate these preliminary findings.

MICROBIOLOGY

Microbial Decomposition of Various Fractions of Ureaformaldehyde

CONSIDERABLE interest has been shown in the mineralization of ureaformaldehyde, a compound with "slow release" properties of value in fertilizer technology. It has been suggested that the release of ammonium–nitrogen from this polymer is biological[1], although Winsor and Lang[2] proposed that the first stage of decomposition may be non-biological. Commercial ureaformaldehyde is composed of various chain length polymers, which can be arbitrarily grouped into the cold water soluble (CWS), hot water soluble (HWS) and hot water insoluble (HWI) fractions.

In these investigations, release of ammonium–nitrogen was followed using the soil perfusion technique and the accumulation of nitrate–nitrogen (nitrification) was used as an index of mineralization. Fifty grams of Guelph loam (2 to 5 mm mesh, *p*H 7·0–7·3) were perfused with 200 ml. of distilled water. The soils were treated with urea, ammonium sulphate, CWS and HWS fractions at concentrations equivalent to 0·4 mg of nitrogen/g of soil. Nitrate–nitrogen in perfusates was measured using the phenoldisulphonic acid procedure and was recorded as μg nitrogen/ml. of perfusate.

Both urea and ammonium sulphate were nitrified after lag periods of 1–2 days, following which nitrate–nitrogen accumulated at about the same rate from both nitrogen sources. The CWS fraction showed a slightly longer lag of from 4 to 5 days, and a lesser slope of accumulation; the HWS had a lag of from 6 to 8 days and a greatly reduced slope of accumulation of nitrate–nitrogen (Fig. 1*A*). It was obvious that the mineralization of the CWS and HWS fractions was limiting the rate at which nitrate–nitrogen accumulated in perfusates containing these materials. If this process of release of ammonium–nitrogen is biological, then it is logical that microbial "enrichment" should occur after the logarithmic phase of mineralization of either CWS or HWS. Moreover, in this particular system a double "enrichment" should occur, first, by the population of organisms capable of splitting or mineralizing the particular ureaformaldehyde polymer, and second, by the population of nitrifiers developing on the released ammonium–nitrogen.

Soils were therefore treated with the CWS fraction and perfused to enrich the soil with both groups; the soils were then washed free of nitrate–nitrogen and replicated units were treated with ammonium sulphate, CWS and HWS fractions and re-perfused with distilled water. In this experiment (Fig. 1*B*) ammonium sulphate was nitrified without any lag indicating that the soils were enriched with nitrifying bacteria in the sense of Lees and Quastel[3]. Both the CWS and HWS fractions were nitrified without a lag, indicating that the initial treatment with CWS enriched the soil with mineralizing organisms as well as nitrifying bacteria. Moreover, the organisms associated with the decomposition of the CWS fraction were also involved in the decomposition of the HWS fraction.

Because the decomposition of the fractions used was obviously microbial, an attempt was made to isolate the soil organisms responsible. This was carried out using a basal mineral salts–glucose liquid medium in tubes, supplemented with CWS–nitrogen at a concentration of 50 mg nitrogen per 100 ml. of medium. The enriched soils were diluted and portions transferred to tubes. After incubation, streak transfers were made from the highest dilutions showing turbidity to a solidified CWS medium. After 7 days at 27° C, representative colonies were selected, purified and maintained on the CWS medium.

One of the isolates (strain *C*2) obtained in this manner was representative of the majority of colonies appearing on plates, and was a Gram-negative rod showing the

peculiar morphology described by Jensen[4] for a species of *Agrobacterium*. Growth was abundant in most routine media; nitrates were reduced. Acid and gas were produced from glucose, fructose, mannose and maltose but not from arabinose, rhamnose, xylose, galactose, lactose and sucrose. Fats were not hydrolysed; urease activity was only slight and gelatine was hydrolysed.

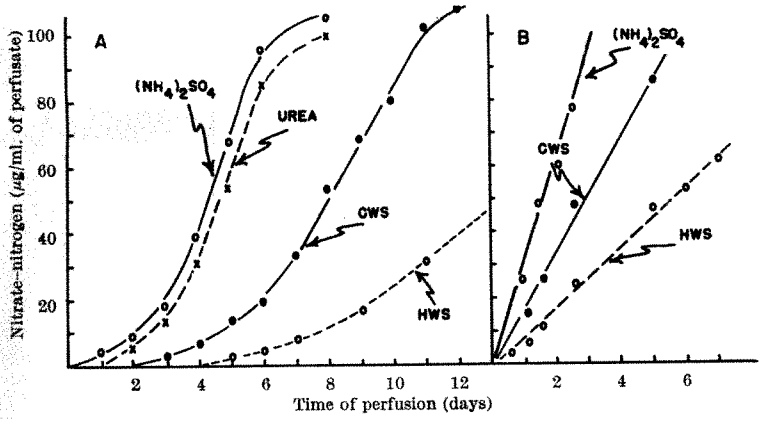

Fig. 1. *A*, Nitrification of ammonium sulphate, urea, CWS and HWS fractions of ureaformaldehyde in perfused Guelph loam. *B*, Nitrification of ammonium sulphate, CWS and HWS fractions of ureaformaldehyde in perfused Guelph loam previously perfused with CWS fraction.

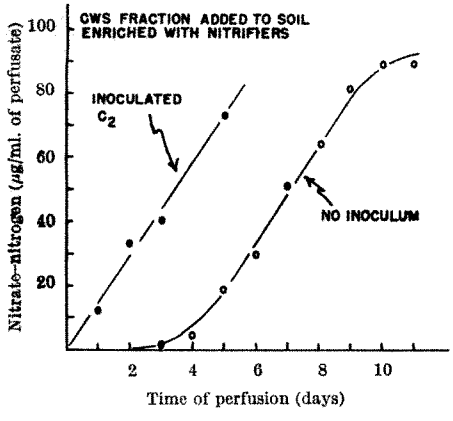

Fig. 2. Nitrification of CWS fraction of ureaformaldehyde in nitrifier-enriched, perfused Guelph loam, uninoculated and inoculated with CWS decomposing bacterium (strain *C*2).

To test the ability of this bacterium to mineralize the CWS fraction of ureaformaldehyde in soil, soils were first "enriched" with nitrifying bacteria by perfusing with N/100 ammonium sulphate solution and then washed free of nitrate–nitrogen. All units received a further CWS treatment and were then perfused again, one set not inoculated, the other set inoculated with $1{\cdot}5 \times 10^7$ washed cells (strain *C*2) per gram of soil. The results obtained are shown in Fig. 2. They indicate that this bacterium was one of those responsible for the decomposition of the CWS fraction, and provide further evidence for the biological nature of ureaformaldehyde mineralization in soil.

Distinctive Behaviour of *Eperythrozoon coccoides* in Plasma and Spleen of Infected Mice

Eperythrozoon coccoides is a minute organism of somewhat uncertain taxonomy, at present classified among the Protophyta[1] (order, Rickettsiales; family, Bartonellaceae). It is indigenous to mice and induces in them a mild disease characterized by splenomegaly and general lymphadenopathy[2]. It is frequently present in transplantable tumours[3] and it is possible that it is, in part, responsible for the splenomegaly which follows transplantation of such tumours. The pronounced synergism of *E. coccoides* with a variety of other infectious agents is now well known.

It was previously reported[4] that, on the fourth day after infection, the plasma of splenectomized mice was about one hundred times as infective as the plasma of intact mice; it appeared, therefore, that the spleen, though itself infective, was a deterrent to the activity of the plasma. The reason for this was not apparent, but it has served to direct attention to the distinctive behaviour of *E. coccoides* in the plasma and spleen as, for example, in thermal stability, and in the apparent association of *E. coccoides* with an inhibitor present in plasma but not in spleen.

Infectious material from mice was prepared[5] and two procedures used to determine biological activity according to methods previously described[4]. Both procedures used to determine biological activity depend on the increase in spleen weight of mice 7 days after intraperitoneal infection. One method expresses results as spleen weight per gram body weight; the other is more elaborate and expresses them in "50 per cent spleen enlarging dose" (SED_{50}) units. The SED_{50} is the infectious unit and is defined as the highest dilution of material which will produce a spleen weight of at least 10 mg/g body weight in 7 days in 50 per cent of the mice when inoculated intraperitoneally. In each method an experimental point represents an average result from five mice.

The thermal lability of *E. coccoides* in spleen extract and its stability in plasma are shown in Table 1. It can be seen that after incubation at 37° C for 30 min the titre of a spleen extract was reduced by more than 99 per cent, whereas that of plasma was unchanged even after 60 min at this temperature.

Table 1. Relative Stability of *E. coccoides* at 37° C in Spleen Extract and Plasma

Time at 37° C (min)	Log SED_{50}/0·1 ml. Spleen extract	Plasma
0	6·0	6·7
30	3·2	6·7
60	—	6·7

Fig. 1 suggests that *E. coccoides* is associated with an inhibitor present in infectious plasma. It illustrates a phenomenon repeatedly observed, namely, a marked increase in response of mice to successive dilutions of infectious plasma. The response reaches a maximum at a dilution of 1×10^{-3}, and decreases thereafter. Fig. 1 also shows that *E. coccoides* does not exhibit this behaviour in spleen extracts. These results are interpreted as indicating the presence in plasma of an inhibitor of *E. coccoides* loosely associated with the organism. Frozen plasma did not exhibit the increase in response on dilution that occurred with the same lot of fresh plasma; its SED_{50} units were, however, unchanged.

It has been reported[6] that *E. coccoides* was "entirely" dissolved by trypsin. This suggests that proteolytic enzyme activity of the spleen may be responsible for the

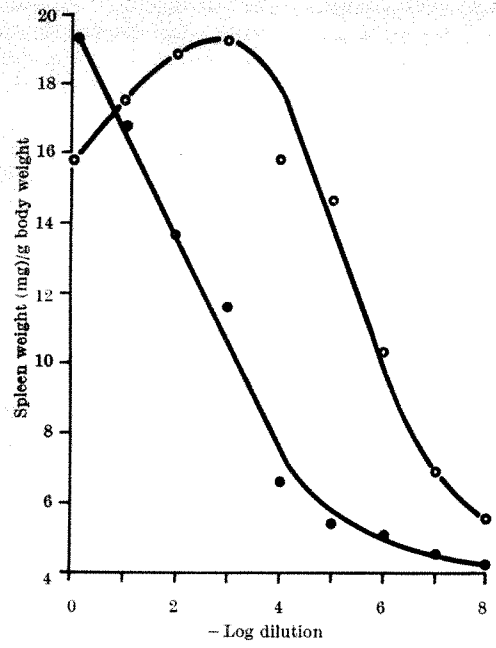

Fig. 1. Comparison of response of mice to dilutions of infectious plasma (○) and spleen extract (●).

lability of the organism in spleen extracts, and for the markedly lower infectivity of plasma of intact in relation to splenectomized mice. The stability of *E. coccoides* in plasma could be explained by the protection afforded it by the property of plasma to inhibit proteolytic enzyme activity[7].

The nature of the inhibitor of the pathological expression of *E. coccoides* that is responsible for the increase in spleen weight, and its site of action, are not known. It seems to be intimately associated with the organism and could, therefore, exert its action at this locus; on the other hand, it could affect the reactivity of the spleen *per se*, inasmuch as increase in spleen weight was the only index of infection used in these experiments. The inhibitor is unlikely to be a conventional antibody because, in contrast to antibody, it was no longer evident after the organism had been stored in the frozen state.

Evidence for such an inhibitor was not found in extracts of spleen, possibly for the same reason that *E. coccoides* is sensitive to incubation at 37° C in this milieu, that is, the inhibitor may be destroyed by the enzyme activity of the spleen.

This investigation was supported by U.S. Public Health Service grants and by an institutional grant to the Detroit Institute of Cancer Research from the United Foundation of Greater Detroit allocated through the Michigan Cancer Foundation.

VIROLOGY

Interfering Component of Vesicular Stomatitis Virus

INTERFERENCE during the replication of vesicular stomatitis virus (VSV) was first described by Cooper and Bellett[1], who suggested that the interfering activity which was present in viruses collected after several successive undiluted passages resulted from a transmissible component. Although they did not identify the component, evidence was presented that it was not the virion. Cantell *et al.*[2] obtained interference whenever a high multiplicity of infection was used, irrespective of the passage history of the virus. Studies in this laboratory[3] have shown that viruses collected from both high and low multiplicities of infection possess interfering activity, although repeated undiluted passage of virus is more likely to give a product with marked interference effects. These studies also showed that the interference does not result from interferon but is probably caused by an incomplete form of the virus.

Cells infected with VSV produce several complement fixing components in addition to the infective particle[4,5]. Among these is a particle which closely resembles the rounded end or "cap" of the virion. Hackett[6] suggested that this particle might be the interfering agent, and Huang and Wagner[7] reported that virus cultures of low titre produced by several successive undiluted passages consisted almost entirely of these smaller particles. The work described here shows that interference, in fact, arises from this small particle.

Virus of the Indiana sub-type was produced by infecting monolayers of baby hamster kidney cells (*BHK* 21—clone 13, ref. 8) at a low virus-cell ratio. The virus thus cultured was separated from cell debris by centrifugation at 2,000 r.p.m. and then fractionated by centrifuging in an *SW* 25 rotor for 2 h at 20,000 r.p.m. through a 15–45 per cent sucrose gradient. This procedure fractionated the virus suspension into four well defined peaks of complement fixing activity[5]. Peak *A* (fractions 7–11) contained the virion, peak *B* (fractions 12–16) consisted mainly of rosettes and helices together with the cap referred to above, and peak *C* (fractions 17–20) contained small rosettes. The antigens in peak *D* (fractions 21–23) were too small to identify in the electron microscope. These individual peaks were assayed for their interfering activity by measuring the depression of virus yield when monolayers of *BHK* cells were incubated with dilutions of the test material and then challenged with a small inoculum of VSV at a virus : cell ratio of $\leqslant 1:100$. The yield of infective virus 24–48 h after challenge was measured.

The results in Table 1 show that peak *B* contained the greater part of the interfering activity, although the virion fraction, peak *A*, was also slightly active. The high activity of peak *B* compared with the virion was confirmed by the observation that incubation with a 100-fold dilution of *B* depressed the yield of infective virus as much as undiluted peak *A*. It is of interest that

* P.F.U., plaque forming units.

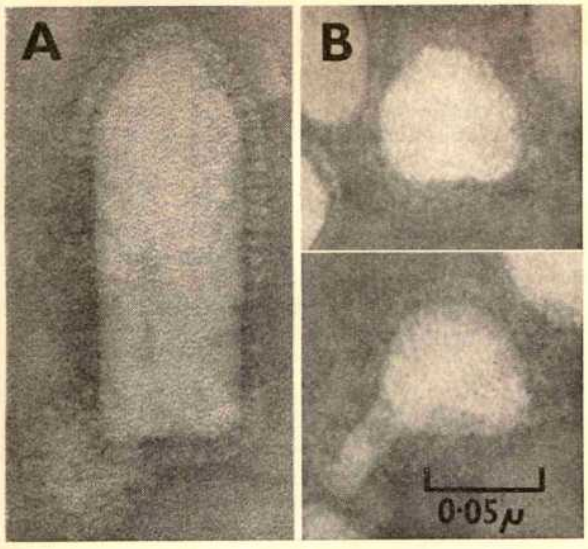

Fig. 1. Electron micrographs of (*A*) the virion and (*B*) the interfering component of VSV. The virion was isolated from a sucrose gradient and the cap from a tartrate gradient. Each sample was dialysed against 0·1 M ammonium acetate, stained with 3 per cent phosphotungstic acid, *p*H 6·0, and examined in a Siemens Elmiskop I electron microscope.

fractions containing considerable interfering activity delay the onset of cytopathic effects so that the sheets remain on the glass. This observation in itself can serve as a rough measure of interfering activity.

To ascertain whether the small activity of peak *A* was a result of contamination with components from peak *B*, portions of each peak were dialysed and then centrifuged through two separate sucrose gradients. The results of this experiment are also shown in Table 1 and provide evidence that the virion itself contains a small amount of interfering activity.

As the major interfering fraction is known to contain at least three components[5], it was fractionated further by centrifuging in a potassium tartrate gradient. A portion of peak *B* from a sucrose gradient was first dialysed to remove the sucrose and 0·5 ml. layered on a preformed gradient prepared from 2·4 ml. of tartrate, density 1·02 g/ml., and 2·0 ml. of tartrate, density 1·30 g/ml. After centrifuging for 2 h at 35,000 r.p.m. in an *SW* 39 rotor of the Spinco ultracentrifuge, fractions each of five drops were collected from the bottom of the tube. The refractive index and complement fixing activity of each fraction was determined. One sharp peak of complement fixing activity was found in fractions 9–13 (density 1·18–1·12 g/ml.) and a second more diffuse area in fractions 2–7 (density 1·27–1·19 g/ml.), which appeared to consist of two poorly separated peaks. On the basis of these determinations the fractions were combined into four groups and these were tested for interference. The results in Table 2 show that the entire activity was present in fractions 9–13. The density of the individual fraction

Table 2. INTERFERING ACTIVITY OF FRACTIONS OBTAINED BY TARTRATE DENSITY GRADIENT CENTRIFUGATION OF PEAK *B* FROM SUCROSE GRADIENTS

Fractions from gradient	Density (g/ml.)	Infectivity (P.F.U./ml.)	Complement fixing activity (ml. 1/30 *C′* fixed by 1 ml.)	Infectivity of culture in interference test (P.F.U./ml.)
1–4	1·29–1·24	11	1·0	$2·2 \times 10^8$
5–8	1·23–1·19	40	2·8	$1·8 \times 10^8$
9–13	1·18–1·12	$1·0 \times 10^4$	2·5	$3·3 \times 10^3$
14–21	1·10–1·02	$4·1 \times 10^3$	—	$2·3 \times 10^8$
Unfractionated peak *B*	—	$1·0 \times 10^5$	—	$2·3 \times 10^4$
Control for interference test minus tartrate	—	—	—	$2·0 \times 10^9$
Control for interference test plus tartrate	—	—	—	$1·3 \times 10^8$

containing the greatest interfering activity ranged from 1·13 to 1·15 g/ml. in five separate tartrate gradients. Fractions 9–13 were dialysed against 0·1 M ammonium acetate for examination in the electron microscope. The only component seen in this portion was the cap already referred to. This component bears a strong structural resemblance to the round end of the virion (Fig. 1); it is probably this similarity which accounts for its interfering activity.

We thank Mr. C. Smale for the electron micrographs.

Inhibition of Neuraminidase by Polyanions

THE function of viral neuraminidase (*N*-acetylneuraminate glycohydrolase, *EC* 3.2.1.18) during the reproductive cycle of myxoviruses is not yet clearly defined. It was therefore considered that potent inhibitors might be utilized to gain further insight into the role of this enzyme. In experiments involving the interaction of myxoviruses with phosphotungstic acid it has been found that this compound is a potent inhibitor of neuraminidases at extremely low concentrations. A closer examination of this phenomenon revealed that the anionic character of this substance is responsible for the effect. Different polyanions were tested and some of them were found to be even more effective inhibitors of neuraminidase.

The following commercial products with oligo- or polyanionic characteristics, respectively, were tested: phosphotungstic acid (Merck, Germany), silicotungstic acid (Merck), yeast RNA (Boehringer), heparin[1], mucin from porcine submaxillary glands (Sigma), sodium dextran sulphate (molecular weights of 2×10^6 and 4×10^4, Pharmacia).

To test the effect of these substances on the activity of neuraminidase, virus preparations obtained by differential centrifugation[2] of infected allantoic fluids of the following virus strains were used: Newcastle disease virus strains 'Italien' and 'Beaudette'; Parainfluenza 1/Sendai; fowl plague strain 'Rostock'; influenza *A* strain A_2/Singapore/57 (Asian)*, influenza *B* strain 'Lee'. In addition, experiments were done with bacterial neuraminidase from *Vibrio cholerae* (*RDE*, Behringwerke, crystallized) and *Clostridium perfringens* (Sigma, purified). The activity of the neuraminidases was measured by estimating free sialic acid after liberation from *N*-acetylneuraminic acid lactose ('Sialolactose' General Biochemicals, Chagrin Falls, Ohio, U.S.A.)[3]. The assay was performed with 0·1–0·3 ml. neuraminidase or virus (giving an optical density of 0·3–0·5), 0·1 ml. of phosphotungstic acid and 0·1 ml. (100 μg) of 'Sialolactose'[4]. All solutions contained either 0·1 M phosphate buffer (*p*H 7) or 0·1 M acetate buffer (*p*H 5·0).

As shown in Tables 1 and 2, polyanions were capable of inhibiting neuraminidase exclusively at acid *p*H. There was a 50 per cent inhibition of all viral neuraminidases tested at *p*H 5·0 by all the substances used at the concentrations indicated. Differences among polyanions were observed. Higher concentrations suppressed the en-

* The influenza concentrates were a gift of Behringwerke *AG*, Marburg, Germany.

zyme activity completely. The neuraminidase of *Cl. perfringens* was inhibited by all polyanions at *p*H 5·0. The 50 per cent inhibitory concentrations were, however, 10–1,000 times greater than for the viral enzymes. 2 μg/ml. of the polyanions inhibited *V. cholerae* neuraminidase to a limited extent (30 per cent) except for the silicotungstic acid, which gave 50 per cent inhibition. Higher concentrations of polyanions did not cause a greater inhibition: only 200 μg/ml. of phosphotungstic acid gave a 50 per cent reduction of the enzyme activity. The mucin, which is known to contain sialic acid, had a pronounced inhibitory effect at *p*H 5·0; however, no significant liberation of sialic acid from the mucin occurred under these experimental conditions.

Table 1. INHIBITION OF NEURAMINIDASE ACTIVITY AT *p*H 5·0 BY POLYANIONS

Virus or neuraminidase	Concentration (μg/ml.)* of polyanions for 50 per cent inhibition: RNA	Dextran sulphate 2×10^6 mol. wt.	Dextran sulphate 4×10^4 mol. wt.	Mucin (PSM)	Heparin	PTA	STA

* Final concentration of inhibitor in the reaction mixture; mean value of 2–4 estimations.

† Not tested.

To determine the activity of the neuraminidase the amount of sialic acid liberation from 100 μg of bovine 'Sialolactose' dissolved in 0·1 ml. of buffer was measured. The concentration of enzyme chosen was that which gave extinction values of 0·3–0·5 (representing from 15 to 25 units/ml.) (ref. 4). The total volume was 0·5 ml. in the reaction mixture. All reagents were dissolved in 0·1 M acetate buffer (*p*H 5·0) or 0·1 M phosphate buffer (*p*H 6·0 or *p*H 7·0). The enzyme was mixed with buffer and inhibitor at room temperature, placed in a water bath at 37° C for 5 min, and the reaction was started by the addition of 0·1 ml. of 'Sialolactose'. The enzyme reaction was carried out for 15 min and stopped by the addition of sodium periodate. The free sialic acid was determined by Aminoff's method (ref. 3). The concentration of inhibitor corrected for a final volume of 0·5 ml. of the reaction mixture which caused 50 per cent reduction of the enzyme activity was taken as the end point. PTA: phosphotungstic acid. STA: silicotungstic acid; NDV: Newcastle disease virus; PSM: from porcine submaxillary glands.

* Represents the enzyme inhibition by phosphotungstic acid before the designated procedure or added substances.

† Represents the enzyme inhibition after the designated procedure or added substances.

At *p*H 6·0 higher concentrations (0·02–200 μg/ml.) of polyanions were required to inhibit the neuraminidases of the Newcastle disease viruses; strains 'Italien' and 'Beaudette' and influenza B/Lee in contrast to Sendai, fowl plague and Asian influenza viruses, which were not influenced (Table 2). Phosphotungstic and silicotungstic acids (2 μg/ml.), respectively, however, inhibited all enzymes tested. Further experiments are in progress to determine whether the differences found are caused by the characteristic properties of the neuraminidases or to virus structure.

There is no correlation between the *p*H optimum of neuraminidases and the inhibition at *p*H 6·0 by certain polyanions. Newcastle disease virus neuraminidase is strongly inhibited by sodium dextran sulphate, whereas the enzyme of fowl plague virus is not affected, even though their optimal activity is at *p*H 6·0. On the other hand, the inhibitory effect of the anions shows a dependence on their molecular weight. A concentration of 0·02 μg/ml. of sodium dextran sulphate with a molecular weight of 2×10^6 has the same inhibitory effect as 3 μg/ml. of sodium dextran sulphate with a molecular weight of 4×10^4 (Table 2). The smaller one of the two polymers required a concentration 150 times as great as that of the larger one.

The only substance active at *p*H 7·0 was phosphotungstic acid (silicotungstic acid was not tested), which inhibited the neuraminidases of Newcastle disease virus, fowl plague virus and Asian influenza virus to 50 per cent, at a concentration of 150, 180 and 240 μg/ml., respectively. About 6,000 μg/ml. were needed to obtain a 50 per cent inhibition of *V. cholerae* neuraminidase at this *p*H value.

Phosphotungstic acid is known to precipitate proteins. Nevertheless, the inhibition of neuraminidases by this compound did not seem to be a simple denaturation of the enzyme, because it could be reversed by dialysis against 0·1 M phosphate at *p*H 7 (Table 3). Dilution with 0·1 M acetate at *p*H 5·0 also causes an almost complete reactivation of the enzyme activity (80 per cent). Inactivation was completely reversed by the addition of 0·5 per cent egg albumen (grade *V*, Sigma) into the enzyme–phosphotungstic acid mixture. Higher substrate concentrations also markedly reduced the inhibitory effect. An evaluation of these data by Dixon's method[5] indicated that a non-competitive inhibition was involved. On the other hand, reactivation did not occur on addition of raffinose, starch or tributyrin to the phosphotungstic acid-inactivated enzyme. The inhibition of neuraminidases by the other polyanions, however, was only partially reversed on addition of 0·5 per cent ovalbumin. An explanation for this different behaviour cannot yet be given.

Polyanions have been found capable of inhibiting neuraminidases at *p*H 5·0 and in some instances at *p*H 6·0 and *p*H 7·0. The concentration needed for 50 per cent inhibition of viral neuraminidases depends on the strain of the virus and on the type of polyanion and its molecular weight. Experiments are in progress to investigate the mechanism of the inhibition.

The data presented indicate clearly that there is an interaction between the myxovirus neuraminidases and phosphotungstic acid at *p*H 7·0. At this *p*H value, phosphotungstic acid is used for "negative staining" in electron microscopy. It is therefore suggested that the dark areas observed in electron micrographs of myxoviruses are not "holes", but may represent components which have bound phosphotungstic acid. This could mean that the surface of myxoviruses may not necessarily have "spikes", but may possess a lamellar-like structure made up of phosphotungstic acid-binding protein alternating with substances such as lipids and carbohydrates which do not bind phosphotungstic acid.

I thank Prof. R. Rott for his interest in this work. The study was supported in part by a grant from the Bundesministerium für Ernährung, Landwirtschaft und Forsten.

BIOLOGY

Distribution of Fat Body around the Air Sacs and Muscle Fibres in the Imago of *Oryctes rhinoceros*

In general, the fat bodies of insects are distributed in two anatomical positions: they exist as a peripheral layer beneath the epidermis and a perivisceral layer surrounding the alimentary canal. The lobes lie freely in the haemocoel; in most insects they are held in position by means of the tracheal branches, but in some the individual cells of the fat body seem to float freely in the haemocoel. In many insects the fat body fills all the available space within the body cavity, and can be seen to surround the visceral organs such as the gonads. They are never directly attached, however, to the organs, but are connected to them by means of tracheae. Recently, we have observed a unique distribution of the fat bodies in the imago of *Oryctes rhinoceros*.

The abdominal cavity is filled with innumerable air sacs of more or less uniform size. A casual observation does not reveal free fat body lobes in the haemocoel as in other insects. It can be seen from Fig. 1 that the fat body surrounds the air sacs in the form of a thin coat. Only seldom are air sacs found which are not surrounded by the fat body. The large tracheae are also invested by a layer of fat body (Fig. 2). Frequently, small independent lobes of fat body occur adjacent to the air sacs or large tracheae and are supplied with small branches of tracheae. Few such lobes, however, are present, and for the most part the fat bodies are distributed around the air sacs and tracheae.

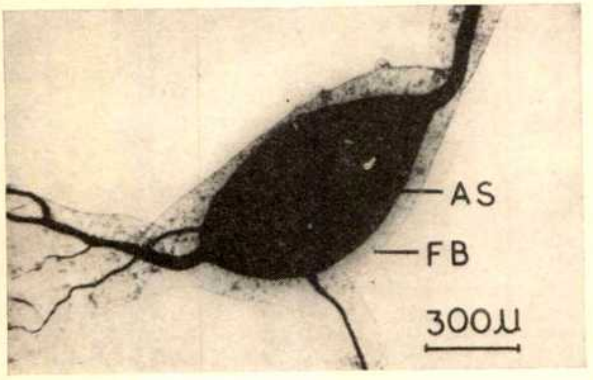

Fig. 1. Photomicrograph showing the distribution of fat body around the air sac in the imago of *O. rhinoceros*. *AS*, Air sac; *FB*, fat body.

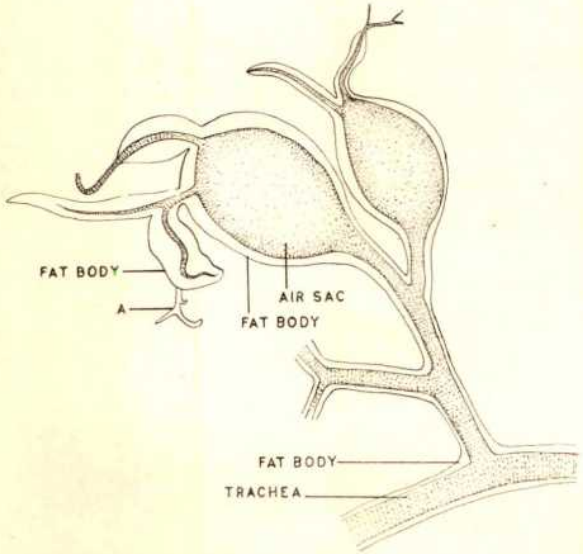

Fig. 2. Diagram showing the distribution of fat body around the air sacs and tracheae. *A*, Explanation in the text.

The fat body of the imago consists of much smaller cells than those of the fat bodies of the larva. The cell boundaries are not visible in paraffin sections of the fat body fixed in Bouin, but owing to a non-specific reduction of nitro-*BT* become clearly demarcated when a fresh fat body is incubated in media for succinic dehydrogenase activity. Attached to the fat bodies are small ribbon-like strands which consist of a double row of cells, arranged side by side, with large nuclei and homogenous cytoplasm (Fig. 2*A*).

In another beetle, *Heliocopris bucephalus*, which we examined, the air sacs do not possess a covering of fat body, and this would seem to apply to many other insects known to possess air sacs. The significance of the peculiar feature in *Oryctes* is not clearly understood. Lazarenko[1] demonstrated that the fat body of *O. nasicornis* is formed continually during larval development. He also showed that when a celloidine tube is introduced into the haemocoel between the lobes of fat body, a layer of connective tissue is first formed around the tube by the transformation of spindle-shaped haemocytes and then a large number of round blood cells is deposited on the surface of the connective tissue layer which later become transformed into fat body cells. In view of this, it can be suggested that the extensive surface area afforded by the tracheae and air sacs in the adult provides a suitable substratum for the formation of the fat body and that, concurrent with the development of the tracheal tubes and sacs, the adult fat body is also formed on their surface. Moreover, the existence of a thin layer of connective tissue around the trachea has also been demonstrated in the larva of *O. nasicornis*[1]. Because the distribution and structure of the adult fat body are different from that of the larva, it is evident that there is a total reconstruction of the fat body in the adult.

The distribution of the fat body around the air sacs may also have some functional significance. It seems possible that an insulation of the thin walled air sacs with a fatty layer would prevent an excessive loss of body heat from their extensive surface which is exposed through spiracular openings. Such an insulation would be of advantage in large flying insects which have to maintain a high body temperature during flight. A fatty interface between the body fluid and the tracheal surface would also safeguard against excessive evaporation of the body fluid.

Fig. 3 shows a muscle fibre from the metathoracic flight muscle invested by small thin lobes of fat body. These lobes are wound around individual muscle fibres leaving

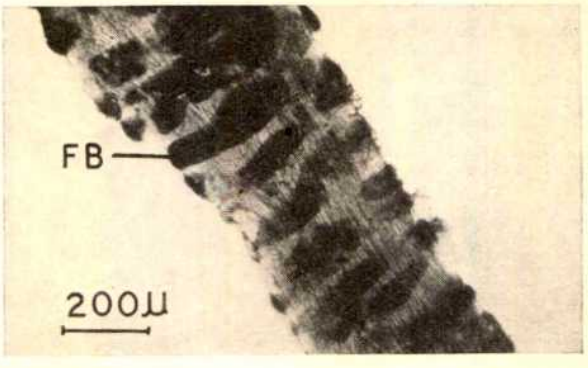

Fig. 3. Photomicrograph of a muscle fibre from the metathoracic flight muscle of *O. rhinoceros* showing the perifibral distribution of fat body. *FB*, A lobe of fat body.

narrow gaps in between. The fat body here has a structure similar to that around the air sacs and tracheae.

In vitro Formation of Adventitious Organs by *Pharbitis* Embryos

WHEN young *Pharbitis* embryos were cultured on an artificial medium, abnormal organs formed which had not previously been reported for embryo cultures of any other plants[1]. This communication presents some additional observations on the formation of the abnormal organs.

Young embryos of *Pharbitis nil* Chois, strain 'Tendan', were isolated aseptically from seeds by the same procedure as was reported previously[1]. The embryos were cultured either in a liquid medium consisting of a modified White's solution[2], 40 g/l. sucrose and 1,000 mg/l. casein hydrolysate, or on a medium which contained 9 g/l. agar in addition to the same components as the liquid medium. The media were steam-sterilized at 100° C for 1 h. Test-tubes, each with 10 ml. of the medium and one embryo, were maintained at 26° C under fluorescent light, and the embryos were transferred to the fresh medium every 2 or 3 weeks.

In the first series of experiments, approximately 10-day-old embryos isolated from the young seeds were placed in the liquid media. At this stage they were 1–4 mm long and were green. Although they were submerged in the media they grew well, and after a week or so were 1·5 cm long (Fig. 1). When embryos were kept in the liquid medium for more than about 1 week, the green cotyledons became discoloured in places and several grey spots appeared; furthermore, the root and plumule did not develop. Several days later, tiny protuberances, which could not be identified as callus or root, appeared circularly and exogenously around the hypocotyl near the radicle in all cultured embryos (Fig. 2). Such protuberances expanded gradually and sometimes appeared as an opening umbrella (Fig. 3). In the meantime parts of these outgrowths frequently stretched downwards into the medium and mostly resulted in petiolate outgrowths (see Figs. 4 and 5). Some petiolate outgrowths which were partially expanded at their "spearhead" had the appearance of an ascidial leaf. Microscopic observation revealed that such outgrowths possessed some poorly developed vascular bundles and minute sacs, which resembled oil sacs—normally only found in the cotyledon of this plant. This suggests that such adventitious outgrowths are of a cotyledonary nature. In prolonged liquid culture, the rate of development of these adventitious outgrowths usually declined, and the embryos did not develop either root or plumule; however, the green cotyledons with grey spots continued to expand and the hypocotyls to thicken.

In another experiment, embryos which had been cultured in the liquid medium for 1 week were transplanted on the agar medium. They were kept partially submerged in the agar medium—that is, the cotyledons were maintained above the surface of the medium and the hypocotyl in the medium. The cotyledons in the air lost

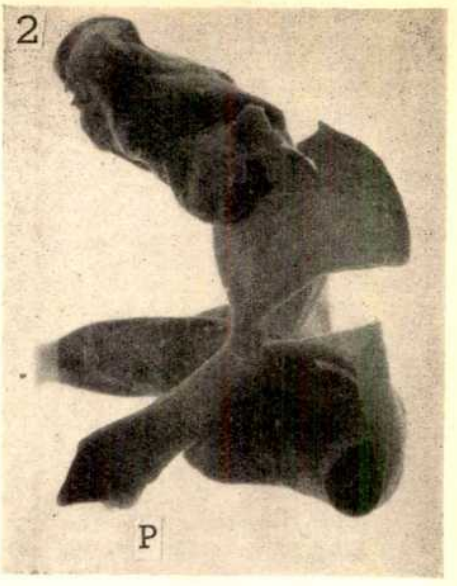

Fig. 2. *Pharbitis* embryo cultured in the liquid medium for about 3 weeks (× *c.* 2·5). Protuberances (*P*) occur circularly around the hypocotyl near the radicle.

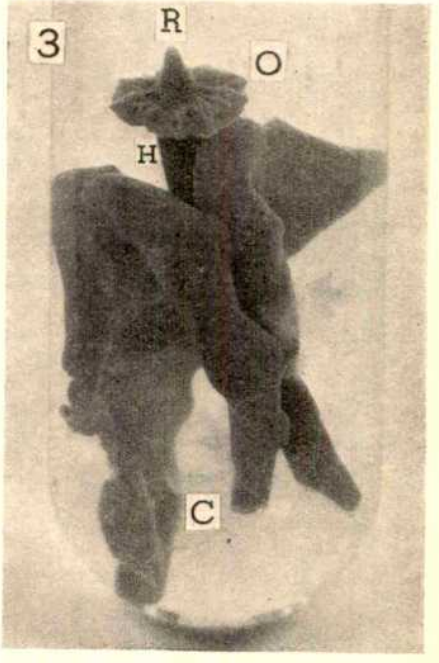

Fig. 3. *Pharbitis* embryo with an adventitious outgrowth similar to an opening umbrella (× *c.* 2·5). The embryo was cultured in the liquid medium for about 4 weeks. *O*, Outgrowth; *H*, hypocotyl; *C*, cotyledon; *R*, radicle.

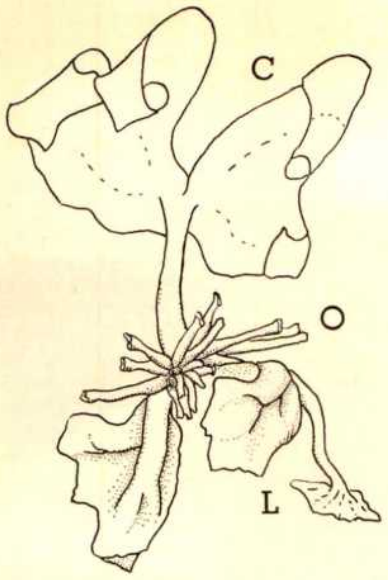

Fig. 4. Drawing of *Pharbitis* embryo cultured on the agar medium for about 1·5 months (×*c.* 2·5). The embryo developed the petiolate outgrowths like ascidial leaf and the cotyledonary "leaf blade" from the hypocotyl. *O*, Petiolate outgrowth; *L*, "leaf blade"; *C*, discoloured cotyledon.

chlorophyll and became pale one week after the transfer, while the hypocotyl in contact with the culture medium remained green in colour. After a further 2 weeks, the embryos attained 3 cm in height. Root and plumule did not develop, but the protuberances appeared from the hypocotyl and developed into the petiolate outgrowths. In the agar medium some of the petiolate outgrowths with partially expanding spearheads developed further into a "leaf blade" with veins in about 1·5 months (Fig. 4). Such a "leaf blade" possessed a number of sacs. This also suggests that the adventitious outgrowths from the hypocotyl are of a cotyledonary nature. In prolonged culture, some embryos with adventitious cotyledonary outgrowths developed a root and first leaf, followed by normal growth of the seedling.

In the second series of experiments, discoloration of the green cotyledons always occurred before initiation of the adventitious outgrowth (as was observed in the previous experiment). This suggests that the green cotyledons play an important part in the initiation of the outgrowths. In order to investigate this influence, three groups of cultures were prepared in the liquid media. In the first group the intact embryos were cultured. In the second group cotyledons were aseptically removed from the embryo 1 week after the start of the culture and only the remaining "hypocotyl" involving the radicle was cultured. In the third group "hypocotyl" and isolated cotyledons were cultured together in the test-tube.

The "hypocotyls" without cotyledons initiated the adventitious outgrowths most rapidly and vigorously, resulting in dishevelled outgrowths with irregular external forms (Fig. 5*a*). The intact embryos in the first group began to exhibit outgrowths later—after the grey spots had developed in the cotyledons—however, the "hypocotyls" cultured with the isolated cotyledons (third group) did not. This indicated that, whether or not the green cotyledon was isolated from the hypocotyl, its presence strongly suppressed the development of outgrowths. It is probable that the green cotyledons produce some diffusible substance which inhibits the development of outgrowths: the nature of this substance is as yet unknown. In prolonged culture, the "hypocotyl" of seedlings in the second group often developed a disfigured first leaf which possessed many sacs. This is believed to result from its cotyledonary nature (Fig. 5*b*).

In young seeds *Pharbitis* embryos are green, but on maturing they yellow. In the third series of experiments, embryos at various stages of development were isolated from the seeds and cultured in the liquid medium. All young embryos which had been isolated when they were green produced adventitious outgrowths within 3 weeks. On the other hand, when old yellowing embryos were cultured, they did not initiate any adventitious outgrowths but grew regularly and developed a root and normal first leaf; however, there were no sacs in the latter.

Thus, in summary, only young green embryos produced the adventitious cotyledonary outgrowths. Nevertheless, green cotyledons do have some inhibitory effect on the development of outgrowths. In other words, to initiate the outgrowth the embryo must be green at the beginning of the culture, but the cotyledon must be partially discoloured before the development of the outgrowths is initiated. It is possible that green hypocotyl without green cotyledon may be able to develop adventitious outgrowths.

Embryos cultured on the agar medium developed their normal first leaf later, and this did not have any sacs, whereas submerged "hypocotyls" of which the plumules were in contact with liquid medium developed the cotyledonary first leaf possessing a number of sacs. A component in the medium would therefore seem to be playing a part in causing such abnormal growth of the embryo.

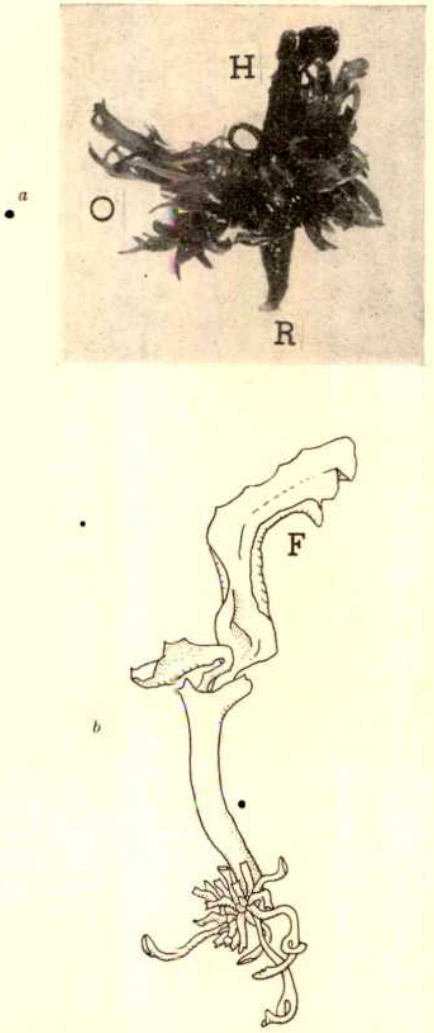

Fig. 5. "Hypocotyl" without cotyledons, developing dishevelled outgrowths (*a*) (×*c.* 1·5) and the cotyledonary first leaf (*b*) (×*c.* 2·5). *F*, Cotyledonary first leaf *H*, hypocotyl; *O*, petiolate outgrowth; *R*, radicle.

In the cultures the young embryos often germinated precociously without full differentiation during the early stage[3,4]. A high concentration of casein hydrolysate is known to retard such precocious germination and to prolong the embryonic stage[5]. The media used in our experiments contained 1,000 mg/l. casein hydrolysate and this might have suppressed normal germination and also caused the excessive cotyledonary outgrowth.

Respiration in Euphausiids

RESPIRATORY rates provide estimates of catabolism in organisms. These rates, together with estimates of anabolism (such as growth rates), are used to assess gross production (assimilation) rates, which themselves are necessary to an understanding of energy transfer in food webs. This communication reports measurements of the respiration of euphausiids (class Crustacea) collected off the Oregon coast in winter. The effect of temperature on respiration was evaluated, and length–weight relationships were determined in order to study the effect of body size on respiration.

The study was confined to the winter months because of the known seasonal differences in respiratory metabolism in certain species of *Calanus*[1,2]. Environmental conditions in our areas of collection are reasonably uniform between November and March. In the upper 200 m of water, temperatures range from 7° C to 10° C, and salinities vary from 32·50 to 33·75 parts per thousand.

The species of euphausiids used in all experiments were *Euphausia pacifica* Hansen and *Thysanoessa spinifera* Holmes, with *E. pacifica* predominating. We collected these animals with either half-metre or metre nets (mesh size 0·239 mm) and placed them immediately in wide-mouth jars containing water of similar temperature and salinity as that from which they were collected. We then placed these jars in black plastic bags and transported them in insulated coolers to a laboratory cold room maintained at 10° C. In the cold room the animals were once again transferred, this time to wide-mouth jars containing filtered sea water. No more than three euphausiids occupied any one jar, with a maximum of one animal per 300 ml. sea water. These jars were then returned to the black plastic bags and held in the cold room. The animals were fed mixed phytoplankton cultures sporadically, and those not used immediately in experiments were transferred to clean water every few days. With this treatment most of the euphausiids, particularly the larger animals, remained healthy for many weeks.

Measurements of respiration were made in a Gilson differential respirometer[3] in the dark. The theory behind this instrument and its application to respiration studies has been discussed by Umbreit *et al.*[4]. Rates determined in the respirometer compared favourably with those found by the Winkler oxygen technique. Using this latter method, we determined oxygen utilization by subtracting the oxygen concentration in bottles in which euphausiids had been kept for 3–6 h from the oxygen concentration in control bottles containing no animals.

Length–weight relationships were determined for the euphausiids using total length measurements and dry weights obtained by desiccation to constant weight with silica gel. Dry weights by desiccation did not differ significantly from those determined at 60° C in an oven.

The dry weight of *E. pacifica* used in these experiments varied as the total length raised to the 3·059 power, which indicates that this species in winter obeys the so-called "cube law". Dry weight of fourteen specimens of *T. spinifera*, on the other hand, varied as total length to the 3·731 power. This latter relationship supports visual evidence that in winter *T. spinifera* is fuller bodied for its length than *E. pacifica*.

Even though the specimens of *T. spinifera* used in our experiments were usually heavier than *E. pacifica*, their weight-specific respiratory rates were not significantly different. Thus, data for both species were dealt with together. The average weight-specific respiratory rate for winter euphausiids at 5° C was 0·75 ± 0·04 μl. oxygen/mg dry weight/h (thirty-three animals), where ± 0·04 sets the limits of the 95 per cent confidence interval. The average rate at 10° C was 1·28 ± 0·07 μl. oxygen/mg/h (thirty-eight animals), and at 15° C 1·61 ± 0·13 μl. oxygen/mg/h (twenty-four animals).

Conover[5] collected three unidentified euphausiids in August 1958 in slope water off the east coast of the United States at about 1,000 metres depth. The rate for these animals averaged 0·67 μl. oxygen/mg dry weight/h at 5·1° C. One of these animals, however, was reported to be in poor condition. A fourth animal respired at 1·29 μl. oxygen/mg/h at 5·1° C. From these meagre data we conclude that respiratory metabolism of euphausiids collected in deep water off the east coast of the United States in late summer is approximately similar to that of winter euphausiids off Oregon. Lasker[6] obtained an average of 1·4 μl. oxygen/mg/h at 10° C for *E. pacifica* collected off southern California.

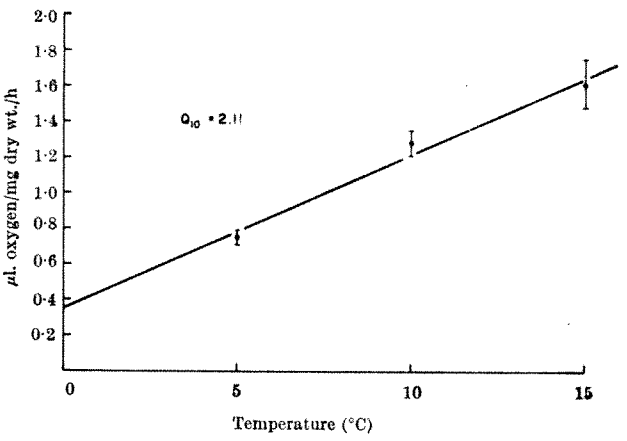

Fig. 1. Average weight-specific respiratory rates, with 95 per cent confidence intervals, of euphausiids from Oregon waters in winter, measured at 5°, 10°, and 15° C.

The Q_{10} for our animals was 2·11, and this was determined from the relationship between mean weight-specific respiratory rates and temperature (Fig. 1). This value clearly indicates non-acclimated respiration at 5° C and 15° C. We removed the euphausiids from the 10° C holding temperature to the experimental temperature 17–24 h before the beginning of each experiment. A Q_{10} of 2·11 under these conditions may indicate that euphausiids, often subjected to temperatures ranging from 5° C to 10° C in diel vertical migrations off Oregon in winter, do not acclimate to these temperature changes during their migrations. These results, in substance, support the hypothesis that a zooplankton that feeds in warm surface waters and "rests" in cooler waters gains an energy bonus that possibly can be put into fecundity[7].

Acclimation may occur with longer residence times in water of uniform temperature, but this remains to be tested with our animals. McWhinney[8] has demonstrated strong temperature acclimation in the Antarctic krill,

Euphausia superba, and Conover[2] has shown that the deep water copepod *Calanus hyperboreus* will regulate its respiratory rate within the known temperature range of the species. The temperature ranges for both these species are relatively narrow.

Respiratory metabolism (R), not corrected for weight and expressed as oxygen consumption per unit time, can be related to body weight (W) as:

$$R = a\,W^b$$

where a and b are constants. In a log–log plot of R and W, b is the slope of the line fitted by the method of least squares, and a the intercept on the y axis. The b values for our data were 0·962 at 5° C, 0·935 at 10° C, and 1·141 at 15° C (Fig. 2). Covariance analysis showed that the differences between these values were not significant at $P = 0{\cdot}05$. This indicated that temperature did not affect the proportionality of respiratory rate to dry weight; that is, the Q_{10} did not vary with size of the animal. For crustaceans, b generally is between 0·667 and 1·000, with such factors as physiological activity, sex, season, etc., affecting the actual value. A b value of 0·667 indicates proportionality of respiration to body surface area, and a b of 1·000 indicates proportionality of respiration to body-weight. In our studies, factors other than body size were controlled or minimized by experimental design, and respiration became a function of body-weight.

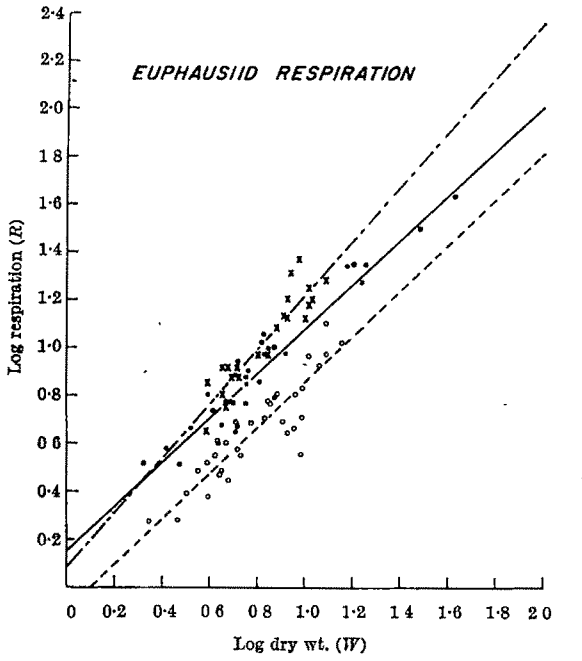

Fig. 2. Scatter diagram and regression lines showing the relationship between log μl. oxygen/h and log mg dry weight, at three temperatures. O - - - O, 5° C, $\log R = 0{\cdot}962 \log W - 0\,102$, $r = 0{\cdot}943$. ●——●, 10° C, $\log R = 0{\cdot}152 + 0{\cdot}935 \log W$, $r = 0\,960$. ×—·—×, 15° C, $\log R = 0{\cdot}083 + 1{\cdot}141 \log W$, $r = 0\,921$.

Our experiments led us to the conclusion that, in general, water temperature and body size are the two factors most significantly affecting the respiration of euphausiids during winter off the Oregon coast. Furthermore, over the weight range of animals used, neither Q_{10} nor weight-specific respiration varies with size, and no short-term temperature acclimation occurs. Whether these phenomena occur through all seasons remains to be determined. Differences might be expected in the spring and summer off Oregon, when food is abundant, surface waters are warmer, and reproduction occurs.

We thank Dr. H. K. Phinney of the Department of Botany, Oregon State University, for use of the Gilson respirometer and technical assistance.

Spermagglutination and Spermadsorption due to Myxoviruses

WHILE studying the interactions between germ cells and viruses, it was observed that spermatozoa of some mammalian and avian species were agglutinated by members of the myxovirus group. This phenomenon was designated as spermagglutination in analogy with haemagglutination. It was further observed that spermatozoa adsorbed to cells which were producing virus *in vitro*; this was called "spermadsorption". This communication describes these two phenomena as well as the conditions under which they occurred.

The bulk of the investigation was performed using bull and rooster semen. Bull semen was received as fresh and undiluted, individual or pooled specimens from an artificial insemination centre; rooster semen was collected from White Leghorn roosters between 6 months and 1 year of age, by the technique of abdominal massage[1]. Altogether, individual semen samples from ten bulls and five roosters were tested.

Semen samples were used up to 1 h after ejaculation unless they were kept for a longer time on purpose. Care was taken to avoid drastic changes in temperature while the semen was handled before the test proper. Before interfacting with the virus all semen samples were sedimented by centrifugation at 2,500 r.p.m. for 20 min, washed once in phosphate buffer (pH 6·0 for bull spermatozoa, pH 7·2 for rooster spermatozoa) and resuspended at a concentration of one per cent in the same buffer.

The viruses used were: one field and two attenuated vaccine strains[2] of Newcastle disease virus (NDV); the Melbourne and Formosa strains of influenza; local field strains of foot and mouth disease virus (types *O*, *A*, *Sat* 1); infectious bovine rhino-tracheitis (1 BR) virus; West Nile and Sindbis viruses. Anti-NDV and influenza hyperimmune sera were prepared in rabbits.

For the spermagglutination test, equal volumes of 1 per cent suspensions of spermatozoa and an appropriate virus dilution in the standard buffer were mixed. In the spermagglutination experiments for Sindbis and West Nile viruses, the procedure for haemagglutination of Clarke and Casals[3] was followed. Spermagglutination-inhibition as well as haemagglutination-inhibition tests were performed by titrating the immune sera against ten spermagglutinating or haemagglutinating units.

Spermagglutination was observed with bull, rooster, human and ram spermatozoa, and there were no qualitative differences between the individual samples. Under

the conditions tested, spermagglutination was observed only with the myxoviruses, NDV and influenza.

The phenomenon of spermagglutination manifested itself by the appearance of clearly visible macroscopic floccules which contrasted sharply with the homogeneous cloudy appearance of the non-agglutinated control suspension of spermatozoa. The time required for spermagglutination to occur was inversely proportional to the concentration of the virus and started in about 5–10 min. The final reading could be made after 60 min although after 30 min there was already a good indication of the titre. The floccules finally sedimented to form a typical dentated pellet, leaving a clear supernatant. Under the microscope, these floccules were observed to consist of aggregates of spermatozoa agglutinated by the mutual apposition of their heads with their tails vibrating at the periphery.

The following physico-chemical requirements for spermagglutination were determined: (1) *p*H: for bull spermatozoa the optimal *p*H range was between 6·0 and 6·6. At higher *p*H values, spontaneous agglutination was liable to occur. For rooster spermatozoa the optimum ranged from 6·5 to 7·2. The optimal *p*H for man and ram spermatozoa has not been studied, but spermagglutination occurred at *p*H 6·6. (2) Temperature: at 37° C, spermagglutination appeared sooner and to a higher titre than at room temperature. At 4° C there was practically no spermagglutination but when such samples were transferred within 1 h to 37° C, they showed the same titre as samples initially incubated at 37° C. (3) Electrolytes: spermagglutination was observed in the standard phosphate buffer, but it did not occur in isotonic 5 per cent glucose solution or when potassium ions were omitted from the standard buffer. The absence of potassium ions resulted in a reduction or loss of motility of the spermatozoa and because of this their agglutinability was diminished (see below). (4) Motility of the spermatozoa: a relationship was found between the motility and the agglutinability of the spermatozoa. Whenever the motility was impaired, it was reflected in the results of spermagglutination tests. Impairment of the motility to different degrees was provoked by heating to 45° C for 20 min or to 56° C for 10 min, by keeping the spermatozoa overnight at 4° C or by omission of potassium ions from the standard buffer. Of these, only the last was found to be reversible, as was cooling for 1 h only at 4° C. Although motility and its impairment could be evaluated by semi-quantitative means only (observing the fraction of motile spermatozoa and the magnitude of their motility), the results were nevertheless rather convincing. Gradual loss of motility coincided with gradual drop of virus titre in the spermagglutination test; immotile spermatozoa gave no spermagglutination. The specificity of spermagglutination produced by NDV and influenza viruses was shown by the spermagglutination-inhibition test with specific hyperimmune sera. Anti-NDV serum inhibited spermagglutination by NDV but not by influenza viruses, and the converse was found in reciprocal tests. The titre of the antiserum for each virus had similar values when measured by haemagglutination-inhibition or spermagglutination-inhibition. It was observed throughout the many trials that the titres of NDV and influenza strains were practically the same in the spermagglutination and haemagglutination systems (Table 1). It was further shown by adsorbing NDV to chicken red blood cells that the drastic fall of virus titre in the supernatant was reflected in spermagglutination and haemagglutination to the same degree. Recovery of the adsorbed virus by eluting it from the red blood cells restored its titre equally for spermagglutination and haemagglutination. Reduction of virus titre in the supernatant after adsorption to spermatozoa could be seen only when tested by spermagglutination and not by haemagglutination because it was found that spermatozoa and their washing fluids are themselves capable of agglutinating chicken red blood cells.

Spermadsorption, by analogy with haemadsorption, implies the attachment of spermatozoa to virus-infected monolayer of cell cultures. Bull and rooster spermatozoa showed this phenomenon only with NDV and influenza virus-infected cells. When infected monolayers of chicken embryo cells were allowed to interact with a suspension of spermatozoa for 10 min at 37° C, a massive adsorption of the spermatozoa to the monolayer could be seen under the microscope. 0·5 ml. of a 1 per cent suspension of spermatozoa for each culture tube was required for a clear picture. The firm attachment thus obtained could not be broken mechanically by washing or shaking (in contrast spermatozoa were floating and actively moving on the uninfected monolayers). NDV and influenza viruses could be titrated in this way (Table 1). The virus specificity of the spermadsorption was shown by inhibiting it; this was achieved by pretreating the infected cells with specific antiserum.

Bull seminal plasma was found to be a potent inhibitor of spermagglutination—sometimes active up to dilution of 1 : 1,000—while rooster seminal plasma showed a weak inhibitory activity. Bull semen, therefore, required to be washed before it was tested with the virus whereas rooster semen could be used directly once diluted to form a 1 per cent suspension. The seminal plasma exerted a similar inhibitory effect on haemagglutination having the same quantitative values. This inhibition could be completely abolished by treating the seminal plasma with potassium periodate and/or trypsin, but only partially by heating to 56° C for 30 min. It should be noted that the seminal plasma of different animal species is known to contain high levels of sialo-mucoproteins[4].

Table 1. COMPARATIVE TITRES OF MYXOVIRUSES BY SPERMAGGLUTINATION SPERMADSORPTION, HAEMAGGLUTINATION AND HAEMADSORPTION*

	CPE (TCD_{50}/ml.)	SAD (TCD_{50}/ml.)	HAD (TCD_{50}/ml.)	SA	HA

† Highest dilution showing clear spermagglutination or haemagglutination.

The agglutinability of spermatozoa from different species by myxoviruses points to the existence of viral receptors on the surface of these cells. This finding may not only provide an additional system for the rapid detection and titration of myxoviruses but may itself be of fundamental biological interest. The study should be extended to an investigation of other viruses and should be carried out under various experimental conditions. In addition to the ability to agglutinate, other parameters which might be influenced by viruses—namely, the motility and the metabolic activity of the spermatozoa—should be taken into account. Another point of interest is the possible part played by male-haploid cells as carriers of virus in congenitally transmitted viral diseases[5].

We thank Prof. N. Goldblum for his advice and interest in this work.

Recovery of Unengorged Larval Trombiculid Mites (Acarina) from Ground Holes

PREVIOUSLY it was found possible to identify the natural habitats of a limited number of species of larval trombiculid mites (chiggers) in Malaysia by recovering them from the ground on black 'Formica' plates[1]. In such habitats as were found, it was possible to observe with the naked eye chiggers both singly and in clusters. Only two species of chiggers have so far been subjected to intensive investigation using this recovery technique and both were vectors of scrub typhus, *Leptotrombidium* (*Leptotrombidium*) *deliense* (Walch, 1922) and *L.* (*L.*) *akamushi* (Brumpt, 1910). In the few localities studied by this means, the former was found in lalang grassland (*Imperata cylindrica*) and the latter on ground leaf-litter of secondary forest galleries[2]. In the course of current investigations of scrub typhus in the primary and secondary forests of Malaysia, we have collected a number of species of larval trombiculids—previously found only on small forest mammals—by insertion of a flat strip of black 'Formica' into ground holes.

The ground holes were probably formed as a result of activities of large animals, although some may have resulted from weathering. They are frequently to be found on the sides of escarpments or small mounds, among the roots of trees, and often in natural rock and earth fissures. In general, however, the holes which are infested occur in shaded areas; their interiors are cool, damp and usually free of litter or debris. Chiggers have been recovered from wide, low crevices on sloping ground and from holes which are as shallow as 4 in., and which vary in diameter from 2 in. to 6 in. Although the mites have generally been recovered from within 1–14 in. of the mouth of the hole, the maximum depth at which they are found has not yet been determined.

About half the holes which we have examined have yielded larval mites. The number of larvae recovered from a single hole may vary from one to more than two hundred. It was found that chiggers could best be recovered by simply inserting the 'Formica' plate into the hole for a second or so; its presence somehow stimulated the mites to drop on to it from the roof of the hole (where they were most frequently situated). (An investigation of the stimulus involved here is at present being carried out; so also is a search for nymphal and adult forms and the identity of their usual hosts.)

The specimens of *L.* (*L.*) *deliense* recovered from holes are white whereas those of *L.* (*L.*) *deliense* collected in abundance from established ground surface habitats are orange in colour. Indeed all but two of the twenty-five collected from holes were whitish in colour; the exceptions were *W. oudemansi* and *E. wichmanni*. The relationship between colour and habitat is also the subject of active investigations.

So far, twenty-five larval species, including several which have not previously been described, have been recovered from ground holes (Table 1). Thirteen of the twenty-five belong to the genus *Gahrliepia*.

Previous attempts to grow nine species of *Gahrliepia* under ambient laboratory conditions were not successful. Fourteen species of chiggers collected have now been successfully bred under conditions simulating the natural micro-environment[3]; seven of these had been recovered from open fields and plantations or from rodents trapped there, while the others were from more heterogeneous habitats. A knowledge of temperature, humidity and food requirements such as could be derived from further studies of these newly recognized habitats should enable us to breed gahrliepiines and other forest chiggers in the laboratory. Because of the relative ease with which these mites can be recovered, investigations of the bionomics of a large number of Malaysian mites and their possible role in the transmission of scrub typhus and other enzootic infections can now be put into operation.

Antagonistic Interaction between *Schistosoma mansoni* Sporocysts and Echinostome Rediae in the Snail *Australorbis glabratus*

IT has recently been shown that antagonistic interaction takes place when schistosome, strigeid or plagiorchiid sporocysts occur together with certain echinostome rediae in the same snail[1]. This interaction results in the total elimination of the first three groups of parasites. This communication discusses the antagonistic interaction between sporocysts of *Schistosoma mansoni* Sambon and rediae of an unidentified *Echinostoma* species in the snail *Australorbis glabratus* (Say).

The *Echinostoma* species was isolated from an *A. glabratus* collected near Recife, Brazil. It is morphologically close to *E. audyi*, but its exact identity is still under study. Cercariae of this echinostome encyst in various freshwater snails, including *A. glabratus*, and these cysts develop into adults when fed to chicks and ducklings. The strain of *S. mansoni* and the experimental snails were obtained from the National Institutes of Health, Bethesda, Maryland. Only albino snails were used because it is then easier to observe rediae and sporocysts and their interaction through the shells.

The *Echinostoma* sporocysts develop in the ventricle cavity of the snail, rediae mainly in the ovotestis but also in the liver, lung, kidney and mantle edge. Daughter sporocysts of *S. mansoni* migrate from the anterior of the snail, where the mother sporocyst develops, to the visceral mass. Development of both species of parasites is apparently normal so long as they occupy different areas in the snail. Observations made on thirty-six snails with double infection have shown that wherever schistosome daughter sporocysts and echinostome rediae are

in direct contact with each other interaction occurs. The sporocysts die and are consumed by the rediae. The mechanism by which sporocysts are killed is unknown, but this is presumably the result of direct mechanical action of the rediae since parasites not attacked develop normally and produce cercariae.

The rate at which sporocysts are eliminated depends largely on relative numbers of both species of parasites in the snail. *S. mansoni* sporocysts are usually numerous, while the rediae of *Echinostoma* species are relatively few, varying from 46 to 432 in snails dissected 19 to 81 days after exposure. Of these, 10–14 per cent are usually located in areas not occupied by the schistosome—that is, in the lung, kidney and mantle region of the snail—and do not participate in such interaction. Because of this, relatively few rediae are usually confronted with numerous sporocysts, which are gradually eliminated. Moreover, rediae of this *Echinostoma* species are active for only 4–5 weeks, after which they become smaller and sluggish and contain few or no larvae. These inactive rediae probably play no part in the interaction and ultimately die. New rediae continue to be produced (as there are many redial generations in this species), but the rate of interaction decreases steadily after the appearance of inactive rediae. Significant interaction is therefore confined to a limited period.

When schistosome sporocysts are already widely distributed in the visceral mass of the snail, newly produced rediae readily interact with them. The rate of interaction increases with the number of vigorous rediae, but declines rapidly as they become inactive. If echinostome rediae are already established in the snail, the rate varies with the stage of redial development at the time schistosome sporocysts invade the visceral mass and is negligible when many rediae have become inactive. Even in the presence of active rediae, however, many schistosome sporocysts may escape immediate destruction and produce cercariae. Sporocysts are first cleared from the ovotestis where rediae are most numerous, then from the distal part of the liver, regardless of which parasite first appears in the visceral mass. Sporocysts persist in the anterior of the viscera where rediae are usually few and sometimes absent.

Table 1 shows the results of interaction. The experiments were carried out at 26–29° C. Double infection was achieved in nine snails by simultaneous exposure to both species of miracidia and in these animals echinostome rediae arrived first in the viscera. In eighteen snails, *Echinostoma* infection was superimposed on *S. mansoni* infection with an exposure interval varying from 9–19 days. In nine other snails the sequence of exposures was reversed, with intervals varying from 7–19 days. Each snail was exposed to ten miracidia of *S. mansoni* and ten and fifteen echinostome miracidia. Nine snails were killed, twenty-six were kept until they died, and all were dissected.

In eleven snails clearance of sporocysts was slight (group 1 in the table) due to one or more of the following factors: too few rediae, early death of the snails, or arrival of *S. mansoni* sporocysts in the viscera after development of many inactive rediae. In fourteen snails (group 2) clearance was achieved in the ovotestis, in eight snails (group 3) also in the posterior part of the liver and in three snails (group 4) in more than half the liver. In one snail of group 3 and one of group 4, clearance occurred in large areas of the liver within a relatively short period because only a few schistosome sporocysts had migrated into the viscera, the majority probably still remaining within the mother sporocyst. When numerous sporocysts invade the visceral mass, clearance of large areas of the snail cannot be achieved quickly. Significant clearance was observed when *Echinostoma* infection was superimposed on *S. mansoni* infection and in snails with simultaneous exposure. Snails with *S. mansoni* superimposed on *Echinostoma* infection showed limited clearance.

Interaction between *S. mansoni* sporocysts and echinostome rediae in *A. glabratus* is similar to that between various trematode sporocysts and echinostome rediae in *Lymnaea rubiginosa* but with a different outcome. In the latter, interaction occurs rapidly; for example, when *Echinostoma audyi* Lie and Umathevy or *Echinoparyphium dunni* Lie and Umathevy is superimposed on *Trichobilharzia* infection, complete elimination of sporocysts is usually achieved before echinostome cercariae are produced, and the snails rarely shed both cercariae at the same time[1,2]. In the former, interaction is slow and only partial elimination of sporocysts is achieved; the snails always shed both species of cercariae. *Lymnaea* snails infected with these echinostomes always have abundant rediae. The difference in interaction is probably due to the larger number of rediae produced by *E. audyi* or *E. dunni* and their longer period of activity. Heyneman[3] introduced twenty-five to fifty *E. dunni* mother rediae into a clean snail and counted about 2,000 rediae 7 days later. Number and activity of rediae are probably related to suitability of the snail host. *Lymnaea rubiginosa* is easily infected with *E. audyi* or *E. dunni* showing high infection rates[2,4]. *A. glabratus* is less easy to infect with the *Echinostoma* species. *Lymnaea* snails are a better host for *E. audyi* and *E. dunni* than *A. glabratus* for the *Echinostoma* species.

Although interaction is direct between rediae and sporocysts, the relative degree of adaptation of both parasites to the snail host is probably of great importance. *E. audyi* and *E. dunni* are at least as well adapted to the snail host as the *Trichobilharzia* species, and *A. glabratus* is undoubtedly a better host for *S. mansoni* than for the *Echinostoma* species. *A. glabratus* is more easily infected with the schistosome (more than 90 per cent infected when exposed to ten miracidia each as compared to 30 per cent on exposure to ten to fifteen miracidia for the *Echinostoma* species). An echinostome species as well adapted to *A. glabratus* as *S. mansoni*, however, might give an efficient interaction.

Antagonistic interaction between rediae and sporocysts may be a feature of all echinostomes. It has been shown to occur in two species of Malayan echinostomes and is now demonstrated in a Brazilian species. The findings of Cort *et al.*[5] in Michigan, and of Martin[6] in Los Angeles, that echinostomes in the freshwater snail *Stagnicola emarginata angulata* (Sowerby) were not found in double infections with other trematodes and in the marine snail *Cerithidea californica* Haldeman only rarely, support this assumption. It would be interesting to know whether rediae of trematodes other than echinostomes are also capable of destroying sporocysts in the snail.

Table 1. EXTENT OF CLEARANCE OF *Schistosoma mansoni* SPOROCYSTS BY *Echinostoma* REDIAE IN THE SNAIL

Sporocysts distribution in snails	Duration of interaction	Number of snails: Simultaneous exposure	*Echinostoma* superimposed on *S. mansoni*	*S. mansoni* superimposed on *Echinostoma*	Total
1. Sporocysts in ovotestis and liver	4–35	2	5	4	11
2. Clearance of sporocysts in ovotestis	5–54	4	5	5	14
3. Clearance of sporocysts in ovotestis and ¼–½ liver	8–40	2	6	—	8
4. Clearance of sporocysts in ovotestis and more than ½ liver	9–36	1	2	—	3
Total		9	18	9	36

Colour Change in Flowers of *Lathyrus hirsutus* during Senescence

ALTHOUGH there has been some work on the nature of changes in flower colour during development[1–3], little is known about changes during senescence. The anthocyanin-pigmented flowers of *Lathyrus hirsutus* L. exhibit as they age a well marked colour change immediately before the petals show obvious loss of turgor. The mature standard petal is bluish red and it fades through blue to greenish blue; the wing petals are pale blue and fade to greenish blue. It was suggested in earlier work that blueness in mature flowers of *Lathyrus* species is promoted by flavonol glycoside co-pigments[3–5]. Thus it was found that the blue wing petals of *L. hirsutus* contain greater quantities of co-pigment relative to anthocyanin than the standard petals[4]. In this species the *p*H of the expressed sap of the wings was found to be rather higher than that of the standard petal, and it was suggested that this *p*H difference might contribute to the bluer appearance of the wing petal.

Three anthocyanins were found in the standard petal—namely, glycosides of delphinidin, petunidin and malvidin[4]. In the wing petals only the malvidin glycoside was detected, and this behaved chromatographically like the 3-rhamnoside, 5-glucoside identified in *Lathyrus* by Harborne[6]. It should be noted that the malvidin 3-rhamnoside attributed by Harborne[2] to *L. hirsutus* was, in fact, from the species *L. sativus* L.[7].

The present work was carried out to determine whether the factors believed to be involved in the determination of the colour of the mature petals are also involved in determining the colour fade.

Hydrolysed extracts of mature and faded flowers were prepared and then examined by filter-paper chromatography[4]. Determinations of the *p*H of expressed sap from other samples of petals were made with a micro-electrode[4]. Small but consistent differences of *p*H were found.

Table 1. CONSTITUENTS OF HYDROLYSED EXTRACTS AND *p*H OF EXPRESSED SAP IN RELATION TO PETAL COLOUR

Petal	Colour	*p*H	Anthocyanidins*			Flavonols	
			D	*P*	*M*	*Q*	*K*
Mature standard	Bluish red	5·6	+	+	+ + †	+	+
Faded standard	Greenish blue	6·1	–	+	+ +	+	+ + +
Mature wings	Pale blue	6·1	–	–	+	+ +	+ +
Faded wings	Greenish blue	6·7	–	–	+	+ + +	+ + +

* *D*, Delphinidin; *P*, petunidin, *M*, malvidin; *Q*, quercetin; *K*, kaempferol.
† + + +, + +, +, Relative quantities of constituents; –, not detected on chromatograms at loading used.

The results (Table 1) confirm that the mature wing petals differ from the mature standard petals in having a higher *p*H and a greater quantity of flavonol glycoside relative to anthocyanin. The data also show that as the standard and wing petals age, the *p*H of the expressed sap increases. The differences are not large but are likely to be important[8]. The chromatographic data (Table 1) clearly indicate that the faded petals, standard and wing alike, contain greater quantities of flavonol glycosides relative to anthocyanin than the mature petals. These changes could arise from a synthesis of flavonol glycoside, from a destruction of anthocyanin, or from a combination of both processes. To determine which of these processes is involved, quantitative estimations of total anthocyanin and flavonol glycoside were carried out. Samples of ten mature and ten faded petals were extracted with 1 per cent methanolic hydrochloric acid. The optical density of the extracts was determined at 535 mμ as an estimate of anthocyanin and at 260 mμ as an estimate of flavonol glycoside[3]. The results indicated that there is no significant change in the quantity of flavonol glycoside during senescence of either the standard or wing petals. The anthrocyanin content of the standard petals decreases by about 37 per cent as the tissue fades, however, and that of the wings falls by about 23 per cent.

It seems very probable that the fading of the petals of *L. hirsutus* results from an increase in the *p*H of the cell sap and to a greater influence of co-pigment, which results from a decrease in the quantity of anthocyanin present. Thus the same factors, co-pigmentation and *p*H, which were suggested as being responsible for the control of the colour of the mature flowers, appear also to operate in the control of the colour change during senescence.

Effect of Cycocel and its Analogues on Growth and Soluble Protein Content of Young Barley Seedlings

CYCOCEL, (2-chloroethyl)trimethylammonium chloride, and its analogues have a profound effect on plant growth[1–3]. The same cycocel analogues which retard stem growth[1,2,4] also inhibit gibberellin biosynthesis in *Fusarium moniliforme*[4], reverse auxin[5,6] and coumarin[5,7] inhibition of lettuce seed germination and root growth and accelerate abscission of petiole in cotton[8]. This communication describes an attempt to find a metabolic basis to explain the action of this class of compounds.

Barley (*Hordeum vulgare*, var. Besbar, 1965 crop) seeds were sterilized for 15 min with clorox (1 per cent) and washed thoroughly with running water. Twenty seeds were germinated in 9 cm deep Petri plates lined with one layer of Whatman No. 1 filter paper and moistened with 8 ml. of test solutions. Seeds were incubated in the dark at 25° C for 4 days. After this, coleoptile (with primary leaves) and roots (all seminal roots) were severed from each seed with a sharp razor blade, weighed and their length measured. In the case of root the length of the longest seminal root was recorded. Dry weight was obtained by drying the tissues at 65° C for 24 h. Coleoptile and root tissues, each weighing 250 mg, were homogenized in cold phosphate buffer[9] (*p*H 6·1) and centrifuged in the cold at 5,000 r.p.m. for 10 min. The supernatants were used for assay. Soluble protein was determined by the method of Lowry *et al.*[10]. Cycocel and choline were obtained from Eastman Organic Chemicals and Merck and Co., Inc., respectively. Other analogues used in this experiment were synthesized by Dr. N. E. Tolbert[1] and were kindly supplied by him.

The effects of various cycocel analogues on growth of coleoptile and soluble protein content at two concentrations are given in Table 1. Cycocel and (2-bromoethyl)-trimethylammonium bromide decreased coleoptile growth

Table 1. EFFECT OF ANALOGUES OF (2-CHLOROETHYL)TRIMETHYLAMMONIUM CHLORIDE ON GROWTH AND SOLUBLE PROTEIN CONTENT OF BARLEY COLEOPTILE

Ten randomly selected coleoptiles were used for fresh weight determination. Length is the mean length of ten coleoptiles.

Treatment	Dry* weight (per cent of fresh wt.)	Fresh* weight (mg)	Length ± S.E. (mm)	Protein (mg/g fresh wt.)
		5×10^{-3} M		
$(CH_3)_3N^+—CH_2—CH_2Cl\ Cl^-$	11·0	360	22 ± 3·8	13·6

* Weight represents weight of coleoptile plus primary leaves.

(length and fresh weight) but increased the soluble protein content of the tissue and dry weight (percentage of the fresh weight). With other analogues where growth was not significantly affected, neither protein content nor dry weight showed any significant difference from the control.

Table 2. EFFECT OF ANALOGUES OF (2-CHLOROETHYL)TRIMETHYLAMMONIUM CHLORIDE ON GROWTH AND SOLUBLE PROTEIN CONTENT OF BARLEY ROOTS

Seminal roots from ten randomly selected seedlings were used for weight determinations. The length of the longest seminal root from each of the ten seedlings was measured and length entered as mean of ten such roots

Treatment	Dry weight (per cent of fresh wt. (mg))	Fresh weight (mg)	Length ± S.E. (mm)	Protein (mg/g fresh wt.)
		5×10^{-3} M		
$(CH_3)_3N^+—CH_2—CH_2Cl\ Cl^-$	10 6	150	30 ± 6 1	15·1

Water	4·2	790	103 ± 18·1	10 0

Similar results were obtained in the case of roots (Table 2). Cycocel and (2-bromoethyl)trimethylammonium bromide reduced the length of root from one-third to one-fourth of the control at 5×10^{-3} M and nearly one-sixth at 10^{-2} M. Choline inhibited root growth by about 50 per cent at 10^{-2} M and this was accompanied by a considerable rise in soluble protein content and dry weight. Choline also had some inhibitory effect on the growth of coleoptile (Table 1).

The results show that the structural requirement for activity of the cycocel analogues is the same as reported earlier[1,2,4–8]. A trimethyl amine moiety plus a -chloride or a -bromide substitution in the carbon chain, as in cycocel and (2-bromoethyl)trimethylammonium bromide, are essential for maximum activity[1]. The naturally occurring analogue choline, with a hydroxyl instead of the halogen group, which has been shown to act as an anti-auxin in germination and root growth[6], was also significantly active in inhibiting coleoptile and root growth in the present work.

The mechanism of action of this class of compounds remains vague. It has been shown that there is a considerable rise in the oxidase and peroxidase activities of indolyl-3-acetic acid following growth retardation by cycocel and other growth retardants[11–13]. A decrease in diffusible auxin content has been shown following pretreatment with cycocel[14]. Furthermore, cycocel and its active analogues have been shown to antagonize auxin effects[6,14,15] in a variety of plant systems. The role of auxin in the growth of coleoptile and root tissues is fairly well known. Thus, it would seem that cycocel and its active analogues act by increasing the level of soluble protein or enzymes which are either unavailable or are destructive to the growth promoting system(s) in the coleoptile and root tissues.

We thank Dr. N. E. Tolbert, Department of Biochemistry, Michigan State University, for samples of cycocel analogues.

Effect of Oxindoles on the Growth of Tobacco Tissue Cultures

IT has been suggested that oxindoles are products of the enzyme oxidation of indolyl-3-acetic acid (IAA)[1,2], but they have generally been found to be inactive as auxins in standard auxin bioassays[3]. Galston and Chen[4], however, recently reported that isatin (indole-2,3-dione) and oxindole-3-acetic acid promote the elongation of etiolated and green pea stem sections. Isatin was also found to be active in stimulating the *in vitro* growth of *Pelargonium* pith tissue—a tissue which requires an auxin for growth[5]. In light of these findings, and the fact that oxindoles do not conform to generally accepted structural requirements for auxins, it was decided to test the effect of oxindoles as auxins on another system which requires an auxin, namely, the growth of tobacco pith tissue.

The tissue used in this investigation was derived from pith cells isolated from the stems of *Nicotiana tabacum* var. Wisconsin No. 38. The control tissues were grown on a basal medium[6] supplemented with $5{\cdot}7 \times 10^{-6}$ M IAA and $2{\cdot}3 \times 10^{-6}$ M kinetin (6-furfurylaminopurine). The test tissues were grown on the basal medium in which varied concentrations of oxindoles were substituted for the auxin or cytokinin additive. All tissues were grown in the dark at room temperature and at the end of the experimental period the fresh and dry weights were determined.

The results in Table 1 show that of the oxindoles tested for auxin activity only isatin, in the presence of kinetin, promoted growth of the tobacco tissues. This growth promotion was noted to increase as the isatin concentration increased. The maximum concentration of isatin used, 10^{-3} M, produced a growth approaching 50 per cent of that of the IAA control. The remainder of the oxindoles tested were either ineffective as auxins or inhibitory. The results of experiments shown in Table 2 indicate that the oxindoles tested are inactive as cytokinins, because in all cases none acted as substitute for kinetin.

The ability of isatin to substitute, at least partly, for the auxin requirement of tobacco pith callus tissue confirms the results found in *Pelargonium* tissues[4]. The possibility was considered that growth attributed to isatin resulted from a contaminant in the sample such as IAA. The melting-point of the isatin used in this

investigation, 201°–202° C, compared with that given for isatin in the *Merck Index*[7], however, and analysis of the sample by thin layer chromatography in two developing solvents showed but a single spot.

The relationship between structure and activity for auxins has been under investigation for many years. Many criteria hypothesized as necessary for auxin activity have been nullified by the finding of new active compounds. The longest standing structural requirement, to possess a carboxyl group[8], seemingly does not hold true for isatin. The auxin activity exhibited by isatin suggests a possible re-evaluation of the whole concept of structural requirement of auxins. Before such a modification is considered, however, more information must be obtained on the metabolic fate of isatin *in vivo*.

This investigation was supported in part by a U.S. Public Health Service postdoctoral fellowship from the National Cancer Institute. The oxindoles used in this investigation were kindly supplied by Dr. B. B. Stowe, Department of Biology, Yale University.

Effect of Seed Dressing with 'Granosan' on the Prevalence of Fungi in the Root Zone of Cotton Plants

VARIOUS investigators have reported that various environmental factors, such as temperature, moisture and light, influence micro-organisms in the vicinity of plant roots in two ways: directly, by affecting the rate of growth and multiplication of these organisms and influencing the availability of nutrients in the soil; and indirectly, by controlling plant growth and thereby affecting the nature and amount of root excretions[1]. Various factors affecting the interaction of micro-organisms and plant roots, such as the nature and age of the plant, the nature and treatment of the soil, and moisture content, have been studied by a number of workers[2,3]. Because seed treatment with fungicides is likely to influence the development of fungi in the vicinity of the roots of plants raised from treated seeds and because the consequences of any changes in the balance of micro-organisms in the soil could be harmful[4] or beneficial[5] to the plant, it was considered worthwhile to carry out a preliminary investigation of the effect of seed dressing with 'Granosan' on the prevalence of fungi in the vicinity of the roots of cotton plants.

This investigation was carried out in parallel with one on the effects of 'Granosan' in the control of damping disease of cotton under various sowing conditions in the United Arab Republic on the growth, yield and fibre characteristics of cotton plants. Soil samples were collected from the root zones of plants raised from untreated seeds or from seeds treated with 'Granosan' at the rate of 0·25 per cent by weight of the dry seed under the various experimental conditions. Using sterilized spoons, samples were collected from the root zone of cotton plants (usually at a distance of 7–10 cm from the root and at a depth of 5–10 cm in the soil); these were thoroughly mixed and kept in sterilized containers for further use. Five samples were taken at random from each replica of each treatment. The five samples of each replica were amassed in one composite sample which was thoroughly mixed. Finally, 10 g (calculated on an oven dry basis) of the mixed composite sample were used for determining the frequency of occurrence of the various genera of fungi by the dilution plate method.

We are fully aware that the soil dilution plate method of sampling soil microflora has been criticized by many workers. It was reported to be of little use in estimating the activity of fungi in soil, it favours fungi which sporulate heavily in soil, and it records only a certain number of the species present in the soil, because not all fungal segments and spores will enter into suspension or grow on plates. Warcup[7] considered the soil dilution method to be thoroughly justified in the case of cultivated soils, and Maciejowska and Williams[8] believed that this method of sampling was adequate for the determination of succession of soil microflora. The soil sample (10 g) was suspended into 100 ml. of sterile tap water in a sterile conical flask of capacity 0·5 l. The flask was shaken, using a mechanical shaker, for about 20 min after which dilution series were made under aseptic conditions (to 1/56,100) in sterile containers using sterile water. One-millilitre portions of the diluted suspension were transferred to each of a series of four sterile Petri dishes. Thus, sixteen Petri dishes were used for each treatment. A tube of melted agar (containing approximately 10 ml.) was cooled to 50° C and then added to each Petri dish. The dish was gently shaken to spread the agar medium evenly. All dishes were incubated at 25° C. The number of colonies developing in each dish was counted after incubation for 2–3 days. A record of the relative abundance of the main types of fungi occurring on the plates was made. The culture medium used for growing the inocula was peptone dextrose agar[9,10]. It had the following composition: 20 g agar, 1·0 g potassium dihydrogen *ortho*phosphate; 0·5 g

$MgSO_4.7H_2O$; 5·0 g peptone; 10·0 g dextrose; 1 l. distilled water; rose bengal 1: 30,000; 30 μg streptomycin/ml. Table 1 gives a representative set of the percentage of isolation of some of the more significant fungi which developed on the isolation plates, at 2-week intervals from April 5 to July 3, 1963. The results presented in Table 1 give the average values of the percentages of fungi isolated from soil samples in the root zones of plants raised under the various experimental conditions. The only variable recorded is that some of the seeds were treated with 'Granosan' at the rate of 0·25 per cent by weight of dry seed.

The general observation revealed by the results of this investigation is that the frequencies of occurrence were highest for the genera *Aspergillus*, *Fusarium* and *Penicillium* followed by *Mycelia sterilia* and the genus *Pythium*. Other fungi showed much lower values for frequency of occurrence. This may be explained by the fact that a relatively high temperature was prevalent in the United Arab Republic when the isolations were made (Fig. 1). It may be recalled here that Waksman[11], Werkenthin[12] and Jensen[13] reported that *Aspergillus* was more common in hot than in cold climates. Sabet[14] found that *Aspergillus* was fairly common in Egyptian soils and attributed this to the hot climate. Waksman[15] stated that the most common genera of fungi found in the soil, both in number of species and in frequency of occurrence, are *Zygorhynchus*, *Mucor*, *Rhizopus*, *Penicillium*, *Aspergillus*, *Fusarium* and *Cephalosporium*. Garrett[16] claimed that the delimitation of an ecological group of soil fungi is based primarily on the ability of such a group to function as pioneer colonizers of a particular substrate. Thus the "sugar fungi", represented mainly by Phycomycetes, are typically found as the first colonizers of injured or dead plant tissues in the soil. Fungi having the ability to decompose cellulose usually follow and most frequently comprise Ascomycetes and fungi imperfecti. This might explain the lower frequency of *Rhizopus* and *Mucor* in the soil used in the present investigation, since it had been cultivated for several years.

Statistical analyses of the results of this investigation revealed the following: (1) Seed dressing with 'Granosan' did not influence the frequency of occurrence of the great majority of fungal genera isolated. This was most noticeable for those genera which revealed the highest frequencies of occurrence. It should be mentioned here, however, that the failure of seed dressing with 'Granosan' to influence the prevalence of these fungal genera does not indicate that such seed treatment has no effect on the microbial population of the soil. The soil samples collected were from soil exposed only once to such seed dressing, and it is quite possible that repeated exposure of the soil fungal flora to the fungicide would affect the balance of such flora. (2) The percentage of isolations recovered on the isolation plates was found to be affected by the date of isolation. Generally speaking, the variations observed in the frequencies of occurrence of the fungal flora at the different dates of isolations fell into four groups: (*a*) Fungi the numbers of which increased on the isolation plates with time. This group included the genus *Cryptomella*. (*b*) Fungi the numbers of which decreased with time and this group included the two genera *Penicillium* and *Pythium*. (*c*) A third group of fungal genera which behaved irregularly with respect to the time of isolation and this included the genus *Sepedonium*. (*d*) Another group which revealed no appreciable change as regards frequency of occurrence at the various dates of isolation. This group included most of the genera, namely, *Aspergillus*, *Cephalosporium*, *Fusarium*, *Humicola*, *Mucor*, *Pullularia*, *Rhizopus*, *Scopulariopsis*, *Stachybotrys*, *Trichoderma* and *Verticillium*. The difference in behaviour of the various fungal genera can be attributed to various factors including soil temperature, and moisture, age of plant, and availability of nutrient material in the soil. No definite explanation of such behaviour can be given at this time, and this point will be further investigated.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, September 14

SOCIETY FOR ANALYTICAL CHEMISTRY, THIN-LAYER CHROMATOGRAPHY GROUP (at the Enfield College of Technology, Queensway, Enfield), at 2 p.m. —Meeting on "Some Applications of Thin-Layer Chromatography in Pharmacy".

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W 1), at 5.30 p.m.—Mr. J. Thomson and Mr. P W. Harrison: "The Development of a New HD Engine Oil for Marine Service".

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (in the Physics Department, Imperial College, London, S.W.7), at 6.30 p m.— Mr. D. A. Bayliss: "Problems of Paint Users".

Thursday, September 15—Friday, September 16

BIOCHEMICAL SOCIETY (at University College, Aberystwyth) 463rd MEETING. Programme will include Colloquia on "Training of Biochemists" and "Biochemistry of Herbicides".

Friday, September 16

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. W. T Underhill "A Four Tube Colour Camera".

Monday, September 19

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at Shell Centre, London, S.E.1), at 6.30 p.m.—Dr. V. E. Yarsley. "Hermann Staudinger, His Life and Work".

Monday, September 19—Wednesday, September 21

CHARLES SALT RESEARCH CENTRE (at the Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry, Shropshire)—Symposium on "The Biological Effects of Phytohaemagglutinin".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURERS (2) (with a good honours degree in chemical engineering and industrial/research experience) IN THE DEPARTMENT OF CHEMICAL ENGINEERING—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, 4, quoting Ref. 493/2 (September 14).

SCIENTIFIC OFFICER, BASIC GRADE (with a science degree) in the Serological Laboratories of the South London Transfusion Centre—The Director, South London Transfusion Centre, Stanley Road, Sutton, Surrey (September 14).

MEDICAL OFFICER (highly qualified in medicine and with extensive experience in cardiovascular research as well as in the organization of cardiovascular disease control programmes) IN THE HEADQUARTERS UNIT OF CARDIOVASCULAR DISEASES, GENEVA. Responsibilities will also involve planning, initiation and international co-ordination of research and control programmes in cerebrovascular diseases—Chief, Personnel, World Health Organization, Geneva, Switzerland (September 15).

SENIOR LECTURER IN SOCIOLOGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (September 15).

EXPERIMENTAL OFFICER (at least 26 on 1st January, 1966, with a degree, Dip. Tech., H N.C. or equivalent qualification in a scientific subject) in London, to provide support for the scientific staff whose task it is to implement the Council's policy over the whole range of its interests in the environmental sciences (geology, geophysics, hydrology, oceanography, marine biology, ecology and forestry)—The Natural Environment Research Council (E), Room 1221A, State House, High Holborn, London, W.C.1 (September 16).

LECTURER IN CLINICAL CHEMISTRY in the recently expanded DEPARTMENT OF CLINICAL CHEMISTRY, Queen's College, Dundee, and the Royal Infirmary, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee (September 17).

LECTURER or ASSISTANT LECTURER (mathematician with research interests in any branch of pure mathematics or mathematical statistics) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (September 17).

SENIOR LECTURER IN THE DEPARTMENT OF CHEMICAL PATHOLOGY—Prof F. T. G. Prunty, Department of Chemical Pathology, St. Thomas's Hospital Medical School, London, S E.1 (September 19).

SUPERVISOR OF PROJECTS IN THE DEPARTMENT OF SOCIOLOGY, to supervise and arrange research projects for graduate and undergraduate students— The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (September 23)

ASSISTANT EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER to work on selective herbicides in vegetable crops—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (September 24).

ASSISTANT LECTURER (preferably candidate who has worked in the field of insect physiology) IN ZOOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (September 26).

SENIOR LECTURER and a LECTURER IN MICROBIOLOGY at the University of the West Indies—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (September 26).

SENIOR LECTURER or LECTURER IN (*a*) the DEPARTMENT OF MEDICINE, and (*b*) the DEPARTMENT OF RADIOLOGY, University of Ibadan, Nigeria— The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W C.1 (September 26).

LECTURER IN BIOCHEMISTRY IN RELATION TO VETERINARY STUDIES— The Secretary of the University Court, The University, Glasgow (September 28).

LECTURER/SENIOR LECTURER (with a distinguished academic record and able to produce evidence of strong research interests and experience) IN THE DEPARTMENT OF STATISTICS, School of Mathematics, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 28).

LECTURER/SENIOR TUTOR IN MATHEMATICS at the Broken Hill Division, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 28).

TEMPORARY LECTURER or DEMONSTRATOR IN ANATOMY—The Registrar, University of Bristol, Senate House, Tyndall Avenue, Bristol, 2 (September 28).

LECTURER IN MEDICAL CARDIOLOGY—The Secretary of the University Court, The University, Glasgow (September 30).

LECTURER or ASSISTANT LECTURER (with experience in, and a good theoretical understanding of, public health engineering and hydrology) IN THE DEPARTMENT OF CIVIL ENGINEERING—The Registrar, The University, Leeds, 2 (September 30)

LECTURER (or possibly, initially, a Departmental Demonstrator) IN PALAEONTOLOGY IN THE DEPARTMENT OF GEOLOGY AND MINERALOGY— The Prof of Geology, Department of Geology and Mineralogy, University of Oxford, South Parks Road, Oxford (September 30).

LECTURER (with a distinguished academic record) IN CHEMISTRY at the Broken Hill Division, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

PATHOLOGIST (Forensic Medicine) (with appropriate professional qualifications and relevant experience) IN THE MINISTRY OF HEALTH, Republic of the Sudan—Appointments Section, Sudan Embassy, 3 Cleveland Row, London, S.W.1, quoting Ref. 4/1200 (September 30).

SENIOR LECTURER (with full training in psychology and special experience in clinical psychology and preferably a higher degree Ph.D. or equivalent) IN CLINICAL PSYCHOLOGY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 30).

TUTORS or SENIOR TUTORS IN THE DEPARTMENT OF MATHEMATICS—The Registrar (Appointment E. 74), The University of Melbourne, Parkville, N.2, Victoria, Australia (September 30).

JUNIOR RESEARCH FELLOW IN GEOGRAPHY; and a CLIMATOLOGIST (preferably honours graduate in geography and/or physics, mathematics or meteorology) to work in a research unit in the DEPARTMENT OF GEOGRAPHY— The Registrar, The University, Sheffield (October 1).

RESEARCH ASSISTANT (with an honours degree in botany, or an equivalent qualification, and preferably with some field knowledge of bryophytes) IN THE DEPARTMENT OF BOTANY to assist in an investigation of the environmental control of reproduction in bryophytes—The Assistant Registrar (Science and Engineering), The University of Birmingham, P.O. Box 363, Birmingham, 15 (October 1).

SUB-LIBRARIAN (graduate, with a professional qualification in librarianship, and appropriate senior experience)—The Secretary, Royal College of Advanced Technology, Salford, 5, Lancashire, quoting Ref. LY/19 (October 2).

SENIOR LECTURER (with a good degree, preferably honours, extensive experience in teaching, advisory or research work in agriculture, and preferably an interest in possible changes in agricultural education) IN AGRICULTURE—The Secretary, The West of Scotland College of Agriculture, 6 Blythswood Square, Glasgow, C.2 (October 5).

PROFESSOR OF MATHEMATICS at the University of Queensland, Australia— The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, October 14).

PROFESSOR (with a medical qualification registrable in the State of Queensland, extensive experience in some branch of pathology, evidence of substantial achievements in research, and preferably some teaching experience) OF PATHOLOGY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, October 14).

SENIOR LECTURER (Pure Mathematics) at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 15).

CHAIR OF AGRICULTURE at Makerere University College, Uganda (The University of East Africa)—The Inter-University Council, 33 Bedford Place, London, W C.1 (October 22).

CHAIR OF MICROBIOLOGY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 25).

PROFESSOR OF PHYSICS (Theoretical) at Flinders University of South Australia, Bedford Park, South Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 31).

SENIOR LECTURER (with an honours degree in electrical engineering or science, and preferably a higher degree; and research or design experience in fields related to digital computers or digital data-processing and instrumentation systems) IN ELECTRICAL ENGINEERING at the University of Adelaide, South Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 31.)

READER IN HISTORY AND PHILOSOPHY OF SCIENCE—The General Board Office, University of Cambridge, The Old Schools, Cambridge (November 16).

ASSISTANT EXPERIMENTAL OFFICERS for (*a*) work on identification and estimation of volatile substances which inhibit the sprouting of potatoes: and (*b*) experiments on the metabolism and storage of soft fruits and vegetables—The Secretary, A. R. C. Ditton Laboratory, near Maidstone, Kent.

BIOCHEMIST (with a degree, or equivalent, in biochemistry) IN THE DEPARTMENT OF ANAESTHETIC RESEARCH, to join a team engaged in work on isolated liver perfusion experiments and on intracellular *p*H measurements—The House Governor, The London Hospital, Whitechapel, London, E 1.

DEMONSTRATOR (graduate in biochemistry or chemistry) IN BIOCHEMISTRY —The Acting Registrar, University College of Wales, Aberystwyth.

PHYSICIST to work on the physics of radiotherapy, clinical applications of radioactive isotopes, and radiation protection—The House Governor, St. Mary's Hospital, London, W.2.

POSTDOCTORAL FELLOW IN BIOCHEMISTRY for work which will involve studies on the control of metabolism by the thyroid hormones—Prof J. R. Bronk, Department of Biology, University of York, Heslington, York.

RESEARCH WORKER (with an interest in the physiological basis of animal behaviour)—The Secretary, Institute of Psychiatry (University of London), The Maudsley Hospital, Denmark Hill, London, S.E.5.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Concrete Block Walls. Fourth (revised) edition. Pp. 32. (London: Cement and Concrete Association, 1966.) 7*s*. 6*d*. [77

The Association of Clinical Biochemists. Scientific Report No. 2: Colorimeters—a Critical Assessment of Five Commercial Instruments. Pp. 62. (Liverpool: Mr. J. T. Ireland, Biochemistry Laboratory, Alder Hey Children's Hospital, 1966.) 15*s*. (Members of the Association, 10*s*.) [77

Philosophical Transactions of the Royal Society of London. Series B: Biological Sciences. No. 766, Vol. 250 (7 July 1966): The Fine Structure of the Centriolar Apparatus and Associated Structures in the Complex Flagellates *Trichonympha* and *Pseudotrichonympha*. By A. V. Grimstone and I. R. Gibbons. Pp. 215–242+plates 22–48. 50*s*.; 7·50 dollars. No. 767, Vol. 250 (7 July, 1966): Investigations Into the Causes of the Rise in Aldosterone Secretion During Haemorrhage, Parts 1 and 2. By Magarethe Holzbauer and Marthe Vogt. Pp. 243–310. 25*s*. 6*d*.; 3.80 dollars. (London: The Royal Society, 1966.) [77

The Overseas Development Institute. French Aid. By Teresa Hayter. Pp. 230. (London: The Overseas Development Institute, 1966.) 20*s*. [87

IS SCIENCE POLICY POSSIBLE?

THE most remarkable feature of the OECD report on science policy in France, briefly reported on page 1226 of this issue, is that it should ever have been produced. Governments are notoriously but understandably reluctant to give outsiders bent on publication an opportunity to discover not merely what policy consists of but how it has come to be constructed. No doubt the French Government was emboldened by the knowledge that the same kind of examination and inquisition would be conducted in other nations belonging to the OECD. (By the same token, readers of the report on France will have their appetites whetted for what there is to come from elsewhere.) A more delicate means of knocking heads together could hardly have been devised.

The report on France is also remarkable for showing that many of the problems which preoccupy the French Government and its machinery for administering science policy are the same as those which appear as almost exclusive national concerns elsewhere. In France, for example, as in Britain and in the United States, the recruitment of teachers of science and mathematics cannot keep pace with the demand for them. In France as elsewhere, the arrangements for higher education, based as they are on long and cherished tradition, are found to be less than perfect means of training young people in the skills of research and then putting them to work where they are most needed. Then France is not the only country in which major decisions, affecting the whole balance of effort within science and technology, are often made without reference to the committees appointed ostensibly to give advice on scientific matters; if chauvinism has influenced some of the decisions on the use of scientific resources in France, so too must it be held at least partly responsible for the space programmes of the United States and the Soviet Union, and for the over-ambitious aircraft projects which from time to time hang themselves like albatrosses around the neck of the British Treasury. Finally, though French administrators are as much at a loss as their counterparts elsewhere to know what criteria to use in the deployment of scientific resources, they are at least manfully trying to find out.

Not all the problems identified in the report are common problems, however. The problem of the *Grandes Écoles* is, for example, uniquely that of France. The OECD report likens the pyramidal educational system to a distillation column, and says that in France there are really two distillation columns in parallel—the *Grandes Écoles* and the ordinary universities. The prestige of the engineering diplomas awarded by the *écoles* goes back to Napoleon, but the traditions which were once a great advantage now seem to be impediments to progress. Obviously it is a serious matter that the *écoles* cream off the best potential scientists and engineers and then somehow assure that they finish up in industry or public service but only rarely in research. This state of affairs may be the envy of those who regret that academic research often has too much pull in countries such as Britain, and it is probable that the flow of graduates from the *écoles* into French industry has something to do with the economic successes of recent years, but in the long run there can be no doubt that the separatism built into French higher education must be bad for science—in industry as well as in the academic laboratories. The OECD report points out that the *École Polytechnique* has taken the lead in showing how vigorous schools of research can be grafted on to the usual intensive *polytechnique* course, and how there are moves to increase the liaison between the *écoles* and the universities, partly by making diplomas and degrees interchangeable and partly by seeing that entrants to the science faculties at the universities should have had some reasonable preparation for the courses they wish to follow. It is plain, however, in spite of the reforms of higher education announced earlier this year (and after the OECD examiners had finished most of their work) that there is still a long way to go. In France, the strictures of the OECD committee may seem insensitive to the great (and undoubted) virtues of the *écoles*, but in the long run should have some of the advantages of the comment from the small boy who first said that the emperor had no clothes.

What the report has to say about the balance of industrial research in France—and which it might well have been saying about most other countries in Western Europe—is less convincing, though this is tricky ground. The essential question is to know what benefits are to be derived from the investment of effort in industrial research and development, and the OECD inspectors are right to say that there should eventually be great value in the careful and comprehensive studies now being made in France of the relation between research and economic benefit in all kinds of industries. This said, it is unfortunate that the report wanders off, somewhat aimlessly, into a discussion of what is called the "technological balance of payments"—the difference between the royalties which a country pays on foreign patents and the licence revenue which it earns from abroad. The implication seems to be that the ideal state of affairs should be one in which these two sums are in almost exact balance, and that effort spent on research should be increased until one side of the balance sheet cancels out the other. But is this necessarily the case? Earning patent royalties is not, after all, the only way of making money.

The examiners are much more sure of themselves on the machinery of the administration of science. From what they have to say, there are obviously great advantages in the existence of the Delegation-General for scientific research—a permanent secretariat serving both the ministerial committee responsible for major policy decisions (and for the final allocation of the budget) and the advisory committee of scientists responsible for making recommendations on these matters. The size and competence of the secretariat are obviously the chief reasons why it has been possible to sustain such a rapid rate of growth of science in France in recent years without too much absurdity. Yet even so, it has not been possible to iron out all the awkward ups and downs in the scale of financial support. Worse still, the consultative machinery seems to have worked less effectively than the examiners would have wished, so that major decisions have been made on grounds which are too exclusively political.

The essential difficulty is the conflict of interest there is almost certain to be between a nation and the scientific community embedded within it. The objectives of the two entities do not necessarily coincide. The extent to which the United States and the United Kingdom were committed to defence research and development in the decade after the war, inevitable though it may have been, often created a fearful unbalance of the pattern of scientific work. (It is to be hoped that the Government of France will not now feel it necessary to mimic the full extent of this pattern; the OECD examiners were alarmed by some of the signs they thought they could discern.) More recently, the space programme in the United States has not been precisely what scientists themselves, with the interests of their craft in mind, would have dictated. But to ask that the efforts of scientists should be deployed only in ways that suit scientists themselves is to ask too much. It is, of course, entirely respectable that the efforts of scientists should be consciously directed at practical objectives. But is it, then, that the relationship between a nation and its scientists should be like its relationship with its armed services? Is it for society to decide what science should attempt, and for scientists to do society's bidding? This thin analogy seems to lie behind some of the machinery for making decisions in France—and elsewhere. But this, too, is an untenable extreme. One difficulty is that objectives defined from outside may prove to be unattainable. More serious, there is the real danger that objectives which are too rigid or too unreal may rob science of its own self-generating intellectual excitement which, in the last resort, is its only stock in trade. Finally, this same excitement is itself a help in defining realizable and valid objectives. All of this argues in favour of a much better balance—in France and elsewhere—between the interests of governments and scientists in the definition of objectives. Most probably, no system of committees will ever be sufficient. The real need is for some much more vigorous involvement of working scientists in the definition of what their work is for.

NEWS AND VIEWS

Home for Microscopes

THE Royal Microscopical Society is one of the most vigorous of the learned societies in Britain. Far from being a kind of club for those concerned with the technology of building microscopes, it has a catholic interest in all those fields of science in which the micron and the ångström are in common usage. It is therefore sad to see the society having to hunt around for a permanent headquarters outside London. The rent of the present offices in Tavistock Square is being enormously increased according to Dr. John Baker, chairman of the society's council, who feels that the society cannot afford to remain in London. He would like to see the society move to another town, probably close to a university, where it could house its offices, microscope collection and laboratories for its courses in optical microscopy. The monthly meetings would still be held in London.

While the council can make no definite plans until a decision is made by the members, they are investigating various sites. One possible site in Oxford was turned down by the City Council because the city wanted the site, but Dr. Baker stated that Oxford is still very much a possibility. Wherever the society decides to go they will certainly be welcomed, but this hunt for living space may be regarded by some as yet another sign of the need for a more generous provision of board and lodging for British societies.

Atomic Agriculture

THE International Atomic Energy Agency of the United Nations is giving Yugoslavia more than 600,000 dollars worth of equipment for research at the Zemun Institute for the Application of Nuclear Energy in Agriculture, Veterinary Medicine and Forestry. The Yugoslav government has contributed about two million dollars worth of buildings, equipment, training and general expenses to make the institute the centre of agricultural research in the country. During the last three years the United Nations Development Programme, with the IAEA acting as the executive agency, has cooperated with the Yugoslav Federal Nuclear Energy Commission in one of the programme's biggest single projects for applied research and training. With this combined support, the institute has undertaken extensive studies of soil fertility and plant nutrition, use of ionizing radiations to produce mutants for plant breeding, and animal nutrition and health protection.

American Rock Names

THAT much has flowed down the geological rivers of North America since 1936 is plainly obvious from the latest milestone in publications from the U.S. Geological Survey. The three volumed *Lexicon of Geological Names of the United States for 1936–1960* (*U.S.G.S. Bulletin 1200*, Washington, D.C., 1966. $13) is the sixth such compilation to come from the Survey since F. B. Weeks's *North American Geologic Formation Names* was published in 1902.

The present 4,340 page work is an admirable successor to Wilmarth's monumental lexicon of 1938. As before, the area covered includes the United States, its possessions, the Trust Territory of the Pacific Islands and the Panama Canal Zone.

In all, 14,634 names are included, together with summaries of stratigraphical papers which were published between January 1, 1936, and December 31, 1960. The number of such abstracts and "original references" now exceeds 35,000. The lexicon differs from Wilmarth's in that it omits all palaeontological and descriptive terms, trade names, moraines, orogenies and miner's terms.

Obviously there has been erosion of many geological names and also deposition of numerous new ones in the literature. Enthusiasts of the "Western" cult will be disappointed to learn that the U.S. Geological Survey has abandoned "Silver Creek Shales" and the "Panhandle Beds". They can take heart, however, that their heroes will still be able to ride high over the "Death Valley Formation" and "Diamond Creek Sandstone".

Nuclear Fuel for Space

THE establishment of an artificial atmosphere on Jupiter's moons, communications from beyond Pluto, water extracted from the surface of the Moon—science fiction turned to fact, with the help of nuclear energy; these and more immediate problems confronting space scientists will be solved with nuclear power according to Dr. Glenn T. Seaborg, chairman of the United States Atomic Energy Commission.

Speaking at the Western Electric Show and Convention in Los Angeles a few weeks ago, Dr. Seaborg outlined the AEC's present joint programme with the National Aeronautics and Space Administration, and the Department of Defense, on atomic energy in space. The two areas of development are the Rover Programme to develop systems for nuclear rocket propulsion and the SNAP Programme to generate electric power. The nuclear rocket is a single engine that would satisfy a number of upper stage and spacecraft applications—a 5,000 MW NERVA engine producing 250,000 lb. of thrust. So far, 1,000 MW rocket reactors have been successfully operated, and Dr. Seaborg stated that this included restarting and operating them at full power through multiple cycles. He added that the AEC had achieved on a single reactor a running time of 30 min at full power—which is approximately the same running time required for a single engine to boost a manned mission to Mars.

Research is also being carried out on a nuclear-electric rocket for use during long voyages. In this system, a highly efficient low-thrust engine is envisaged which will produce a high specific impulse and use electrical energy to accelerate the propellant. Because such a system could be used continually throughout a long voyage, the rocket could eventually build up to a far greater velocity than a chemical or nuclear rocket. NASA and the Air Force are developing the necessary thrust components; the AEC is developing the power source under its SNAP programme. SNAP's broad aim is to provide long-lived electrical power systems for all the scientific and communications equipment in satellites and to provide the energy needed to keep men alive in space. Dr. Seaborg explained that of the two general categories of SNAP systems, the first was based on the generation of electricity from the heat created by decaying radioisotopes while the second used the heat from fission reactors to produce electricity. The first isotopic power system to be used was powered by plutonium-238; this went into orbit on a U.S. Navy navigational satellite in 1961 and its signals are still being monitored. Dr. Seaborg stated that a SNAP unit will power the *Apollo* lunar surface package left on the Moon by the *Apollo* astronauts.

Looking further into the future, Dr. Seaborg visualized the place of nuclear rockets in lunar and planetary exploration. He sees the more efficient nuclear rockets transporting enough supplies to a lunar base camp to last several months. Later nuclear rockets would be used as lunar ferries, shuttling between re-usable chemical rockets travelling from the Earth or Moon to a rendezvous in orbit with the nuclear rocket. A similar system could be used for voyages to Mars and beyond. As Dr. Seaborg said, "The combination of high-thrust nuclear rockets for escape from planetary gravity fields and low-thrust, low-weight, nuclear-electric systems for interplanetary propulsion promises to do great things for solar system exploration".

Vetlesen Prize

JAN HENDRIK OORT, the Dutch astronomer, has won the 1966 Vetlesen Prize for distinguished achievement in the earth sciences, President Grayson Kirk of Columbia University announced last week. Dr. Oort received the Vetlesen Gold Medal and $25,000 for "outstanding achievement in the sciences resulting in a clearer understanding of the Earth, its history or its relation to the universe". The Vetlesen Prize was established at Columbia University in 1960 by the G. Unger Vetlesen Foundation.

Dr. Oort, 66, is a professor at the University of Leiden and is director of the Leiden Observatory. He has achieved world-wide recognition for his studies of the rotation of our galaxy and of radio astronomy. In 1927, Dr. Oort showed that the galaxy rotates about its centre and determined the speed of rotation and the direction of the centre of rotation. Since the early fifties Dr. Oort has worked in radio astronomy. The mapping and detailed study of the spiral structure of the galaxy, during the fifties, was made possible through his research and other research under his leadership.

Food Research

THE first annual report (1965) of the Food Protection and Toxicology Center, University of California at Davis, describes the foundation, objectives and progress of the centre. The centre is carrying out research, has established an information and documentation service in chemical and microbiological toxicity, and has started new undergraduate and postgraduate courses in agricultural toxicology, fundamentals of radiation biology and environmental engineering. Research at the centre covers a diversity of topics—rapid tissue culture methods for detection of chemical residues and toxins in foods and feed stuffs; the use of isolated organs for detecting the precise location of toxic effects and the nature of the effects; methods to increase mobilization and excretion of DDT in cows; and isolation of breakdown products and determination of the mode of decomposition of agricultural chemicals.

Biochemical mechanisms are being studied to determine how cell division is inhibited by radiometric compounds and an investigation is being undertaken into the biochemical composition and detoxifying function of lysozymes. A wide study of the movement of pesticides and agricultural chemicals in and over soil is being made to show how pollution of surface and ground waters is effected and how the movement may affect plants and animals in their uptake of such polluted waters. A three phase study has been completed of food-borne *Salmonella* infections of avian origin, and an investigation of botulism in foods has been started.

Four more projects have been proposed but still need money. One of these is the isolation of natural plant toxins and assessment of their toxicity—these toxins are mainly of academic interest, but it is surprising that no proposal has been made for work on mycotoxins, which are of some economic importance in the United States.

New Zealand Science

THE New Zealand Department of Scientific and Industrial Research continues to increase the scale of its activity. According to the Annual Report for the year to March 31, 1966, just published (Government Printer, Wellington, 3*s*.), the scientific staff of the department increased by 42 to a total of 553. The total expenditure during the year amounted to £3·477 million, more than 10 per cent of which was spent on grants to various research institutes and research associations.

In its research policy the department is hoping to give increasing attention to the problems of particular concern to the economy of New Zealand, in particular a more efficient use of labour and materials. The Institute of Nuclear Sciences, which supplies radioactive isotopes to users in New Zealand, is particularly pleased with the profit being derived in industry from the use of its materials. Prospecting for minerals continues and there has been some success in research for ilmenite, and there is a possibility that "the commercial climate" will become more favourable for the use of titanium ores in New Zealand in the years immediately ahead. Attention is also being given to the possible extension of the present use of geothermal steam at Wairakei and elsewhere. Preliminary studies for underground reservoirs have suggested that each of these may be big enough to support a geothermal power station similar to that operating at Wairakei. There, during the past ten years, the pressure of the hot water at the bottom of the bore holes has dropped, presumably because of the increasing rate at which steam is being used at the power station. Although the causes of this decline in pressure are not properly understood, it is expected that it will be 70 years before the present reservoir has shrunk by as much as 10 per cent.

The department is making what use it can of parasitic insects in pest control. In the past it has proved possible to control the oak leaf miner and Mexican devil weed by such means. In the current growing season, record numbers of insects are being released to control pests. In the South Island female thynnid parasites are being released in the hope that they will control grass grub, and similar methods are being used against the ryegrass stem weevil, the potato tuber moth and the passion vine hopper.

University News:

British Columbia

PROF. J. H. QUASTEL has been appointed professor of neurochemistry, in the Faculty of Medicine, and honorary professor of biochemistry.

London

THE title of professor emeritus has been conferred on the following: Prof. F. Bergel (chemistry, in respect of his former post as professor of chemistry in the Institute of Cancer Research : Royal Cancer Hospital); Prof. J. C. Buckley (helminthology, in respect of his former post as William Julien Courtauld professor of helminthology in the London School of Hygiene and Tropical Medicine); Prof. J. A. V. Butler (physical chemistry, in respect of his former post as professor of physical chemistry in the Institute of Cancer Research : Royal Cancer Hospital); Prof. G. A. H. Buttle (pharmacology, in respect of his former post as Wellcome professor of pharmacology in the School of Pharmacy); Sir Aubrey Lewis (psychiatry, in respect of his former post as professor of psychiatry in the Institute of Psychiatry); Sir John McMichael (medicine, in respect of his former post as professor of medicine in the Postgraduate Medical School of London); Prof. C. M. White (fluid mechanics and hydraulic engineering, in respect of his former post as professor of fluid mechanics and hydraulic engineering at the Imperial College of Science and Technology); Prof. D. Williams (mining geology, in respect of his former post as professor of mining geology in the Imperial College of Science and Technology).

Pennsylvania

DR. D. WHITE, professor of chemistry at Ohio State University, has been appointed chairman of the Department of Chemistry. Dr. J. Donohue, chairman of the Department of Chemistry in the University of Southern California, has been appointed professor of chemistry.

Appointments

MR. J. A. RATCLIFFE, director of the Radio and Space Research Station of the Science Research Council until his retirement this year, has been appointed president of the Institution of Electrical Engineers for the session 1966–67. He will take office as president as from October 1.

DR. H. KING, scientific director of the London Planetarium, has been appointed first curator of the McLaughlin Planetarium of the Royal Ontario Museum of the University of Toronto. Dr. King is also secretary—and a former president—of the British Astronomical Association.

MR. M. H. LOVELL has been appointed director of the British Society for International Understanding on the retirement of Mr. J. Eppstein. Mr. Eppstein, who for the past 27 years has been director, remains editor of the Society's publications.

Announcements

A COMMITTEE of chemists closely associated with the activities of Prof. T. P. Hilditch, who died on August 9, 1965, have been considering a suitable permanent tribute to his memory in the form of memorial lectures to be delivered at a frequency determined by the sum realized. All those interested are invited to contribute to an appeal fund. A trust fund will be set up. Donations should be sent to Martins Bank, Ltd., Water Street, Liverpool 1, and made payable to the "Hilditch Memorial Fund".

THE Deutsche Akademie der Naturforscher Leopoldina recently elected the following new members in the sections indicated: *Mathematics*, Prof. M. Kneser (Göttingen);

Prof. W. Rinow (Greifswald); *Astronomy*, Prof. C. Fehrenbach (Marseilles); *Physics*, Prof. O. Haxel (Heidelberg); *Geophysics and Meteorology*, Prof. T. Nagata (Tokyo); *Physical Chemistry*, Prof. G-M Schwab (Munich); *Botany*, Prof. H. Mohr (Freiburg/Br.); *General Biology*, Prof. W. Beermann (Tübingen); Prof. M. W. Nirenberg (Bethesda); *Anatomy*, Prof. A. Schabadasch (Moscow); *Physiology*, Prof. A. Gutmann (Prague); *Internal Medicine*, Prof. F. Grosse-Brockhoff (Düsseldorf); Prof. F. Lenoch (Prague); Prof. S. Milcu (Bucharest); Prof. K. Oberdisse (Düsseldorf); *Paediatrics*, Prof. K. Betke (Tübingen); Prof. J. Svejoár (Prague); *Psychiatry*, Prof. T. Bilikiewicz (Gdansk); *Surgery*, Prof. W. Bross (Wroclaw); Prof. D. Juzbašić (Zagreb); *Oto-Rhinolarnygology*, Prof. J. Berendes (Marburg); *Orthopaedics*, Prof. M. R. Francillon (Zürich).

PROF. A. H. MASLOW, Philip Meyers professor of psychology at Brandeis University, has been elected president-elect for 1966–67 of the American Psychological Association. G. Lindzey, of the University of Texas, has now taken office as president of the Association for 1966–67. The Association has also awarded three distinguished scientific contribution awards to: N. Bayley, Institute of Human Development, University of California; Prof. C. H. Graham, professor of psychology in the University of Columbia; Prof. R. L. Solomon, professor of psychology in the University of Pennsylvania. These awards, which were established in 1956, are given annually for "outstanding contributions to the science of psychology". The American Psychological Foundation also presents annually one gold medal for a distinguished lifetime career in psychological research, and Prof. K. M. Dallenbach, professor emeritus at the University of Texas, has been awarded the 1966 gold medal.

A MEETING of the Association of Clinical Biochemists (Southern Region) is being held at Bristol on September 17. Further information can be obtained from Dr. V. Marks, The Area Laboratory at West Park Hospital, Epsom, Surrey.

THE one hundred and thirty-third meeting of the American Association for the Advancement of Science is being held in Washington, D.C., during December 26–31. Further information can be obtained from Mrs. T. C. Heatwole, 5110 West Franklin Street, Richmond, Virginia.

A SYMPOSIUM, arranged by the British Scientific Instrument Research Association, is to be held at the Royal Aeronautical Society on October 5. Further information can be obtained from Mr. I. M. Watt, SIRA, South Hill, Chislehurst, Kent.

AN evening course in photoelasticity is to be held at the City University. The course, which begins on October 11, is intended for engineers holding a degree or diploma in technology, or an equivalent qualification. Further information can be obtained from The City University, St. John Street, London, E.C.1.

A NATIONAL conference on "Profiting by Quality and Reliability", organized by the British Productivity Council on behalf of the National Council for Quality and Reliability, will be held at Blackpool during November 8–10. Further information can be obtained from the National Council for Quality and Reliability, Vintry House, Queen Street Place, London, E.C.4.

A NEW certificate in field biology, replacing the certificate of proficiency in natural history, is now being awarded by the University of London. It is available to all persons interested in the study of living things in their natural habitats. Further information can be obtained from the Assistant Director (Room 14), Department of Extra-Mural Studies, University of London, 7 Ridgmount Street, London, W.C.1.

ERRATUM. In the review by Dr. R. F. Ruth entitled "Tissues and Organs" (*Nature*, **211**, 348; 1966), the second sentence of the fifth paragraph should read, in part, "the presumptive heart cells then migrate anteriad over the surface of the endoderm which itself shifts caudad and mediad as both tissues swing into the midline during the formation of the foregut;".

SCIENCE IN FRANCE—A REPORT BY OECD

FRANCE'S scientific achievements are falling short of her intentions, according to a study which has been carried out by the Organisation for Economic Co-operation and Development (*OECD, Reviews of National Science Policy: France, 1966*). The report is one of a series of studies of science policy in member nations of the OECD. The examiners were Dr. A. H. Haley of the University of Oxford, Professor H. Johnson of the University of Chicago, Professor G. B. Kistiakowsky of Harvard University, and Dr. L. Morandi, vice-president of the Montecatini Company. The survey holds that France, where science planning since 1958 has worked towards an overall concept of science policy and coordinated national options, may be losing her courage. Its authors point to the fact that the Committee of Ministers, which is responsible for coordinating science policy, has met on an average only once a year since 1961 and that it has had a progressively weakening influence on the budget "since the number of decisions in the scientific sphere left to the decision of the Prime Minister is steadily increasing from year to year". As further evidence, they note that the major options such as the construction of the *Concorde* aircraft, the development of the Pierelatte programme for gaseous diffusion and the nuclear developments at Chinon were undertaken without consulting the central agencies responsible for advising the government on science policy, and, finally, that even where definite targets had been put forward in the IVth Plan, it has been reported that only 79·7 per cent of these targets have been reached. The report concludes that, while this may just be a temporary lull between conception and implementation of a unified policy, there is some fear that the government is afraid to take the plunge and commit itself completely.

The report traces science policy in France from tentative beginnings in the late thirties, when the Under-secretariat of State for Scientific Research and the National Centre for Scientific Research were established, through the post-war expansion with new agencies for atomic research, aeronautics, health and agriculture. Until the early fifties France was content to remain dependent on foreign technology. Since then France has moved ahead rapidly on research expenditure—the government alone spent 1,073 million francs in 1965 against 249 million in 1959 and the gross expenditure on research and development in all sectors came to 6,248 million francs, or 1·6 per cent of the gross national product, in 1963. This is still below the corresponding GNP figures for Britain and, of course, the United States (where the percentages of GNP were 2·2 and 3·1, respectively, in 1962), but France is spending far less on defence research; in 1962 only 37·5 per cent of government research expenditure went to the armed forces compared with more than 60 per cent in the two other countries.

France is breaking into space and atomic energy in a big way. She has allocated 33 per cent of her scientific expenditure to these two fields in which the United States is investing only 29 per cent in atomic and space research and the National Science Foundation. Another interesting aspect of the French budget for research is the 19·5 per cent spent on national education, primarily for research in the universities and other higher scientific establishments such as the *École Normale Supérieure*. Of course, in the United States many of the grants for university research are made by the National Science Foundation, the National Institutes of Health and the various branches of the Department of Defense, but the universities still account for only 12 per cent of the basic research in the United States, with 74 per cent originating in private firms (over 40 per cent of the costs are met by the government, however). In France, 47 per cent of the research was carried out by private firms, with the government meeting half the costs.

The first formal attempt to integrate scientific and political objectives took place in France when the IVth Economic and Social Development Plan was being prepared (1962–1965). Since 1965 the ministry in charge of scientific research and responsible to the joint secretariat of the two science committees—the General Delegation for Scientific and Technical Research—has been replaced on the political side by a Secretariat of State for Scientific Research and Atomic and Space Questions and on the scientific side by a Delegate-General for Scientific and Technical Research to work in liaison with the Commissaire Général du Plan. This increasing emphasis on central control by the General Delegation and its Secretariat and various committees, coupled with a recognition of the importance of science to all economic and political questions, is still unique to France.

The examiners, like all those concerned with the role of science, welcome the development, but also express the fear that some scientific decisions are being made for political rather than economic reasons. They applaud the desire to increase contributions to international research efforts, but do not feel that France can afford a policy of "going it alone" in prestige areas of science; they are afraid that in practice there is not yet a realistic dialogue between statesmen and scientists, in which case "there is a fear that considerable sums may be spent without research deriving the full benefit".

The examiners found educational policy to be also more indicative than active—the government has not yet worked out a general policy for training senior scientific staff nor has it developed a concerted plan for technical training. As for the training of engineers and scientists, the examiners question the early specialization required by the baccalaureat and the dual stream of university-level education offered by the universities and the *Grandes Écoles*. When the *Grandes Écoles*—such as the *École Normale Supérieure* and the *École Polytechnique*—were founded about 1900, they filled the need for engineering training that was not met by the universities. But though they are still the most influential science schools in the country, the study does not feel that they have changed sufficiently to meet the increasing need for researchers and teachers in France. About 20 engineering schools are regarded as *Grandes Écoles* and take roughly 1,500 first-year students or about 20 per cent of the intake of all engineering schools. But more than twice as many as this have studied for two or three years to gain a place, thereby forgoing admission to university. Another complaint of the examiners is the emphasis in the *Grandes Écoles* on engineering and administration rather than research.

In contrast to the continuing pressure for admission to the *Grandes Écoles*, the universities are finding it more and more difficult to attract able young scientists; many places are left vacant for lack of candidates. The examiners would like to see closer cooperation between the universities and the *Grandes Écoles* to make it easier to transfer from one type of institution to the other and to enable engineering graduates to do postgraduate research at university.

In all areas of science policy, the examiners feel that the gap must be filled between "the remarkable effort being made to rationalize the preparation of decisions affecting both science and the economy, and the universal tendency to choose certain scientific objectives for political reasons without always realizing their economic implications".

SEA WATER DESALINATION — IN PERSPECTIVE

By Dr. E. GLUECKAUF
Atomic Energy Research Establishment, Harwell, Berkshire

Largely as the result of the initiative of the Office of Saline Water (OSW) of the United States Government, research into new methods of providing additional sources of fresh water has become front page news.

The idea of obtaining water from the sea is not new[1], and indeed most of the modern flash distillation plants of the world are of British design and manufacture. But the change in outlook during the past few years brought about by the American initiative is nevertheless fundamental. It means that the development of new techniques which might have been achieved in the normal way in half a century is suddenly telescoped into a decade—assisted by the prodigious contribution of a single government.

It is most important for others to realize that this is the pattern of the world of to-morrow, and that to reach the forefront in any major field of technology in the future will require a punch backed by a nine figure number. In Britain this has been done in the field of atomic energy. We may need to do it again in those fields which are vital for us.

It is relevant to ask the question whether Britain could have afforded an expenditure similar to that in the United States in the field of desalination, where Britain had a good start. Financially, the answer is an unqualified "yes". Britain is at present using about $6{\cdot}5 \times 10^9$ gal. of water each day, about 15 per cent for domestic requirements, about 8 per cent for agricultural uses and the rest for industrial consumption. A levy of 1*d.*/1,000 gal. of water, which would pass unnoticed in the cost of living, would provide £10 million per annum, a figure which is roughly the annual OSW expenditure. Whether Britain could also divert the thousand or so scientists and engineers without serious consequences is another matter. The main point, however, is that viewed from Britain's angle, desalination is an interesting technological field but not a vital one, at least—according to the Water Board—not before the end of this century. Atomic energy, on which Britain spends about one hundred times as much as on desalination, is vital to us.

In the United States, where vast areas of California and other southern regions are short of water, the point of view is a different one. There, the availability of fresh water transcends the technological interests and affects the pattern of development of the country as a whole. The same political motivation exists also in Israel, where manpower expenditure on desalination research greatly exceeds that normal to a population of 2·5 million.

In Britain the theoretically available rainfall is about 48×10^9 gal./day, of which the present consumption represents about 14 per cent. Unfortunately most of the rainfall is in the north and west and most of the water consumption is in the midlands and the south-east, so that even now there are regions where dry summers regularly result in water shortages. But this means only that in the future, new industries requiring much water will have to move to where the water is plentiful, and that in the industrial regions short of water, better water management will have to be introduced. (The manufacture of plastics, for example, may require more than 2,000 times their weight in water.) At present London uses and then throws away about 500 million gal. daily. Recovery of 75 per cent of this water by conventional sewage treatment followed by partial desalination (for example, by electrodialysis) and recycling would make locally available an extra 1,500 million gal. daily. As the water consumption is doubling every 15 years, this action alone would provide the needed increase in water supply almost up to the end of this century. The technology of these recycling processes is now being seriously developed. Naturally, even though Britain will not need desalination plants much before the end of the century, her industries will want to remain in the export market for such plants and so a modest effort in research and development must continue.

The processes for obtaining water from saline water can be conveniently divided into:

(1) Processes involving a phase change: (*a*) evaporation, (*b*) freezing. (2) Processes involving semipermeable membranes: (*c*) electro-dialysis, (*d*) hyperfiltration (reverse osmosis). (3) Processes involving chemical equilibria: (*e*) ion exchange.

(*a*) *Evaporation.* (i) *Flash distillation.* The best known process to obtain water from saline solutions is evaporation. Indeed, if a large sea water desalination plant—say, between 10^5 and 10^8 gal./day—is required to-day, then this is the only process for which commercial plants can be readily obtained. Invariably a multistage system is used (Fig. 1), where the steam flashed off from each stage is condensed to pure water by preheating the incoming sea water. Each stage operates at a temperature and pressure slightly lower than the previous stage. The water condensed in each stage thus has a temperature slightly above that of the water in the following stages, and this energy too can be extracted by flashing through the successive stages.

Plant units of 12 million gal./day of purified water designed for delivery at present use between twenty and forty such stages, so that allowing for heat losses, as much as 8–12 lb. of water can be produced by 1 lb. of steam. For 1,000 gal. of water produced, this reduces the heat consumption to 350 kWh using low grade steam of 260° F which is no longer useful for power production. An additional 18 kWh of power are required for pumping. The unit capital cost is \$0·69/gal./day (ref. 2). The cost of product water for a 36 million gal./day (MGD) plant using three twelve MGD units is \$0·50/1,000 U.S. gal. (\$1 per 1,000 U.S. gal. = 105*d.*/1,000 Imp. gal.) For the still larger units which may be produced in the more distant future, there could be a further reduction of steam consumption and cost. It has been estimated[3] that by using 3,300 MW reactors providing 675 MW of electricity and 250 MGD of water in units of 50 MGD, a unit capital cost for the flash distillation plant of \$0·41/gal./day and a water cost of \$0.16/1,000 gal. can be achieved.

Comparing the two sets of figures, a unit capital cost reduction from \$0.69 to \$0.41/gal./day may be reasonable for the envisaged scale increase by a factor of seven. The water costs cannot be compared as they depend predominantly on the rate of interest charged. Reactors up to 10,000 MW are now being studied in the United States, but it has to be borne in mind that plants of that size are only useful for densely populated areas.

(ii) *Distillation with vapour compression.* If saturated steam at a temperature (t_1) is adiabatically compressed, its temperature rises to (t_2). If this steam is then condensed at a temperature t_3 (between t_1 and t_2) slightly more than the original heat of evaporation is recovered

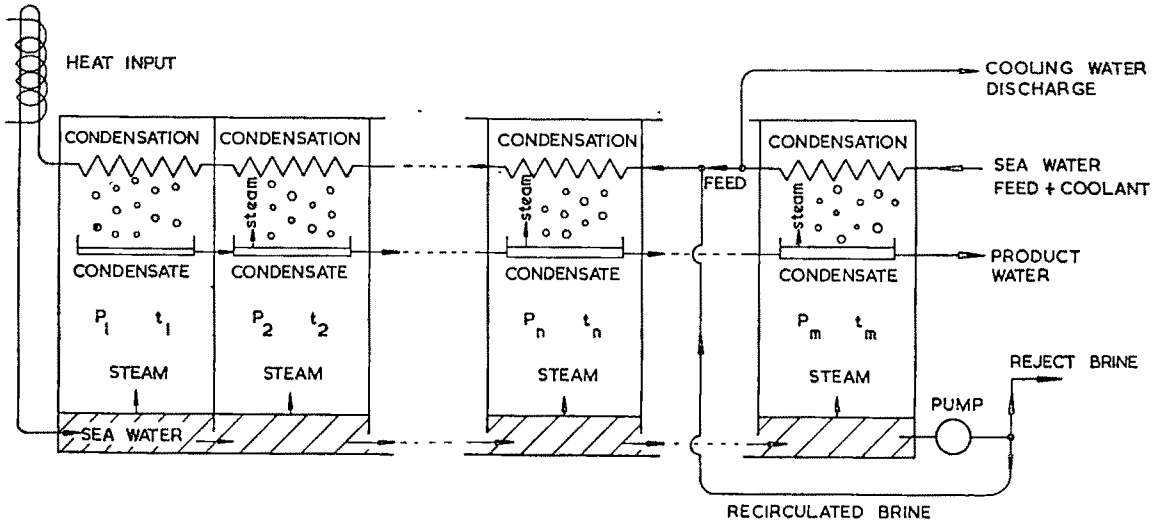

Fig. 1. Multistage flash distillation.

at a temperature t_3 above t_1, which can therefore be used to repeat the original evaporation process at t_1. Thus water can be evaporated with the expenditure of the work needed for the compression, which need be only about 3–4 per cent of the heat of evaporation. Work energy can be produced from heat energy with a loss factor of about three, so that the actual heat consumption in this case represents about 9–12 per cent of the heat of evaporation. This offers roughly the same heat economy as flash desalination with twenty stages, but it gives it in a single stage of operation as the recovered energy can be fed back into the same evaporator. The equipment is thus smaller but requires expensive compressors and comparatively large heat exchangers. It has an obvious advantage for the production of water on a small scale, but it is not clear whether it will compete economically with flash distillation on a large scale.

In both distillation processes the quality of the product water is very good; the solid content is usually guaranteed to be less than 25 p.p.m. and can be less than 1 p.p.m.

(*b*) *Freezing processes.* Because of their highly organized structure, ice crystals cannot accommodate other molecules or ions without severe local strain, and consequently salts are rejected by the advancing surface of a growing ice crystal. This offers the possibility of producing pure water from sea water in a single operation.

Thermodynamically, the process is very favourable, requiring (theoretically) only 6·3 kWh/1,000 gal. of product water. As a result of the irreversible effects in any practical system, however, the value which has so far been achieved is 40 kWh/1,000 U.S. gal. by Colt Industries, Inc., Beloit, Wisconsin, United States. One of their plants in Eilat, Israel, presumably as a result of the higher external temperature, shows a power consumption of 69 kWh/1,000 gal., which it is hoped will be improved to 49 kWh. These values have been achieved by evaporative cooling of sea water, forming a "mush" of small ice crystals, which are separated in a vertical column (by density difference) from the brine, and washed free from adhering brine by recycling some of the purified water. The water–ice slurry is then moved to a melting unit where the latent heat of the compressed water vapour is used to melt the ice.

Theoretically there is no limit to the purity of the water produced, but the considerable difficulties of washing the ice pure from adhering brine have so far led to a compromise at 500 p.p.m. of dissolved solids, which is adequate for drinking purposes. The cost of water has been estimated to lie between $0·5 and 0·7/1,000 U.S. gal. for a 5 MGD plant. Thus while energy consumption is considerably less than in the case of distillation process, the cost of the water is similar, and its quality is not nearly so good.

(*c*) *Electrodialysis.* Electrodialysis makes use of the transport of ions in solution in an electrical field. The most commonly applied method of electrodialysis uses multiple cell assemblies with alternating cation- and anion-semipermeable membranes through which an electric current is passed, so that alternate compartments will produce a reduction and an increase in concentration respectively.

Electrodialysis (and also ion exchange) has the great advantage over most other methods of desalination in

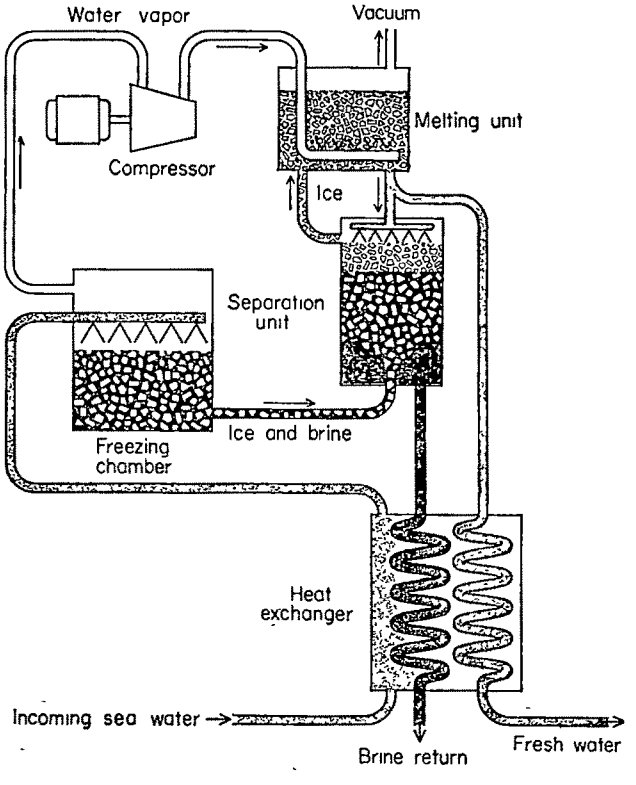

Fig. 2. Vacuum freeze-vapour compression method. [Reprinted from Spiegler, K. S., *Principles of Desalination*, by permission of Academic Press Inc. (London), Ltd.]

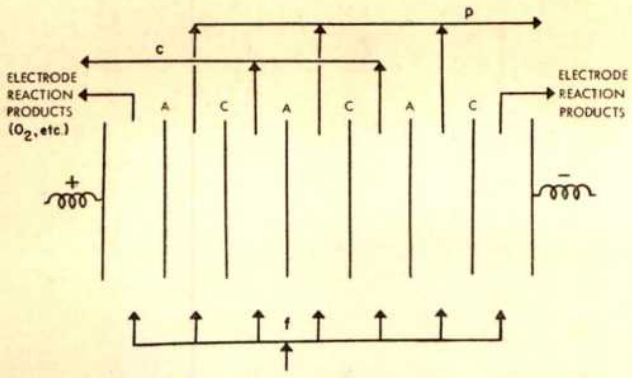

Fig. 3. Conventional electrodialysis. *A*, Anion-permeable membrane; *C*, cation-permeable membrane; *f*, feed; *p*, product; *c*, concentrate. [Reprinted from Spiegler, K. S., *Principles of Desalination*, by permission of Academic Press Inc. (London), Ltd.]

that it removes the minor component (the salt) from the major component (water). As a result of this, power consumption is more or less proportional to the salt content of the feed solution: roughly 2 kWh/1,000 gal. for a feed concentration of 2,000 p.p.m., 5 kWh for 4,000 p.p.m. and about 80 kWh/1,000 gal, for a feed concentration of 40,000 p.p.m., if a product of 300 p.p.m. is required in each case. Further reductions of the salt content are possible, but power consumption then increases as a result of increased electrical resistance of the dilute salt solutions. Though power consumption is low for brackish water, equipment cost remains high, so that the final water cost is not very much less than that of flash desalinated sea water.

On the basis of present-day experience the cost of desalinating water from 3,000 p.p.m. to 500 p.p.m. (on a 10 MGD plant scale) has been estimated as high as \$0.35/1,000 U.S. gal.[4]. It is conceivable that these costs can be substantially reduced by the manufacture of cheaper membranes, and by electrodialysis at higher temperatures. Any increase in temperature could be particularly important for the desalination of sea water, as the resultant reduction of electrical resistance and the higher permissible current densities permit a reduction of both power and capital expenditure. This problem is being seriously attacked at the Institute for Arid Zone Research at Bersheva, Israel, where solar pond heat could provide the energy for an operating temperature of 90° C, at which temperature sea water can be desalinated with an energy consumption of 22–29 kWh/1,000 gal.—a saving of 50 kWh/1,000 gal. If the technological development of membranes which can stand up to an operating temperature of 90° C is successful—and there are indications that this may be so—then this technique of desalting may well become the most economic method in hot climates, even for sea water.

(*d*) *Hyperfiltration* (*reverse osmosis*). Hyperfiltration is achieved when a salt solution is forced under pressure through a membrane which has a high permeability for water, and very little permeability for electrolytes. The pressure must be large enough to overcome the osmotic pressure and the friction loss in the membrane. As the salt rejected at the membrane surface must diffuse back into the solution, the salt concentration at the membrane surface can become considerably higher than that of the water to be desalted (concentration polarization). Agitation of the feed water is therefore important (high Reynolds numbers). Under ideal conditions the osmotic pressure of sea water is about 25 atm. at room temperature, but concentration polarization can increase this pressure considerably. Thus in order to obtain reasonable water throughput (10 gal/ft.²/day or more), pressures of 60–100 atm. have to be applied, as well as adequate agitation of the flowing saline solution.

The membrane material used for this purpose to-day consists of a partially hydrolysed cellulose acetate of 39·8 per cent acetyl content in which 5/6 of the available OH-groups are acetylated. Lower acetylation gives materials showing too little salt rejection; higher acetylation reduces the water throughput below the level of usefulness. The water flux through a membrane is given by the equation

$$f_w = \frac{P_w}{RT} \cdot \frac{\Delta(P - \pi).\bar{v}}{\Delta x}$$

where f_w is the water flux in cm³/cm²/sec; P_w, the permeability of the membrane for water in cm²/sec; $\Delta(P - \pi)$, the excess pressure above the osmotic pressure π, in atm.; $\bar{v}$, the molar volume of water (18 cm³); RT, the product of gas constant and temperature = 24,000 cm³ atm. at room temperature; Δx, the effective thickness of membrane in cm. It follows from this that for a flux of 10 gal./ft.²/day = $4{\cdot}7 \times 10^{-4}$ cm/sec and $\Delta(P - \pi) = 50$ atm., $P_w = 2 \times 10^{-7}$ cm² sec⁻¹, we require a membrane thickness Δx of $1{\cdot}6 \times 10^{-5}$ cm and smaller thicknesses for larger fluxes. Such a thin membrane is quite an obstacle for use in technical equipment, and so hyperfiltration only became feasible after Loeb and Sourirajan (at the University of California, Los Angeles) succeeded in producing a composite membrane where this thin "active" film was backed by a relatively thick porous layer of the same material (about 0·01 cm or more). Rejection of up to 99 per cent of the salt combined with water flow rates of 7 gal./ft.²/day have been obtained with these membranes. Larger water flow rates can be achieved, at the expense of a lower salt rejection.

Although hydrolysed cellulose acetate is so far the only known material which gives the right degree of water permeability and salt rejection, many other polymers and liquid films are known to show similar behaviour. It is therefore likely that increased research into the nature of these polymers will eventually lead to materials with superior properties. This is particularly desirable, as these cellulose acetate membranes, when exposed for longer periods to pressures of 100 atm., lose much of their water permeability, probably as the result of internal structural deformation.

Another feature of cellulose acetate is that it hydrolyses slowly when in contact with aqueous solutions of low and

Fig. 4. Mobile 10,000 gal./day desalination unit produced by Havens Industries Inc.

high *p*H. The speed of hydrolysis is lowest at a *p*H of about 5 so that for solutions of a *p*H between 4 and 6 a lifetime of at least 1 year can be expected.

The mechanism of the transport of salt and water through hyperfiltration membranes in general and cellulose acetate membranes in particular has not yet been fully established. The salts exist in the membrane as dissociated ions despite the low dielectric constant of cellulose acetate, which presumably means that they must be surrounded by a considerable shell of water molecules in order to avoid ion pair formation. The diffusion of ions is very slow ($D \sim 10^{-9}$ cm²/sec for sodium chloride) and their permeation coefficients are highly dependent on ionic charge. With water the permeation coefficients are surprisingly high for a polymer containing only about 15 per cent of water. Also, if calculated from osmotic flow they are higher by a factor of 2·5 than those obtained from the self-diffusion through the membrane of isotopically traced water[5]. This indicates a substantial amount of water–water friction in the latter case. This can be interpreted either as diffusion through bulk material—a view expressed by Merton of General Atomic—or as flow of water through pores of about 9 Å diameter, a view which I favour. Clearly much more work needs to be done.

It is apparent from this that the hyperfiltration technique has not been as fully developed as other methods of desalination. There is, therefore, still a considerable development potential. It is also not yet clear which type of physical arrangement of the membrane surface offers the most economical way to provide the vast areas required for large scale technical application.

Loeb, at the University of California, Los Angeles, favours a tubular system with the cellulose acetate membranes on the inside of perforated metal tubes. Havens Industries, San Diego, California, use 0·5 in. fibre glass tubes with the cellulose acetate cast directly on to the inside of the tubes. Seven of these are then assembled within a plastic tube acting as conduit for the purified water (see Fig. 3). Aerojet General Corp., Azusa, California, have developed a flat plate assembly within a pressure containing vessel. General Atomic at San Diego, California, use a spiral arrangement of alternating membrane—porous support—membrane—spacer layers with withdrawal of the purified water from a central perforated metal tube, the whole being pressurized inside a 3 in. metal tube.

There have been only few economical assessments for plants on a large scale. Energy consumption (assuming recovery of energy from the rejected brine) lies in the region of 20 kWh/1,000 gal. and Aerojet General have estimated a capital cost of $0.55/gal./day for a 10 MGD system, and a total water cost of $0·44/1,000 gal. water produced[6]. This presumably includes membrane replacement at intervals of 6 months. That this estimate is reasonably realistic can be seen from the fact that Havens Industries offer a plant 1,000 times smaller mounted on a trailer for a unit capital cost which is only four times larger. Further improvements on this cost are possible if further research produces a membrane which permits use at somewhat higher temperatures and pressures. The flow viscosity of water at higher temperatures permits larger water flow rates and so reduces the comparatively high capital cost component in terms of water produced. Even so, it is hard to see that the cost of water could fall much below $0·33/1,000 gal.

(*e*) *Ion exchange.* We shall not discuss here the various methods of using ion exchangers, because they seem economical only for the desalting of brackish waters of lower salt content.

Conclusions

It is useful to compare the optimized cost estimates for the different techniques of sea water desalination on the 10 MGD scale approximately (Table 1).

Table 1

Type	Unit capital cost of plant ($/gal./day)	Water cost ($/1,000 (U.S.) gal.)	Purity (p.p.m.) of product water
Flash distillation*	0·69	0·35	< 25
Freezing†	1·4	0·5–0·7	30–500
Electrodialysis‡	(0·5 to 1·7)	0·48	500
Hyperfiltration (reverse osmosis)§	0·55	0·44	500

These figures do not include the cost of distribution.

* To make the data of ref. 2 comparable with United States estimates, they have been converted to an interest rate of 3 per cent and a capital amortization over 30 years, which is the usual practice in the American estimates.

† Ref. 7, p. 338.

‡ Ref. 7, pp. 280–282.

§ Ref. 6.

Bearing in mind the uncertainties of extrapolation in scale for all cases except flash desalination, there is little significant difference in the water costs, except that flash distillation provides purer water and that the other methods, not being fully developed, still have a greater development potential than flash distillation, which has already produced plants capable of desalinating several million gallons of sea or brackish water each day. But the component of power cost of all these methods is such that, without reduction of power cost, the cost reduction potential is limited. Power cost reduction can arise apparently only from the use of super-reactors.

In any event, available information and cost studies do not permit us to predict how the different desalination processes will compete against each other. The outcome may depend not only on the "local conditions"—the size of a given plant and maintenance cost—but also to a considerable extent on the financial terms offered by the supplier.

There are a number of points which are often forgotten when discussing the economics of water desalination, namely, that the water which is desalinated may have to be distributed over some distance. If the intake of water is at the shore of the sea, the pure water may have to be pumped inland. If the supply is a brackish inland water, the concentrate may have to be disposed at some distance, otherwise the salinity of the source water will gradually increase. If water consumption fluctuates, considerable storage may be necessary to smooth out the fluctuations, otherwise the desalination equipment cannot work at its design level of production, which would greatly increase the capital charges.

Even when there is no desalination necessary, the cost of impounding, treatment and distribution is of the order of $0·2/1,000 gal. for a 10 million gal./day supply, and pumping over some distance would easily add another $0.1 to this figure.

As matters stand now, desalinated water at these prices is cheap for domestic purposes, is acceptable for industrial consumption, but is too expensive for indiscriminate agricultural irrigation. Only when used for high priced products (fruit or market gardening) or with sophisticated irrigation systems avoiding surface evaporation could it contribute to raising the food production in the arid zones of the world to a desirable level.

POPULATION DYNAMICS OF THE BLACKBIRD

By Dr. D. W. SNOW
British Trust for Ornithology

Studies of population dynamics in birds have usually been concerned with comparatively small sections of a much larger population, and these small sections have been intensively and professionally studied with the view of elucidating the main factors regulating numbers. With such an approach it is rarely possible, however, to obtain all the information that one would wish on both recruitment and mortality. Often there is some phase of the life cycle where consistent observation is difficult, and in species with populations continuous over wide areas, movements in and out of the study area may upset calculations to an unknown degree.

The present study is of the opposite kind: it is based on numerous data collected on a country-wide scale by many observers, but in the main without any intention that they should be brought together for a study of population dynamics in the way attempted here. Thus it suffers from the opposite disadvantages from those affecting a more intensive local investigation, in that the records are patchily distributed in time and place, and the standard of accuracy cannot be expected to be as high as in a professional investigation. Against these defects can be set the sheer quantity of the data available; there is also an advantage in the fact that the records are derived from several different schemes and were supplied by many independent observers without previous knowledge of the uses to which they might be put.

The data are drawn primarily from the "Ringing Scheme" and the "Nest Records Scheme" of the British Trust for Ornithology. A third major enquiry by the Trust, the "Common Birds Census", has not been in operation for a sufficient time for its results to be more than briefly mentioned, though they will eventually be relevant to the questions under consideration. These schemes have been in operation for various lengths of time, and have expanded with the years. Results of the schemes for ringing and nest records have been the subject of many analyses, which have thrown light on mortality and reproductive rates, migrations and movements; however, it has usually been necessary to treat all years collectively in order to obtain a sample adequate for analysis. It is only in the past ten years or so that they have been operating at a sufficiently high level to permit analysis on an annual basis.

The blackbird (*Turdus merula*) is by far the most suitable species for a study of this sort. It is common almost everywhere, is ringed in larger numbers than any other species, and is recovered in good numbers. Its nests are easy to find and are recorded in greater numbers than those of any other species. Finally, it offers the advantage that not only are the sexes distinct but also birds in their first year can be distinguished from older birds with a high degree of certainty. It has the slight disadvantage of being a partial migrant—a proportion of the population, especially from northern Britain, migrates to Ireland in the winter, and a very small proportion, especially from southern England, migrates south to France. The tendency to migrate is, however, independent of age[1].

Annual Mortality

Coulson[2] described a method of calculating annual mortality for each year separately from recoveries of ringed birds. He presented annual mortality figures for the starling and later[3] for the blackbird from 1932–33 to 1953–54. The samples for the earlier years were, however, so small that the significance of the annual differences is doubtful. In Fig. 1 the same method has been used to calculate the annual mortality of the blackbird from 1948–49 up to 1963–64. Instead of the calendar year, a "mortality year" running from April 1 to March 31 has been adopted, so that the whole of the winter falls within one year.

The numbers of recoveries on which the percentages for recent years are based are large (more than 300 from 1955–56, more than 1,000 from 1960–61), so that if sampling biases could be discounted, the standard errors of the percentages are so small that the larger annual differences could be confidently interpreted as reflecting real differences in the mortality of the blackbird population as a whole. It is certain, however, that those blackbirds that are ringed and recovered are not drawn at random from the entire blackbird population. For example, birds are more likely to be ringed in some habitats (for example, gardens) than others, and in some parts of the country than others, and these biases may not be quite the same every year. It is impossible to guard against these and other sources of bias, and the only practicable course is to divide the data and compare the sub-samples. When the simplest division is made, into the north and

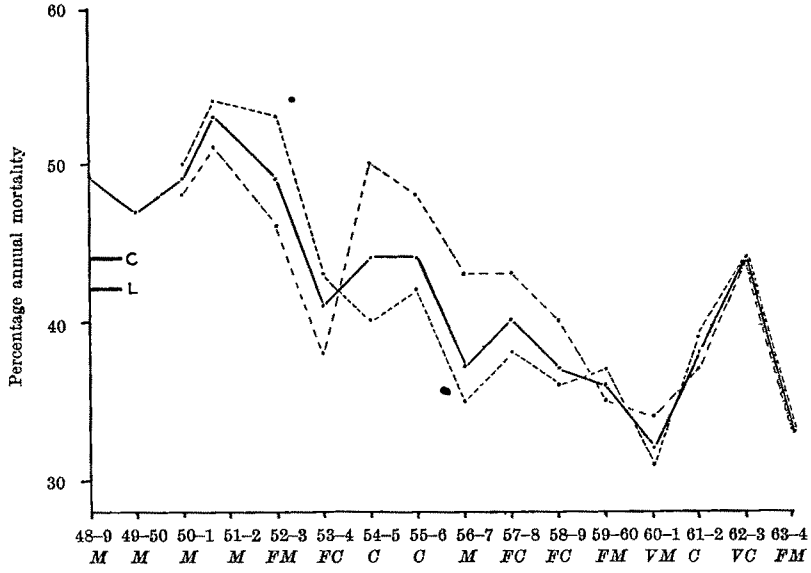

Fig. 1. Annual mortality of British blackbirds, 1948–64. ——, Data from all areas combined. – – – –, Data from southern half of Great Britain. —·—·—·—·—, Data from northern half of Great Britain. *C* and *L*, Average annual mortality calculated by Coulson and Lack respectively. The "mortality years" (abscissa) run from April 1 to March 31, winters being classified as very cold (*VC*), cold (*C*), fairly cold (*FC*), fairly mild (*FM*), mild (*M*) and very mild (*VM*).

south of Great Britain, the calculated mortality rates for recent years, for which the largest samples are available, are extremely similar for the two halves of the country (Fig. 1); thus it may be concluded that sampling bias is not important and the annual differences in calculated mortality are genuine and refer to the total population.

The most striking point shown by Fig. 1 is that from 1951–52 to 1960–61 there was a decrease in the annual mortality, from about 50 per cent down to 32 per cent. The decline was not quite steady; there were irregularities in it which are probably attributable to the differing severity of the winters. Thus the winters of 1954–55 and 1955–56 were cold and the annual mortality was higher than in 1953–54, while the winters of 1956–57 and 1960–61 were mild or very mild and the annual mortality was correspondingly low. The general decline over these years cannot, however, be attributed to weather. For example, the four winters preceding the decline were all mild and yet the annual mortality in those years was higher than in any of the subsequent eleven years. In 1961–62 the winter was cold and the annual mortality rose to 38 per cent, and in the following year the winter was exceptionally severe and mortality rose to 44 per cent. The following year it was down again to a very low level.

Fig. 1 also shows the average annual mortality of the blackbird as calculated by Lack[4] and Coulson[3]. From 1948–49 to 1952–53 the annual mortality exceeded these averages in each year, whereas in most subsequent years it was lower. It is noteworthy that even in 1962–63, when the winter was the most severe for many years, the mortality only just reached the average calculated by Coulson.

Relation between Mortality and Recruitment

The causes of the progressive decline in the annual mortality will be discussed later. Its effect on the numbers of the blackbird must have depended on what happened to the recruitment rate over the same years. If the recruitment rate remained constant, at the level originally needed to maintain the population, numbers would have increased by about 70 per cent over the years 1952–61. But it may be that the recruitment rate fell correspondingly, so that the population level remained much the same. Or the recruitment rate might have fallen a little, but not enough to balance the reduced mortality, resulting in a smaller increase in population.

There is no really satisfactory information on the level of the blackbird population over these years. A small population studied at Oxford for five years (1953–57) reached its highest level in 1957 (the year after the greatest decrease in calculated mortality)[5], and a farmland population of which a census was taken during 1954–57 was also highest in 1957[6]. Data on these and three other small populations over the years 1952–58 (summarized by Beven[7]), however, suggest no general rise in this period, the annual changes being largely attributable to the severity of the winters. Finally, a suburban population of which a census was taken by Simms[8] remained extraordinarily constant from 1951 to 1962, but this was probably a saturated population, because first-year blackbirds tend to settle in gardens in preference to more open habitats[5]; thus it might not have reflected changes in the general population level. While, however, the data are inconclusive, they strongly suggest that there was no marked increase in population over the years 1952–61.

The recruitment rate, that is the number of young birds, born in one year, which survive to form part of the breeding population of the following year, can be measured by the proportion of first-year birds in the population at the beginning of the breeding season. For this purpose, information on the age (whether first-year or older) of all male blackbirds ringed in March in each year has been extracted from the ringing schedules, and in Table 1 the results have been compared with the adult annual mortality for the years 1957–58 onwards (in earlier years ringers were not consistent enough in ageing blackbirds for the information to be reliable).

Table 1. ANNUAL MORTALITY AND RECRUITMENT RATE CALCULATED FROM RINGING DATA

Year (April–March)	Annual mortality	Percentage of first year birds (March)	Calculated population level (March)
			100
1957–58	38	29	87
1958–59	36	31	81
1959–60	37	34	78
1960–61	31	41	92
1961–62	39	37	89
1962–63	44	41	85
1963–64	33	46	105

Data are for the southern half of England only. The "percentage of first year birds" is based on males only (mortality of males and females does not differ significantly). Calculated population level is based on an index of 100 for the breeding population in 1957.

Table 1 indicates that in the three years 1957–58 to 1959–60 the recruitment rate was even lower than the mortality, so that there was probably a slight decline in the population. In 1960–61, the annual mortality was the lowest in the years under review but the recruitment rate increased. In 1961–62 and 1962–63, with respectively hard and very hard winters, mortality and recruitment were almost equal and in 1963–64, with a mild winter, recruitment was considerably higher than mortality, suggesting a population increase of about 20 per cent.

In a few more years, with the "Common Birds Census" in full operation, it will be possible to test the validity of such calculations by the observed population level on a country-wide basis. At present, a comparison can be made only with the census figures for the years 1962–64. Between 1962 and 1963 the census showed a decrease in the blackbird population of 18 per cent, and between 1963 and 1964 an increase of 57 per cent. Thus the changes are in the same sense as those calculated from ringing data but are much more marked. Because the census methods were being modified in these years, and the blackbird is a difficult species of which to take an accurate census, the agreement is probably as good as can be expected.

Nesting Success and Post-Fledging Survival

The recruitment rate depends both on the number of young successfully reared by each pair in the previous breeding season, and on the subsequent survival of these young birds through the autumn and winter. Nest record cards help to provide information on the first of these, while later survival can be calculated from ringing data. For an understanding of population dynamics the main questions to be asked are: whether recruitment rate is related to the number of young produced in the previous breeding season, and whether either or both of these are related to the population level. Until more census data are available for further years, only the first of these questions can be tackled.

Table 2 summarizes breeding statistics for the years 1951–65, derived from nest record cards. There are a

Table 2. SUMMARIZED BREEDING STATISTICS OF BLACKBIRD, 1951–1965

Year	Mean clutch	Family size	Partial loss	Hatching success	Fledging success	Percentage of desertions	Percentage of success
1951	3·9	3·2	0 7	89–94	82	13	38
1952	3·8	3·2	0 6	88–93	83	14	34
1953	3 9	3 3	0 6	92–94	87	14	37
1954	3·7	3·2	0·5	90–95	84	13	39
1955	3·9	3·3	0·6	91–96	83	12	33
1956	3 8	3·3	0·5	91–95	83	13	42
1957	3·7	3·1	0·6	89–94	82	13	28
1958	3·8	3·2	0 6	89–95	83	13	21
1959	3·7	3·0	0 7	88–94	82	14	29
1960	3·8	3·1	0·7	90–94	83	12	28
1961	3·7	2·9	0·8	87–93	81	16	30
1962	3 9	3·2	0·7	89–95	83	12	30
1963	3·9	3·3	0·6	90–94	86	16	40
1964	3·9	3·3	0·6	92–97	85	11	36
1965	3·9	3·3	0·6	91–95	85	14	33

few salient features. Clutch size varied little, with no obvious long-term trends, most of the variation being attributable to weather[9]. Hatching success (excluding predation and desertion) was nearly constant. The number of nestlings surviving the age of 9 days or more showed, however, an irregular fall from 1956 to 1961, owing to the fact that partial losses of young in the nest increased slightly in these years. The survival of young rose again in 1962 and remained high from 1963 to 1965.

The figures for percentage nest success (the percentage of all nests started which produced one or more fledged young) are much influenced by the chances of predation, both human and natural, in which sampling biases may have a very marked effect. It seems, however, that the generally low values for the years 1957–63 may be significant. The percentage of nests reported to have failed through desertion was nearly constant throughout the period.

Table 3. Percentages of Young Birds in the Population in September

Year	North	South
1961	64	61
1962	68	72
1963	86	84
1964	79	79
1965	74	82

Table 4. Survival of Adults, Juveniles and Nestlings, 1959–1961

Year of ringing	Age when ringed	Percentage recovered after following April 1	Percentage of survival until following breeding season
1959	Adult	6·1	63
	Juvenile	3·7	38
	Nestling	0·9	9
1960	Adult	5·0	69
	Juvenile	3·1	43
	Nestling	1·7	23
1961	Adult	3·7	61
	Juvenile	2·5	41
	Nestling	1·3	21

A much better idea of the ultimate success of the breeding season is given by the percentage of juvenile birds in the population in the autumn. Table 3 gives the figures for 1961–65, based on ringing schedules. The annual variations are much more marked than could be accounted for by variations in nesting success in the previous season, suggesting that variations in post-fledging survival were playing the chief part. A comparison of the survival of nestlings born in 1959–61 with the survival of adults in the same years shows that this was indeed the case (Table 4). The survival after leaving the nest of birds born in 1959 was less than half as good as that of birds born in 1960 and 1961. In 1959 there was a hot and dry summer, which lasted to the end of September. There seems little doubt that drought caused heavy mortality among young blackbirds, which at this season feed largely on the ground fauna; it probably affected them mainly in the immediate post-fledging period, because birds ringed as juveniles, which had thus survived the earliest post-fledging period, survived about as well as in the other two years. This calculation cannot unfortunately be made for birds born in 1962 or later, as insufficient recoveries have accumulated.

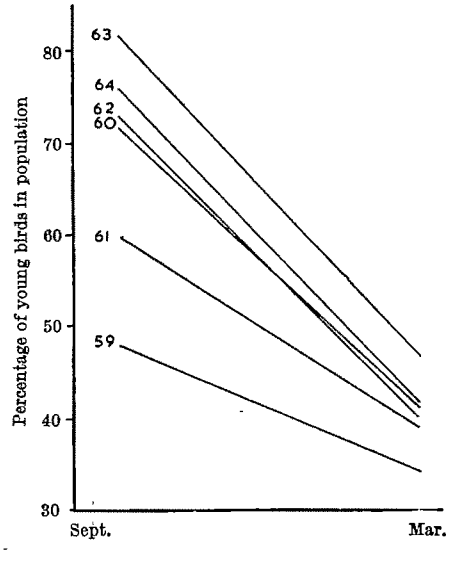

Fig. 2. Change in percentage of young birds in the population of blackbirds between September and the following March, for the six years beginning September 1959 (southern England only); based on male birds trapped for ringing.

Fig. 2 shows that despite a very different proportion of juveniles alive in the population in September each year, by the following March the percentage of first-year birds was rather similar in each year. This suggests that the autumn and winter mortality of young blackbirds is largely determined by the "carrying capacity" of their environment. There is, however, a tendency for a high or low proportion in September to be followed by a respectively high or low proportion in the following March, so that the level of the breeding population is probably affected to some extent by the success of the previous breeding season.

Discussion

Because no increase in the breeding population of blackbirds was recorded over the years 1951–61, despite a reduction of about 10 per cent in the annual mortality, the recruitment rate presumably decreased. The alternatives are that the surplus numbers were absorbed by an expansion of range, that numbers increased in marginal habitats and peripheral areas, or that there was an increase in non-breeding birds unable to acquire territories; good evidence does not exist for any of these alternatives, at least so far as the population of British blackbirds is concerned.

The analysis of many thousands of nest record cards gives no evidence of any change in nesting success sufficient to balance the decreased mortality. The post-fledging survival of young birds may, however, have changed, and this is suggested by the low percentages of first-year birds in March in the years 1958–60 (Table 1). It should be emphasized that a change in the mean post-fledging survival only would be expected, not in that for each year, because survival in any one year depends very much on weather, as already mentioned.

This analysis does not show what was the cause of the reduced annual mortality. It could either have been a change in the environmental conditions affecting the survival of adults (for example, improved winter food supply), in which event the reduction in the survival of young birds would be a consequence of increased competition with adults for the limited territories available. It might be a change in conditions affecting the survival of young birds in their first months of life (ringing shows that after the beginning of January young blackbirds survive as well as old ones), in which case the reduced adult mortality would be a consequence of reduced competition with young birds. If the permanent enquiries of the British Trust for Ornithology continue to operate at their present level, it will be possible to follow the fortunes of the blackbird population year by year and eventually to test such possibilities, and much should be learnt about the factors controlling bird populations.

BOOK REVIEWS

MUTUAL IMPROVEMENT

Benjamin Franklin and Eighteenth-Century American Libraries

By Margaret Barton Korty. (Transactions of the *American Philosophical Society*, n.s. LV, pt. 9, 1965.) Pp. 83. (Philadelphia: American Philosophical Society, 1965.) $2.00.

NOBODY who knows the academic centres of the United States can be unaware of the tremendous enthusiasm with which great libraries are endowed, maintained and enriched by private benefactions. That it is not a new trait and that it showed itself at a very early stage in the colonial period is a reminder that this regard for the high educational value of libraries is indeed a part of the Anglo-Saxon tradition.

When, in 1728, the young Benjamin Franklin drew some of his friends together in a club "for Mutual Improvement" which he called the "Junto", his chief aim was to facilitate the study and discussion of new books on every subject, from history and art to medicine and the "mechanic arts". Only three years later, the books which the Junto had brought together became the nucleus of a private subscription library incorporated on July 1, 1731, as The Library Company of Philadelphia.

"So few were the Readers at that time in Philadelphia", wrote Franklin in his *Autobiography*, "and the Majority of us so poor, that I was not able with great Industry to find more than Fifty Persons, mostly young Tradesmen, willing to pay down for this purpose Forty shillings each, and Ten Shillings per annum. On this little Fund we began."

The importance of this act of faith can hardly be overestimated, for the Library which was thus established became not only a great educational influence in the lives of the colonists but also a political institution of such consequence that no less than ten of its members signed the Declaration of Independence and six the United States Constitution, and the Library served as the Library of Congress during the early years.

Franklin's own scientific bent, which was shared by a number of his associates, was reflected in the types of books which accumulated on the Library's shelves. The very first book order included such titles as *Boerhaave's Chemistry*, *Drake's Anatomy*, *Dechall's Euclid*, *Johnson's History of Animals*, *Keill's Astronomical Lectures*, *L'Hospital's Conic Sections*, *Parkinson's Herbal*, and several others. In 1738, the Library became a centre of scientific experiment with the gift by John Penn of an air-pump, later to be joined by a microscope and electrical apparatus which became the nucleus of a scientific museum and the occasion for several courses of public lectures on scientific subjects. In 1749 Franklin brought out his plans for an Academy and in 1750 he became the first President of the Board of Trustees of the institution which is now the University of Pennsylvania.

Benefactions allowed the purchase of books for the Academy's sole use, and its library was stocked "with suitable books in the different Branches of Science". About half the fund was also used to purchase "mathematical and philosophical apparatus", which emphasizes the strong bias towards scientific subjects apparent in the Academy from the start. In this project Franklin had secured the support of James Logan, a wealthy scholar who had a private library of over 2,000 volumes, including a 1516 edition of Euclid for which Franklin printed a facsimile title-page as a substitute for the missing original. Logan had carried out a series of experiments on the maize plant of which he published an account in Latin, later to be translated into English by the well-known English physician John Fothergill, who was Franklin's personal physician when he was in London. On his death, Logan left his library for the use of the public, which it continued to serve for forty years until, in 1792, it was absorbed into the Library Company, bringing with it many early scientific books which reflected Logan's own interests.

Franklin was also the moving spirit in expanding the scientific section of the Harvard College Library, especially after the disastrous fire of 1764, when 5,000 volumes were destroyed. He also encouraged scientific experiments, especially in electricity, at both Harvard and Yale, where he sent an electrical machine in 1749.

It was among the members of the Library Company that Franklin found his greatest support when he promoted the foundation of the American Philosophical Society in 1743 on the lines of the Royal Society. Franklin was its first Secretary and later its President for more than twenty years. The first volume of its *Transactions* appeared in 1771. The respect which it won from foreign savants is indicated by the names to be found in the lists of donors, for among them are those of Buffon, Lavoisier, Ingenhousz, Herschell, Fothergill, Priestley, Pringle, Banks, and Torbern Bergmann. Its success was the chief factor in encouraging the establishment of the Boston and other scientific societies, including medical societies such as the Medical Society of New Haven County.

The Pennsylvania Hospital, America's first permanent hospital and home of the first American medical library outside the Spanish American colonies, was born from the inspiration of Dr. Thomas Bond and the promotion of Benjamin Franklin, who became secretary, and later president, of the Board of Managers. Fothergill sent books, drawings and anatomical casts from London and after his death his protégé, Dr. J. C. Lettsom (founder of the Medical Society of London), became London agent for the library there.

This inspiring story of self-help and communal effort, which can only be hinted at in a review, is well told in Miss Korty's closely documented study. When asked by a young member of the Junto how to judge a good book, Franklin replied that "it ought to benefit the reader, by improving his virtue or his knowledge . . . it should be *smooth*, *clear*, and *short*". One feels that Franklin himself would have been satisfied that his requirements had been met in this account of his own great services to libraries and to science in the British colonies in America.

F. N. L. POYNTER

THE CHANGING ZULU

Zulu Tribe in Transition

The Makhanya of Southern Natal. By D. H. Reader. Pp. xii + 363 + 8 plates. (Manchester: Manchester University Press, 1966. Distributed in the U.S.A. by The Humanities Press, Inc., New York.) 45*s*. net.

To those for whom the name "Zulu" conjures up a picture of fierce and intractable warriors conquering all before them under their colourful ruler Shaka, Dr. Reader's

conscientious and carefully constructed if perhaps rather pedestrian monograph will make somewhat depressing reading. After a short but useful account of the history of the tribe and of its brief years of glory, the social system of one of the several small tribal fragments of the Zulu, the Makhanya, who live, about 15,000 strong, on a location about 25 miles south-west of Durban, is described in detail. The book has three main parts, dealing informatively with land use and economics; family, kinship, descent and marriage; and the politico-legal system. It concludes with two brief chapters on theoretical aspects of the study of social change which, like most theorizing by social anthropologists in this field, add little to our already reasonably clear picture of what is going on.

When Dr. Reader studied the Makhanya in the early fifties they had long ceased to be the proud warrior tribe familiar to Victorian schoolboys. With traditional values appropriate to unlimited land resources, a largely pastoral way of life, and shifting cultivation, the restricted area they now occupied was quite inadequate for their support. They had shown little response to the Administration's sporadic and somewhat feeble attempts to persuade them to adopt the changed methods of cultivation and animal husbandry which might have enabled them to sustain a wholly agrarian economy in modern conditions. Instead, 50 to 80 per cent of adult men engage in migrant labour (mainly in Durban) to provide themselves with the means for participation in the cash economy in which all Makhanya are now involved. The consequent increase in individualistic values, paralleled in almost every part of Africa, is expressed in numerous modifications of the traditional culture, ably documented by the author.

But, surprisingly, some traditional institutions, notably the basic essentials of the former military regimental system, survive with astonishing tenacity. Although the Makhanya are down they are by no means out. Traditional values, though changing, still survive and a sense of Makhanya identity is still strong. As the author rightly observes, the society he studied (like many another) is neither wholly "tribal" nor quite assimilated to Western norms, but is in a state of transition. And he wisely declines to prophesy what the final result of this process may be.

CARNAP'S PHILOSOPHY

Philosophical Foundations of Physics

An Introduction to the Philosophy of Science. By Rudolf Carnap. Edited by Martin Gardner. Pp. x + 300. (New York and London: Basic Books, Inc., 1966.) 45*s*.

RUDOLF CARNAP is one of the most distinguished American philosophers of this century. Most of his writings have been on formal logic and on the philosophy of logic, but he began his career as a philosopher of science with the publication of his doctoral thesis on "Space" in 1922, and has always retained his interest in it. The present work originated from a lecture course given regularly by him. A transcript of the course was taken, and was edited and simplified by Martin Gardner. The result is a brilliantly clear introduction to the philosophy of science. There is considerable lack of good introductory textbooks on the philosophy of science. Such textbooks as there are either make very awkward reading or presuppose too much in the way of logic or mathematics. Carnap's book suffers from neither of these deficiencies. It is clear and simple, and will prove a great boon to teachers of the subject.

Topics covered include explanation and prediction, probability, measurement, the structure of space, causality and determinism, and the structure of scientific theories. Carnap deals more thoroughly with measurement and the structure of space than with the other topics. He analyses what rules we must have in order to make a measurement of extensive or intensive magnitude, and shows to what extent our reports of measurements made reflect our arbitrary conventions and to what extent they are informative about the physical world. He deals with other topics more briefly, merely setting forward alternative points of view and stating without argument his preference. He does this, for example, when considering whether a numerical measure can be given to the likelihood of a scientific theory being true, and, if so, whether it is a measure of probability in the sense in which we use that term to make judgments about the probability of the occurrence of events. This approach is inevitable in a book dealing briefly with many different topics within a controversial area, and Carnap, unlike many philosophical writers, has recognized the inevitability.

It is hard to fault this book, but one general criticism of Carnap's approach might be appropriate. In many passages Carnap seems to assume that the only evidence for the correctness or incorrectness of a scientific theory is that predictions made from it turn out to be true or false. But there is at least one further criterion used in judging the correctness of scientific theories—their relative simplicity. If one theory orders the data in some field in an evidently simpler way than another theory, that is grounds for saying that the first theory is correct and the second incorrect. I do not think that Carnap would wish to deny this point without qualification, but there are many passages in the book where he seems to ignore it. Thus, in discussing alternative time scales, he rightly claims that if we choose a man's pulse beat rather than the tick of a pendulum as our clock, the laws of physics would become extremely complicated. If we record our observations in terms of the former time scale and devise a theory which adequately accounts for them more simply than any other theory, that theory will still be an extremely complicated one. But, he argues (page 83), "there is no sense in which it is 'false' to measure time on such a basis". But surely the vast complexity of the resulting theory is ground for claiming that the alternative theory which accounts more simply than any other theory for the observations described in terms of the pendulum time scale is more likely to be true and so for saying the same of the time scale which it uses.

R. G. SWINBURNE

AVIATION PHYSIOLOGY

A Textbook of Aviation Physiology

Edited by J. A. Gillies. Pp. viii + 1226. (London and New York: Pergamon Press, Ltd., 1965.) 200*s*. net.

THIS book is the combined work of 22 authors, and presents, as Air Vice Marshal W. K. Stewart says in the preface, "a picture of the principles practised at the R.A.F. Institute of Aviation Medicine" at Farnborough. The Institute houses extremely well-equipped laboratories of human physiology, and, while the research at the Institute must embrace immediate practical problems, the Institute has been continuously concerned with their underlying fundamental basis. The high standards set and maintained at the Institute will be apparent to the readers of this volume.

The book is addressed to those attending courses in aviation physiology, to practitioners in aerospace and aviation medicine, and as a supplementary text to students reading for an honours degree in physiology or ergonomics. It will, however, appeal to many readers outside these fields. Aviation physiology is concerned with defining the limits of human tolerance to a great many different stresses, and the nature of the response to such stresses. There is no aspect of physiology which is unimportant to the aviation physiologist, although from the practical point of view some aspects are more important than others.

This book assembles and synthesizes in a lucid and convenient form information that is otherwise scattered.

It starts with an account of the physics of the atmosphere, and of the physiologically relevant aspects of aerodynamics. All aspects of the effects of reduced barometric pressure are then considered, including decompression sickness and the effects of the rapid decompression that follows failure of a pressure cabin at high altitude. The effects of hypoxia, thermal stress, acceleration in various axes, and of noise and vibration, and the means that may be adopted to counteract these stresses occupy a major portion of the book. Visual auditory and spatial perception are accorded an important place. The concluding sections on factors affecting aircrew performance, and on the causation, results and prevention of accidents contain lessons that could be, and should be, immediately applied more generally, and in particular in relation to the quantitatively much more important case of road accidents. It is remarkable that only very recently has there been any widespread interest in applying to road vehicle design and passenger protection principles that have been well understood for many years by aviation physiologists.

The editor and authors are to be warmly congratulated. The production is good, but the weight (3·2 kg) restricts in some measure the circumstances in which the book can comfortably be read. A. D. M. GREENFIELD

RUSSIAN TREMATODOLOGY

Essentials of Trematodology

By K. I. Skrjabin. (Trematodes of Animals and Man, Vol. 18.) Translated from the Russian. Pp. 532. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 135*s*.

THIS book is a translation of Volume 18 of a Russian series about which I have made some comments in a previous review[1].

It provides a good impression of the tremendous effort which Academician K. I. Skrjabin and his colleagues have made to record what is known about the structure of the digenetic trematodes and to use this information to formulate a system of classification. Descriptions of species are transcribed in great detail from original papers and books; accounts from various authorities sometimes given, always separately. Such a huge compilation may represent a sense of fairness as well as a craving for completeness down to the last detail, but the reader must often use his own judgment and sometimes his discretion because, sad to say, many examples of bad workmanship have been accepted at their face value. The text is overburdened with unsifted information and loaded with unusual terms such as "pedicellate suckers", "large scanty eggs", "cuticle unspinose", "ovate unlobed ovary" and "sexual anlage", as well as innumerable roundabout expressions. The edges of the body may be "decurving ventrally", "eyelets" are said to be "strewn over the 'cervical' region" and one organ may wind "convolutedly anteriorly directly behind" another. Measurements are given (in mm) to one, two or three places of decimals indiscriminately, the dimensions of eggs sometimes to four places, with a pretence of accuracy to one-tenth of a micron. Figures are often devoid of scales indicating sizes and captions are generally inadequate. There are 21 diagrams in Figs. 128 and 129 representing developing cercariae and their parts but the single scale which each figure carries clearly does not refer to all the diagrams, none of which is explicable in terms of a common caption which simply states "developmental cycle".

All these shortcomings transcend mere blemishes and the reader can hardly be expected to agree that the "essentials of trematodology" have been presented succinctly. I have already expressed my opinion (loc. cit.) about the use of keys, which entails constant revision as the bounds of knowledge expand, sometimes revealing previous misconceptions. It is certain that we shall need to know much more about the development and life cycles of the Digenea before we can contemplate "the creation of a new and superior system". Russian attempts to formulate such a scheme may be praiseworthy but they also seem to be premature. We may have to apply the principles of numerical taxonomy by the use of computors and with greater international co-operation than has been practised so far before attempting to formulate a practicable scheme. Some readers may welcome the compilation of such information as appears in these pages but others may feel disposed to check original descriptions and formulate more usable diagnoses for themselves. This appraisal is not intended to be harsh but only to indicate that the approach to "truth" must be gradual and not final and irrevocable. BEN DAWES

[1] Dawes, B, *Nature*, **203**, 1318 (1964).

MICROBIOCHEMISTRY

Chemical Microbiology

By Anthony H. Rose. Pp. viii+247. (London: Butterworth and Co. (Publishers), Ltd., 1965.) 37*s*. 6*d*.

ONE of the signs of the rapid growth of both biochemistry and microbiology in recent years has been the proliferation of textbooks for these subjects. Well over twenty-five texts, published *de novo* or revised since 1960, are available for undergraduate students of biochemistry. A similar situation exists in the case of microbiology. In spite of the increasing use of biochemical concepts and techniques by microbiologists, and the immensely useful contributions that have been made to general biochemical knowledge as the result of using micro-organisms, relatively few textbooks exist which cover the interdisciplinary area of chemical microbiology. This may be a consequence of the compartmentalization of the physical and biological sciences in institutions of advanced education, and it is certainly not a reflexion of the research situation, in which rapid progress continues to be made in the study of microbial life at the molecular level.

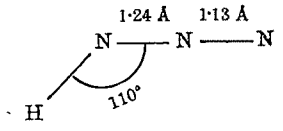
In the forties Marjorie Stephenson's *Bacterial Metabolism* inspired a whole generation of chemical microbiologists, and a limited number of monographs on the life and chemical activities of bacteria have since stimulated the enthusiasm of undergraduates for the subject. Such monographs rapidly become outdated, however, and if revised tend to increase in size and cost. The time was ripe for the appearance of a concise, well balanced, intellectually rigorous and yet readable undergraduate text of chemical microbiology. Dr. Rose's book suits the need admirably.

The book is intended for students with a basic knowledge of both microbiology (*pace* bacteriology) and biochemistry, but is introductory for those wishing to combine such knowledge in further studies. Familiarity with basic biochemistry is essential for an understanding of the various and numerous metabolic schemes, most of which indicate the nature of intermediates by name only. Although about half the text is devoted specifically to different aspects of microbial metabolism, additional chapters are concerned with "chemical anatomy", the environment, growth, reproduction and survival. In general, the author's intention to balance a consideration of microbial metabolisms against the relationship between structure and function and the more physiological aspects of microbial activity, has been realized. This balance, together with the carefully planned structure evident in each chapter, and the pleasing narrative style should make the book popular with its intended readers. References at the end of each chapter are mainly to review articles, although particularly significant reports in the primary literature are also included. It is noteworthy that more than 70 per cent of the references are to material

published since 1960, and that one-quarter of the references are to material appearing within the two years preceding publication of the book.

The format and lay-out of the book are pleasing, and the rather extensive list of *errata* and *addenda* appears to be complete. The book should be valuable to students taking a variety of courses in biochemistry, microbiology, or both, and at the price is extremely good value for money. J. M. TURNER

GRADUATE INORGANIC CHEMISTRY



The Structure of Small Molecules

By W. J. Orville-Thomas. (Principles of Modern Chemistry: a Guide to Advanced Study, Monograph 1.) Pp. ix+189. (Amsterdam, London and New York: Elsevier Publishing Company, 1966.) 52*s*. Paperback 30*s*.

THIS book is the first volume in a series, edited by Profs. Forbes and Orville-Thomas, aimed at North American graduate students. The object is to provide material for courses intended to take the student beyond his own speciality.

This volume may be roughly classified as the structural inorganic chemistry of the first short period of the Periodic Table. About half the book is devoted to explaining the qualitative and quantitative principles for understanding structures, and the rest shows how the principles may be applied by discussing the structures of a number of individual molecules, classified by the bonding of one of their central atoms. The balance is right for the American market, where the students have a markedly professional approach and demand facts well mixed with modern theory.

At present the teacher of structural inorganic chemistry is faced with a difficult situation. To account for a bond length or an angle he may apply, qualitatively, molecular orbital theory, delocalized bonding, resonance structures, $p_\pi \rightarrow d_\pi$ bonding, varying hybridization, hyperconjugation and so on. These effects are combined until a "plausible" explanation is obtained; all the arguments are, necessarily, after the fact. This is illustrated by the following argument. Hydrazoic acid has the structure

From the bond angles, a hybridization can be assigned to each nitrogen atom (sp^2, sp, ground state) and then Hückel theory applied to the π electron system. The result is that one bond between the nitrogen atoms is shown to be stronger, and presumably shorter, than the other. What has been shown by this argument? If the angles could be specified the bond lengths were already known. So may the agreement of the theoretical explanation with the experimental facts be merely a consequence of the initial specifications? Has the language of theory said merely what was anyway known?

Prof. Orville-Thomas has tried to find a way out of these problems; he has not succeeded completely, but he has produced an interesting book with a worth-while quantitative approach. He has made much use of molecular orbital theory and compared his results with force constants and dipole moments, as well as bond lengths and bond energies. Empirical correlations are used to relate these quantities, but one thing that is clearly lacking is any reliable overall correlation between them. It is a pity that only the first short period of the Table is dealt with, since by this restriction discussion of the ubiquitous $p_\pi \rightarrow d_\pi$ bonding is precluded, together with that of many interesting molecules including, of course, the rare gas halides, which provided many teachers and students with their only experience of using principles to predict structures before the structures were actually known.

In short, it is an interesting book and should provide both teachers and students with a more genuine approach to the subject and with useful sidelights on some familiar problems as well. PETER BORRELL

DRY SOLVENTS

Inorganic Chemistry in Non-Aqueous Solvents

By A. K. Holliday and A. G. Massey. (The Commonwealth and International Library of Science, Technology, Engineering and Liberal Studies: Chemistry Division.) Pp. viii+143. (London and New York: Pergamon Press, Ltd., 1965.) 17*s*. 6*d*.

THIS is a concise, easily read monograph nicely balanced with respect to the solvents it covers. A quarter of the book deals with liquid ammonia and a good proportion of this space is devoted to the properties of metal solutions in this medium and theories relating to them as well as their reactions with elements, ions, and covalent compounds. The ordinary chemistry of reagents in liquid ammonia is dealt with concisely. Two pleasing features of the book are the tabulations of pertinent physical data for the solvents discussed and some degree of detail in describing experimental manipulations. The contrasting properties of amine solvents, notably ethylenediamine, receive brief mention before passing on to other protonic solvents of current interest. Sulphuric acid, exemplifying a hydrogen-bonded self-ionizing medium with its specialized self-ion conduction mechanism, is treated fairly fully and its interactions with salts, acids, bases and covalent compounds (free radical formation) described. Liquid hydrogen fluoride receives slightly more space; its probable ionization and fluoride ion conduction mechanisms are discussed and its mode of interaction with covalent fluorides and other substances to give the fluoronium ion is explained. The other hydrogen halides, as solvents, receive appropriately brief treatment. Protolysis, metatheses and ion association in glacial acetic acid, its differentiating action on the "strong" acids and its suitability as a medium for quantitative iodine and permanganate oxidations end the protonics section.

The non-protonic field represented by bromine trifluoride, sulphur dioxide, dinitrogen tetroxide and phosphorus oxychloride is briefly but interestingly reviewed. The analogues of protolysis in these media are considered and the once-postulated self-ionization of sulphur dioxide dismissed. As with all media, solvation, complex formation and metatheses receive mention. The effects of co-solvents, particularly with otherwise uninteresting solvents such as dinitrogen tetroxide, are treated, especially bromine trifluoride in the latter. The self-ionization of phosphorus oxychloride and the structure and properties of its solvate compounds are critically treated. Xenon hexafluoride, its properties and possible self-ionization briefly complete this section.

The final chapter of the booklet is devoted to the high-temperature solvent systems afforded by fused salts, their degrees of ionic structure and the physical chemistry of mixed melts. Protolysis in fused ammonium salts and analogous behaviour in non-protonic systems, notably mercuric halides and antimony trifluoride, is discussed. The Lux–Flood acid-base classification dependent on oxide ion donation provides a contrast with the more generalized Lewis theory. It is interesting to see silicate slag formation and the "borax bead" test interpreted on this basis, which is extended to the polymerization equilibria of sulphates, phosphates and chromates and also to the halide melts of aluminium, beryllium, titanium, cadmium and cobalt. Reductions in melts notably by

dissolved metals, the aqueous electrode potentials of which are broadly related, and also by anions; oxidations by anions and free halogens; metatheses involving the reciprocal Coulombic effect complete a neatly arranged section.

It is a matter for conjecture whether the page title heading "Non-aqueous Solvents in Inorganic Chemistry" might not have opened up a slightly wider field than the cover title but the authors are presumably the best judges of the area to which they wished to confine themselves.

S. R. C. HUGHES

Molecular Beams

Edited by John Ross. (Advances in Chemical Physics, Vol. 10.) Pp. viii+419. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1966.) 113*s*.

THIS volume of the *Advances in Chemical Physics* is in the form of a series of review articles by leaders in the field of elastic and inelastic molecular scattering: polarizabilities, repulsive intermolecular forces, quantum effects on elastic scattering, chemical reactive scattering, excited atom collisions, charge transfer, ion-molecule reactions and supersonic molecular beam sources are discussed.

Although the upsurge of interest in these and related topics has produced much understanding of importance, it is likely that the decisive working out of the subject will take place over the next five or ten years. This volume is therefore not definitive but it does represent a great advance on ten years ago when Taylor and Datz discovered the first molecular beam detector capable in itself of responding differently to different molecules; this can be said to have made possible the commencement of study of a limited number of chemical reactions by particle scattering technique, years before it could otherwise have been achieved.

The field is one which the British chemical fraternity largely ignores, to its ultimate discomfort. This volume should go some distance towards stimulating the necessary interest.

J. B. HASTED

Solar-Activity Forecasting

By Yu. I. Vitinskii. Translated from the Russian by Z. Lerman. Edited by R. Hardin. Pp. iv+129. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 54*s*.

SOLAR radiation rules the lives of everyone on Earth, and its fluctuations, though barely noticed by the sunbathers on our beaches, are vitally important for satellites in low orbits, which end their lives prematurely if the Sun is unduly active and makes the air density increase. The fluctuations will be even more vital for interplanetary travellers, who may end their lives prematurely if the Sun is unduly active in shooting out streams of ions.

The prediction of solar activity is at present even more chancy than long-range weather forecasting, because there is no accepted physical theory of solar disturbances and no agreement on the best index of activity. The Wolf sunspot numbers are usually regarded as the best index, although, as the author of this book points out, the Wolf numbers are even to-day slightly subjective and used to be far less reliable. Nevertheless the Wolf numbers provide the only index which goes back more than 100 years, and have to be used by anyone attempting long-term prediction.

Sunspot maxima recur on average every 11·1 years, but the period can be as low as 7 years (as in the 1830s) or as high as 17 years (1788–1805). The maximum monthly smoothed sunspot number in a cycle can be as low as 50 (in 1805) or as high as 200 (in 1957–58); the minimum is usually less than 10. So far no satisfactory method of predicting the dates and intensities of future cycles has been developed, though various recurrence tendencies have been detected. Predicting the monthly smoothed numbers a year ahead offers a better chance of success, essentially because each cycle, once it has started, shows some resemblance to a previous cycle, or to the average of several previous cycles, and is open to statistical treatment. On a still shorter time-scale, prediction is bedevilled by the unexpected appearance of new sunspot groups.

Vitinskii's book, published in the Soviet Union in 1962, is the most thorough survey available and can be strongly recommended to anyone interested in the subject. The author reviews all the methods that have been suggested, with admirable impartiality, and does not hesitate to conclude that many of them are worthless. It still seems likely, however, that a causal relationship underlies the seemingly irregular variations; and if any mathematician, intoxicated by such a thought, wishes to enter this dangerous field, the book will provide him with both an excellent guide and a sobering view of the reputations lying slaughtered among the man-traps.

D. G. KING-HELE

Solids

Elementary Theory for Advanced Students. By Gabriel Weinreich. Pp. xii+163. (New York and London: John Wiley and Sons, 1965.) 53*s*.

THIS textbook is based on lectures to American graduate students and presupposes a thorough grounding in quantum mechanics, including operator theory, second quantization, and perturbation theory using Feynman diagrams. The term "elementary" in the subtitle is to be understood in the Gibbsian sense.

The ground covered consists mainly of selected portions of the quantum theory of solids and includes Brillouin zones, band theory, the use of Bloch and Wannier functions, vibrational properties of solids and singularities in the vibrational spectrum. The treatment is succinct but thorough, and can be studied with profit given the requisite background.

The opening chapter is devoted to crystallography and is particularly well set out; the illustrations both of lattices and of crystallographic point groups are presented with unusual clarity.

The experimental consequences of the theory have been consciously—one might also add conscientiously—ignored. In a book of limited size, this attitude is certainly justified.

The book is written in a pleasant as well as lucid style and the presentation leaves nothing to be desired. It is warmly recommended.

M. BLACKMAN

Dog Breeding

Reproduction and Genetics. By S. A. Asdell. Pp. viii+194. (London: J. and A. Churchill, Ltd., 1966.) 45*s*.

THE dog is much the oldest of domesticated animals. He is also, not excluding man, physically, emotionally and mentally the most diverse. The breeding of dogs is therefore, as Darwin has explained, of evolutionary interest beyond the range of dog-lovers. Prof. Asdell, however, has written his book from the veterinary or dog-lovers' point of view. To be sure he mentions Darwin by name and he also devotes a chapter to "The Science of Genetics". But the account he gives us is a personal one in which he adds to the established misconceptions a few new ones of his own. The dog breeder will do well to skip this chapter.

On the practical side Prof. Asdell describes the breeding experiments of Stockard—which were carried out in his own university 25 years ago—but he misses the point of this classical work. The four photographs he gives from Stockard will, however, show the reader something of what he has missed.

C. D. DARLINGTON

MEETINGS

BIOCHEMISTRY OF MITOCHONDRIA

A COLLOQUIUM on the biochemistry of mitochondria was included as part of the third meeting of the Federation of European Biochemical Societies, which was organized in Warsaw during April 4–7, 1966. The colloquium was arranged by Prof. E. C. Slater (Amsterdam) and organized by Dr. Z. Kaniuga and Dr. L. Wojtczak (Warsaw). Seven invited addresses were included and delivered by B. Chance (Philadelphia), J. B. Chappell (Bristol), L. Ernster (Stockholm), M. Klingenberg (Marburg), H. A. Krebs (Oxford), P. Mitchell (Glynn Research Laboratories, Bodmin) and E. C. Slater (Amsterdam), together with eighty-one short communications by research workers from seventeen countries. Although almost all current problems of mitochondrial biochemistry were discussed, the invited addresses and most of the short communications were concerned with the following topics: (1) the structure and function of the respiratory chain; (2) the mechanism of energy conservation; (3) transport mechanisms in mitochondria; (4) the regulation of substrate utilization; (5) activation and oxidation of fatty acids; (6) metabolic interrelationships between mitochondria and the cytoplasm.

Immediately after the Federation's meeting a "closed" symposium was held in Warsaw during April 8–9. This was organized by the departments of biochemistry of the Universities of Amsterdam and Warsaw and of the Nencki Institute of Experimental Biology in Warsaw. The symposium, which was attended by sixty-five invited scientists from fourteen countries, was devoted to discussions of data already presented during the Federation's colloquium. The following six topics were discussed: (1) the place of ubiquinone and cytochrome *b* in the respiratory chain; (2) the chemiosmotic theory of oxidative phosphorylation; (3) uptake of cations by mitochondria; (4) the chemical coupling theory of oxidative phosphorylation; (5) regulatory mechanisms of substrate utilization; (6) oxidation and activation of fatty acids.

The present report is concerned with both meetings.

Two alternative theories dealing with the role and the position of ubiquinone in mitochondrial respiration were proposed by M. Klingenberg (Marburg) and E. R. Redfearn (Leicester), respectively. M. Klingenberg, in his invited address, presented several lines of evidence in favour of the view that ubiquinone is located on the main pathway of electron transport, and that it acts as a common pool for reducing equivalents from various flavoproteins. This was supported by data on the redox state of ubiquinone, compared with nicotinamide-adenine dinucleotide and cytochromes, for both forward and reversed electron transfer, and by studies of the kinetic of either the reduction of ubiquinone after substrates have been added to the terminally inhibited respiratory chain, or its oxidation after oxygen has been added in the anaerobic state. E. R. Redfearn postulated the existence of a branching pool of ubiquinone in the respiratory chain. Related problems concerning the place of cytochrome *b* were not discussed in detail, presumably because of the lack of sufficient new experimental data.

As E. C. Slater pointed out in his introductory address, three theories have been proposed for the energy coupling mechanism in mitochondria: (i) the chemical coupling theory; (ii) the concept of phosphorylation driven by proton transport (proposed by P. Mitchell); (iii) the concept of conformation changes in specific proteins (proposed by P. Boyer). Lively discussions of both the first two theories took place at the colloquium and the "closed" symposium. P. Mitchell presented new experimental evidence in favour of his concept. He postulated that both the *p*H changes produced by submitochondrial particles catalysing forward and reverse electron transport, and the burst of proton ejection after a rapid transition from the anaerobic to the aerobic states support the concept that adenosine triphosphate is synthesized by a mechanism involving the ejection of protons and which is intimately connected with the respiratory chain. On the other hand, B. Chance, J. B. Chappell and J. M. Tager presented evidence that proton transport is a secondary effect of the conservation of energy. The basic differences between these two theories were depicted by E. C. Slater in the following scheme:

CHEMICAL COUPLING THEORY

Respiratory chain → high-energy intermediate ⇌ ATP

⇅

cation uptake = H^+ production

CHEMIOSMOTIC THEORY

Respiratory chain → H^+ production ⇌ ATP

↓

cation uptake

A new concept of the action of arsenate on the energy-coupling mechanism was proposed by L. Ernster. He postulated the formation of a relatively stable arsenylated derivative of a high energy intermediate.

Ion transport in mitochondria was extensively discussed by J. B. Chappell, B. Chance, E. Carafoli (Modena), G. F. Azzone (Padua) and A. Azzi (Padua). The main topic in the discussion of cation transport was the stoichiometry (or its lack) between the calcium and oxygen taken up by, and the protons ejected from, mitochondria.

Of considerable importance for a better understanding of the utilization of substrate in mitochondria are the problems of anion transport. J. B. Chappell classified anions (including respiratory substrates) into four groups: (1) those which easily penetrate mitochondrial membranes, for example phosphate and arsenate; (2) those which penetrate mitochondrial membranes only in the presence of phosphate (for example, D- and L-malate, succinate and *meso*-tartrate); (3) those which penetrate mitochondrial membranes in the presence of phosphate and L-malate (for example, citrate); (4) those which are unable to penetrate the mitochondrial membrane, such as chloride ions and fumarate. He also postulated the existence of specific carriers for these different groups of penetrants, as did E. J. de Haan (Amsterdam) for α-oxoglutarate.

Another factor which controls the citric acid cycle is oxaloacetate. Its effect on the oxidation of succinate and the factors controlling the level of oxaloacetate itself were discussed by A. B. Wojtczak (Warsaw), A. M. Roberton (Oxford) and S. Papa (Bari).

New concepts on the activation and oxidation of fatty acids were discussed both at the colloquium and at the "closed" meeting. The group at the University of Bristol working under P. B. Garland was represented at the meetings by D. Shepherd and D. W. Yates. The essential point of their theory is that an intramitochondrial pool of coenzyme *A* involved in the β-oxidation of fatty acids can be acylated only by acyl-carnitine formed either extramitochondrially or intramitochondrially. On the other hand, S. G. van den Bergh presented evidence in favour of his view that carnitine is not involved in the normal pathway of fatty acid oxidation.

Sir Hans Krebs dealt with the problem of the transport of reducing equivalents between mitochondria and the cytoplasm. He showed that the reduced nicotinamide-adenine dinucleotide which is required in the cytoplasm for glucogenesis is formed primarily within the mitochondria and is transferred to the cytoplasm by way of an oxaloacetate-malate system. The same system, working in the reverse direction, transports reducing equivalents, which are produced during glycolysis, from the cytoplasm to mitochondria.

OBITUARIES

Evgeniya Nikolaevna Sinskaya

THE death occurred on March 4, 1965, in Leningrad of Professor Evgeniya Nikolaevna Sinskaya, the distinguished Soviet biologist, well known for her studies in taxonomy, plant breeding, ecology, genetics and physiology.

E. N. Sinskaya was born into the family of a teacher in the city of Pskov on November 25, 1889. After she had obtained her school-leaving certificate, she studied from 1911 until 1917 as an external student at the former Petrov Academy of Agricultural Sciences in Moscow. In the summers she used to carry out practical agricultural work and also participate in scientific expeditions. Graduating as an external student from the Academy in 1917, she obtained a diploma with the title of scientific agronomist. In 1918 she joined an expedition to Central Asia to study the plants of the solonchaks (saline soils), and in 1919 started her work as a specialist on meadow culture at the Saratov Province Land Department. In Saratov she happened to meet Professor N. I. Vavilov, who then held the chair of plant production at the Saratov University, and was invited by him to join his department. In 1921, together with other colleagues of N. I. Vavilov, Sinskaya moved from Saratov to Petrograd. Here, N. I. Vavilov became head of the institution then named the Bureau of Applied Botany which in 1925 became the All-Union Institute of Plant Industry (VIR). E. N. Sinskaya worked at this Institute up to the last days of her life. She took an active part in the organization and direction of various divisions of the Institute—the Technical Crops Division, the Forage Crops Division, and the Ecology and Taxonomy Division.

A woman of great erudition, tireless activity and energy, Sinskaya soon became a leading scientist of the Institute. Her scientific activity led to the publication of more than 140 works. Among the most important are: *Oleiferous and Root Crops of the family Cruciferae* (1928), *Breeding of Forage Crops* (1936), *Meadows of the Mountain Foothills in the North-western Caucasus* (1939), *Dynamics of Species* (1948), *Alfalfa* (1950), *Annual Forage Crops of the USSR* (1957), *On Categories and the Laws of Variability within Populations of Higher Plants* (1963). A large work of forty printed sheets on *Historical Geography of Cultivated Plants* was left in manuscript. In 1936 the degree of Doctor of Biological and Agricultural Sciences was conferred on her for her studies on oleiferous Cruciferae and on forage crops.

Each year, Sinskaya actively participated in expeditions collecting plant resources. She organized collections of local cultivated and wild plants in the Far East, in the Altai Territory, and her most detailed investigations were carried out in the Caucasus and Transcaucasus regions. She brought back from her Far East expeditions many samples both of cultivated and of useful wild plants from Japan.

Prof. Sinskaya was a person of ready sympathy. She was always greatly interested in the work of other research workers, and gladly shared her knowledge and experience with those who asked her help. She maintained wide relations with many scientists both in the Soviet Union and elsewhere.

E. N. Sinskaya was decorated in 1957 with the Order of Lenin.

V. BORKOVSKAYA

Dr. Erna Bennett adds:

Professor Sinskaya's death at the age of seventy-five is a grievous loss to biology. Her work extended over more than four decades which saw deep and fundamental changes in the concepts of evolutionary genetics. Her own contribution to these changes has been very considerable.

Although her biological interests were diverse to an unusual degree, and enriched not only ecology, geography and taxonomy but also plant breeding and population genetics with a wealth of new data and ideas, throughout her whole work there can be found a strikingly single-minded concern with the nature and causes of genetic variability. From her first published paper in 1922—"On the Study of the Laws of Variability in the Family Cruciferae"[1]—to one which appeared in the last year of her life—"On the General Regularities of Ecological–Geographical Variability within Populations of Wild and Cultivated Plants"[2]—Sinskaya's preoccupation with this problem is very clear. It is a problem to which she brought a fluent and erudite knowledge of plant taxa and the skilled application of the phyto-geographical techniques of Vavilov.

Working with oil and forage crops and their related wild species for most of her life, Sinskaya drew heavily on the evidence they evinced of speciation processes in order to build into the growing structure of genecology her own specific contribution of the ecoelement concept. Sinskaya's ecoelements—character complexes, maintained by linkage groups of adaptive origin—carried the ecotypic analysis of plant populations a stage further than did most concepts by other genecologists of her day. Ecoelements resemble the genetic inertias formulated by Darlington and Mather which rested on the polygenic theory of inheritance, and the cohesion theory of Anderson. They also supplied the link between ecology and genetics from the direction of ecology that the work of Dobzhansky and others provided from genetics. Recognizing the importance of Sinskaya's work, J. W. Gregor invited her to prepare one of her very rare contributions in English[3].

J. K. Dixon

DR. J. K. DIXON, a prominent research scientist and director of the Department of Scientific and Industrial Research Soil Bureau, Taita, died on July 30, 1966, at his home in Karori, Wellington, New Zealand.

Dr. Dixon was educated at Christchurch Boys' High School and Canterbury University from which he graduated in 1929. For the next two years he worked on causes of bush sickness in the Te Kuiti area; then in 1931 he received a National Research Scholarship to spend two years at the Imperial College of Science and Technology, London. In 1933 he gained a Ph.D., was awarded the Diploma of Membership of Imperial College of Science and Technology (London) and was elected a Fellow of the Royal Institute of Chemistry.

After his return to New Zealand Dr. Dixon worked for three years at the Cawthron Institute, Nelson, and established that "Morton Mains disease" in animals in Southland was a disorder resulting from cobalt deficiency. He joined the D.S.I.R. Soil Bureau in 1936 and became its chief soil chemist in 1940, assistant director in 1952, and director in 1962.

Dr. Dixon served as president of the Royal Society of New Zealand, the New Zealand Institute of Chemistry, the New Zealand Soil Science Society and the New Zealand Institute of Agricultural Science. He was the senior New Zealand Government representative at the eighth International Congress of Soil Science in Bucharest in 1964.

Dr. Dixon was well known for his research on problems associated with cobalt deficiency in animals and for his work on the use of organic waste matter in composting. I knew Dixon personally for the past thirty-six years and, together with all those with whom he was associated, shall sadly miss a former colleague who not only left his mark in the field of soil science but has at the same time been outstanding in his dedication to the service of his fellow men. He is survived by his wife and two sons.

L. W. TILLER

STRUCTURE OF THE RADIO SOURCES 3C 46, 66, 129 AND 465

By G. H. MACDONALD, A. C. NEVILLE and SIR MARTIN RYLE

Cavendish Laboratory, Free School Lane, Cambridge

A SERIES of observations has recently been carried out with the Cambridge one-mile radio telescope[1,2] to determine the angular structure of a large number of relatively intense radio sources. Many of these sources comprise two components, as Maltby and Moffet[3] have already demonstrated, but a number have been found to be of considerable complexity and their structure has not previously been known. This article describes four of these complex sources which are believed to be extra-galactic; any theory of radio galaxies should account for these sources in addition to the more numerous double sources.

The observations have been made at frequencies of 408 Mc/s and 1,407 Mc/s, using a method which has already been described[2,4,5] in which 12 h observations are made with the movable aerial at each of a number of positions along the full length of the rail track. These observations, when combined in the computer, provide a pencil beam surrounded by a series of elliptical grating responses; the angular separation of the first grating response from the main beam can be increased by the use of a larger number of aerial positions, but for minimum observing time it is normally arranged to be at an angle rather greater than the greatest extent of the source being observed.

In the present observations four positions of the movable aerial were used for 3C 46, 66 and 129, and eight positions were used for 3C 465; because the signals from the movable aerial are combined with those from two fixed aerials, these observations provide eight and sixteen spacings respectively. The main response has widths, to half power, of 23 sec arc and 80 sec arc in right ascension and (23 cosec δ) and (80 cosec δ) sec arc in declination at the two observing frequencies of 1,407 Mc/s and 408 Mc/s. The first grating response is an ellipse with a semi-minor axis of 4·8 and 16·4 min arc at the two frequencies for the observations of 3C 46, 66 and 129, and a semi-minor axis of 9·5 and 32·8 min arc in the observations of 3C 465.

These angles are sufficient to provide maps, unaffected by grating responses, of all the sources, except for the 1,407 Mc/s observations of 3C 66 and 129; for these two sources a complete map has been obtained at 408 Mc/s, but the present 1,407 Mc/s observations have only been used to investigate the detailed structure of the two main components.

The maps are presented in Figs. 1–4. The declination scales have been reduced by sin δ in order to make the aerial response circular and thus simplify the distinction between resolved and unresolved features; the factors by which the scales are compressed are indicated in the figure legends. In each case the half-intensity beamwidth is indicated by the shaded area. The observations were made using linearly polarized radiation with the E-vector in position angle 0° at 1,407 Mc/s and 90° at 408 Mc/s except for 3C 465, where these angles were reversed.

3C 46. This source has been reported as double[3] but in fact it has four elongated components (Fig. 1), although the preceding pair is not fully separated; none is resolved perpendicular to the axis of the source. Their approximate flux densities at 1,407 Mc/s are 0·5, 0·12, 0·1 and 0·48 × 10^{-26} Wm^{-2} $(c/s)^{-1}$.

The separation of the two intense components is 144 sec arc in position angle 67°. They are connected by a strong ridge of emission which contributes about 15 per cent of the total integrated flux. The relative intensities of the components at 1,407 and 408 Mc/s are similar, and correspond to a spectral index $\alpha = 0{\cdot}97$. The source closely resembles 3C 452. which has already been described[5].

Three optical objects in the region of the source have been measured from the *Palomar Sky Survey* prints, and their positions marked with crosses. Object a is a faint red galaxy of $m_{pg} \simeq 19{\cdot}5$ suggested as an identification by Wyndham[6] and b is another slightly nebulous red object of $m_{pg} \simeq 18{\cdot}0$; both are probably members of a cluster of galaxies. Object c is stellar with $m_{pg} \simeq 17{\cdot}0$. There are no other optical objects within 30 sec arc of the centres of the sources.

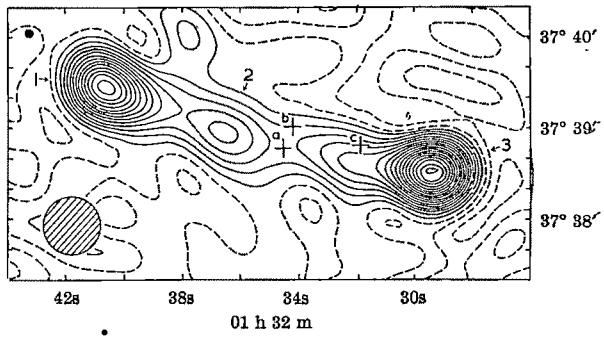

Fig. 1. Map of 3C 46 at 1,407 Mc/s. a and b are faint red galaxies and c is probably a star. Assuming that a is the identification with $M_{pg} = -20{\cdot}5$, the red-shift is about 0·12 and the separation of components 1 and 3 is 260 kparsec. The declination scale is compressed by a factor of 0·61.

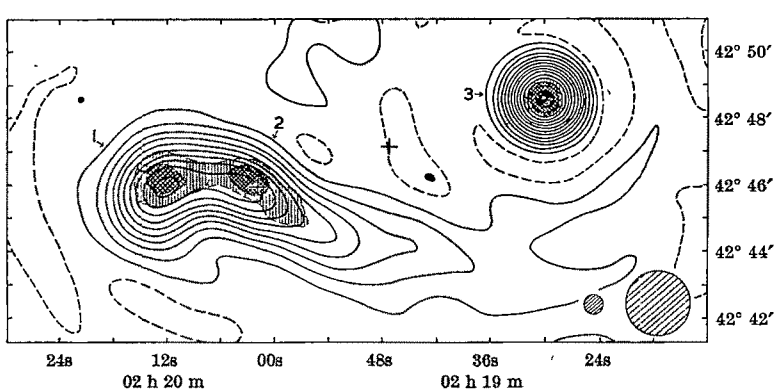

Fig. 2. Map of 3C 66 at 408 Mc/s; the structure revealed by the 1,407 Mc/s observations is shown by shading. The 408 and 1,407 Mc/s beams are shown by shaded circles. The object coincident with component 2 is a 14m 2 elliptical galaxy with red-shift 0 0215; another elliptical galaxy of 15m lies between components 2 and 3. The declination scale is compressed by a factor of 0 68.

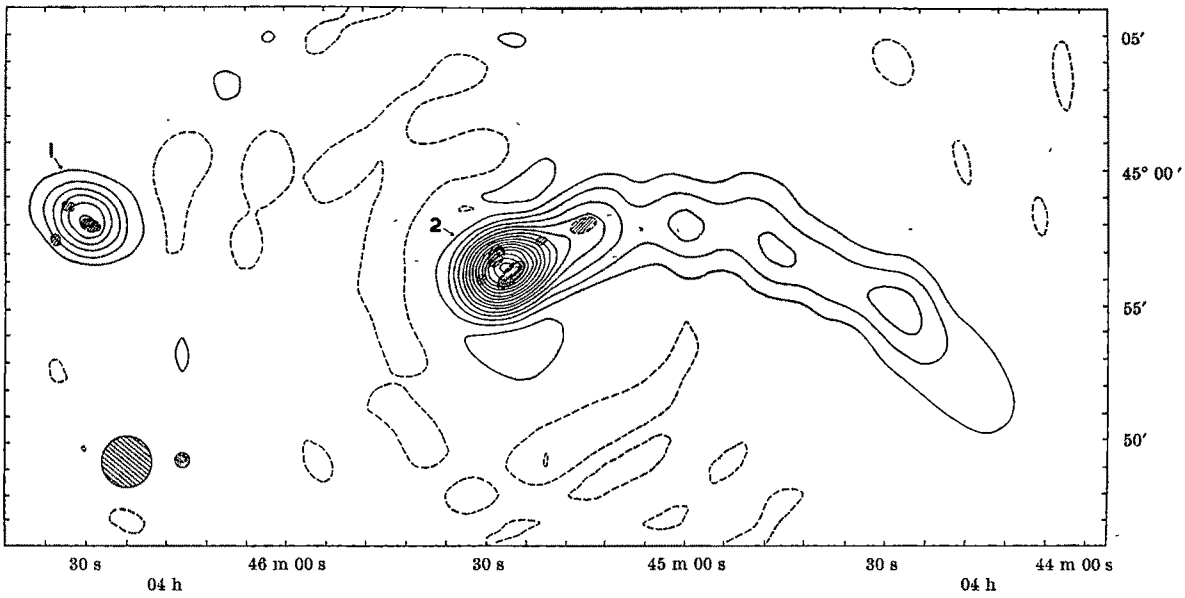

Fig. 3. Map of 3C 129 at 408 Mc/s; component 1 is 3C 129.1. At 1,407 Mc/s both sources are resolved into a number of components as indicated. The 408 and 1,407 Mc/s beams are shown by shaded circles. The declination scale is compressed by a factor of 0·71.

3C 66. Although previous observations have revealed the presence of double structure[3,7] these observations show that one of the components is very much extended and also shows fine structure. Fig. 2 shows the 408 Mc/s contours, with shadings which represent the areas within three of the contours obtained at 1,407 Mc/s; the extended component may be seen to consist of two main sources (1 and 2) linked by a bridge which extends south of, and beyond, the compact component 3. The latter is unresolved at both frequencies and therefore has an angular diameter < 10 sec arc.

An elliptical ($ED2$) galaxy of $m_{pg} = 14{\cdot}2$ coincides precisely with component 2. The position was measured by Griffin[8] and its red-shift has been found to be 0·0215 (ref. 9). There are no optical objects which can be associated with components 1 and 3, but a second elliptical galaxy of $m_{pg} = 15{\cdot}0$ lies almost exactly mid-way between components 2 and 3. Both galaxies appear to be members of Abell[10] cluster A-347.

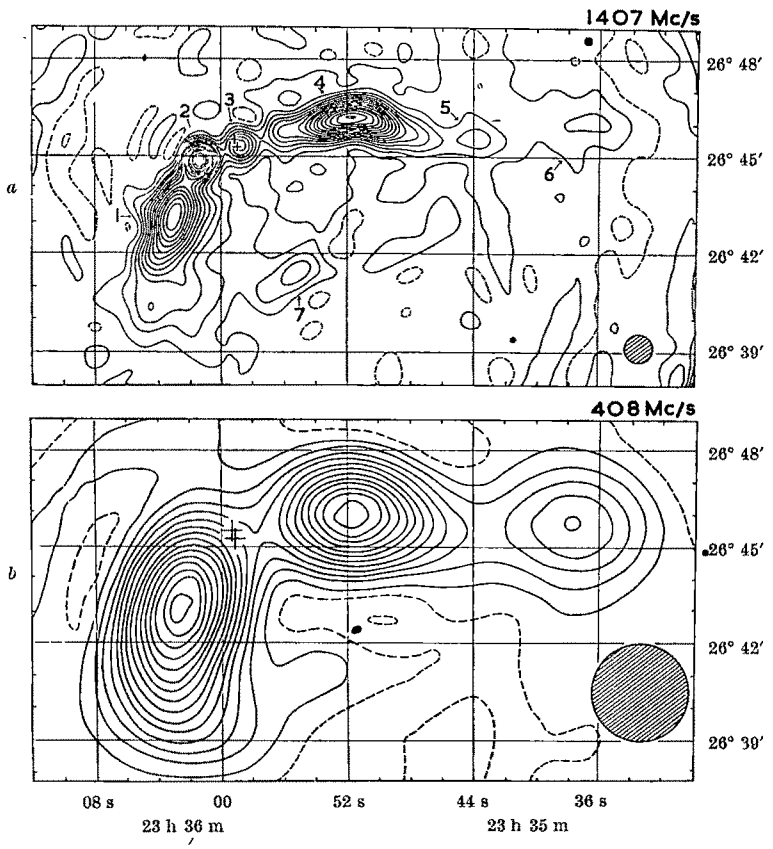

Fig. 4. *a*, Map of 3C 465 at 1,407 Mc/s. The position of the double galaxy *NGC* 7720 is marked with two crosses. There appear to be no other optical objects associated with the radio source. *b*, Map of 3C 465 at 408 Mc/s. It may be seen that component 6 is here relatively much more intense than at 1,407 Mc/s. The declination scale is compressed by a factor of 0·45.

3C 129. Previous observations[3] showed this source to have an angular extent > 6 min arc with structure < 1 min arc. The present observations at 408 Mc/s are presented in Fig. 3 which shows that the intense central source has an extension which develops into a curved ridge of emission, 13 min arc in length and about $\frac{1}{2}$ min arc wide with three weaker peaks at almost equal intervals of 3 min arc; the ridge contributes about 20 per cent of the total flux density. It seems likely that the source (1) lying 11 min arc east of the central source (3C 129·1) is associated with 3C 129.

The observations of 3C 129 at 1,407 Mc/s are confused by grating responses beyond 4·8 min arc from the central source, but they may be used to investigate the detailed structure of the two main components. It is found that the central source is resolved into five separate components, two of which are intense and elongated almost parallel to the extension of the 408 Mc/s map with three weak ones in line with the extension. These are indicated by shaded areas superposed on Fig. 3. 3C 129·1 is similarly resolved into three components, one with about twice the intensity of the other two.

The source lies close to the galactic plane in an area where there is appreciable obscuration. Although it is possible that 3C 129 might be a supernova remnant, the well-defined limits of the arc and the very large

surface brightness of the main component make an extragalactic origin seem more likely. Wyndham[6] has suggested as a probable identification a 19^m red galaxy which lies close to component 2, but the area within which a related object might lie is too large for this to be regarded as definite.

3C 465. The association of *3C* 465 with *NGC* 7720 was originally suggested by Dewhirst[11]. Previous radio observations[3] showed it to extend over several minutes of arc with complex structure. Fig. 4*a* is the map of the radio emission observed at 1,407 Mc/s which shows seven components. The positions of the two components of the double galaxy *NGC* 7720 as given by Griffin[8] are marked with crosses. They are associated with the only unresolved feature of the 1407 Mc/s map (component 3), which has an angular size less than 10 sec arc. There are a number of bright galaxies, members of Abell[10] cluster *A*-2634, in the region of the source, but none appears to be related to any other radio component; a 16^m galaxy lies 19 sec arc west of the centre of component 4.

Although the resolution of the 408 Mc/s map (Fig. 4*b*) is inadequate to show all the details visible at 1,407 Mc/s, it is clear that most of the features are similar at the two frequencies. There is, however, a remarkable exception in component 6, which is strong at 408 Mc/s, but extremely weak in the 1,407 Mc/s map.

By convolution of the 1,407 Mc/s map with the appropriate function to reduce the resolving power to that of the 408 Mc/s beam, a direct comparison can be made of the total integrated flux of the seven components at the two frequencies. An estimate of these fluxes and the corresponding spectral indices α are given in Table 1.

Matthews, Morgan and Schmidt[12] have investigated *NGC* 7720 in detail. It is a $13^m{\cdot}5$ *D*-galaxy, with an elliptical nucleus surrounded by an extensive asymmetric envelope of higher ellipticity. There is a circular 15^m companion galaxy in the same envelope. The spectrum shows a weak emission line of OII and absorption lines which give a red-shift of 0·0301[13]. At the distance of *NGC* 7720 (88 Mparsec), the upper limit of 10 sec arc on the angular size of component 3 corresponds to a linear dimension < 5 kparsec. This component appears to be associated with (but is smaller than) the brighter member of *NGC* 7720, and it is probably significant that this is the galaxy showing an excited emission line in its spectrum.

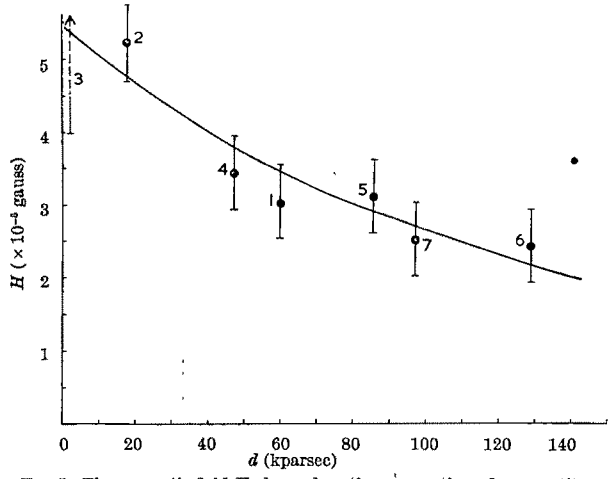

Fig. 5. The magnetic field H, derived on the assumption of equipartition between particle and field energies, is plotted against d, the projected distance of each component of 3C 465 from the brighter member of *NGC* 7720.

The details of the four sources are summarized in Table 1, which gives the co-ordinates, flux densities and spectral indices of each main component.

Red-shifts are available for *3C* 66 and 465, and the projected physical separation (d) of each component from the optical object has been derived using a value of the Hubble constant $H = 100$ km sec^{-1} Mparsec^{-1}. In the case of *3C* 46 an approximate red-shift of 0·12 has been obtained assuming that source *a* is the identification, with $M_{pg} = -20{\cdot}5$. The volume of each component has also been computed; in the case of elongated features, it has been assumed that they have a circular cross-section, with an extent in the line of sight comparable with the width. For elongated features making a small angle with the line of sight, this assumption will lead to an underestimate of the volume.

From the corresponding luminosities and volumes it is possible to determine the minimum energy requirements for each component assuming that there is equipartition between the particle energy and the magnetic field; it is assumed that the protons have 100 times the energy of the electrons[15]. These figures, and the corresponding values of magnetic field, are given in columns 10 and 11.

Since the volumes of the components must originally have been considerably less (and presumably less than that of the galaxy) the adiabatic losses require the initial energy to be greater by a factor of at least the ratio of the linear dimensions. In the case of *3C* 46 and 66 the minimum total energies are therefore of the order of 2 and 0·7 × 10^{59} ergs respectively.

The magnetic fields for all the components in *3C* 465 are plotted in Fig. 5 as a function of d, their projected distance from the brightest member of *NGC* 7720. It is probable that the value of d is related to the age of the component, and this relationship may be of importance in connexion with theories of the evolution of radio galaxies.

The evidence provided by the present observations of *3C* 46, 66, 129 and 465, the earlier observation of *3C* 452 (ref. 5) and the multiple source 5*C* 1·47 and the association of 5*C* 1·71, 76, 77 and 79 (ref. 16), confirm the occurrence of multiple explosions in galaxies. The marked curvature in *3C* 129 suggests that ejection may have occurred along a fixed axis in a rotating galaxy. The relative magnitudes of the energy released in successive explosions, and the intervals between them, are clearly of great importance in understanding the mechanisms involved in radio galaxies.

We thank Mr. B. Elsmore for assistance with the observations. One of us (G. H. M.) is indebted to the Science Research Council for a Maintenance Award.

SONIC BANG SIMULATION BY A NEW EXPLOSIVES TECHNIQUE

By S. J. HAWKINS and J. A. HICKS
Explosives Research and Development Establishment, Ministry of Aviation, Waltham Abbey, Essex

THE study of the effects of the so-called "sonic bangs"—that is the disturbance produced by the passage of a supersonic aircraft—requires an experimental approach. The response of most real systems, both animate and inanimate, to this type of stimulus is so complex that useful theoretical work is limited respectively to statistical studies or to simplified model treatments. On the grand scale, experiments can be conducted using supersonic aircraft, as at Oklahoma City[1], but these are expensive and for small-scale experiments a simulation technique has the advantages of cheapness, localization of effects and the potential ability to produce bangs characteristic of future aircraft types, for example *Concord*.

A typical sonic bang waveform at ground level (Fig. 1) is an *N*-wave (ref. 2) with front and rear shocks of equal amplitude (about 1 mbar), lasting up to 300 msec for supersonic transport aircraft. Waveforms vary somewhat according to atmospheric conditions, the shock rise-times being normally between 0·1 msec and 20 msec.

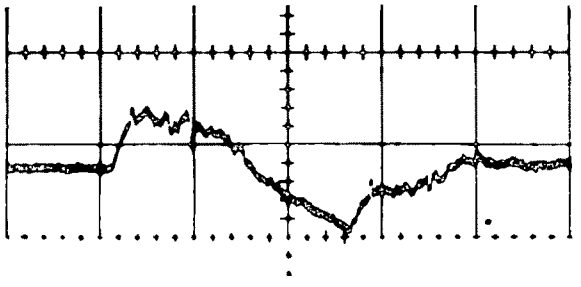

Fig. 1. Typical sonic bang waveform at ground level. Ordinate, 0·5 mbar per large division; Abscissa, 50 msec per large division.

To simulate waveforms of these durations using conventional "point source" explosive techniques is impracticable; charges of many tons weight would be required situated many miles distant and no control of waveshape would be possible.

We were led to investigate the new line charge technique reported here by the realization that an extended explosive charge must give rise to a pressure waveform the duration of which—whatever its shape—is approximately its line-of-sight extension divided by the average air shock velocity across that extension. For charges of small weight such as ours the air shock rapidly decays to sonic velocity (1·1 ft./msec), and because of this a distant observer experiences a pressure wave the duration of which in milliseconds is roughly equal to the extension, in feet—the shape is governed by the distribution of explosive along the extension.

Theoretically, we consider the extended charge as a spatial array of infinitesimal point charges detonated simultaneously, the combined effects of which we approximate by the assumption of linear superposition. Thus if

$$p = p(m,r,t-\theta) \qquad (1)$$

is the pressure waveform from a point source explosion, m,r,t and θ being respectively the explosive mass, observation distance, time and propagation delay (that is, the time for the wave front to reach the observer), then our assumption yields a formal description of the pressure waveform from a charge distribution of density σ by integration of p over an appropriate range of a certain variable x. This variable must be such that σ, r and θ may be expressed as unique functions of it and must also be such that the pressure increment $dp(t)$ can be expressed in terms of the first power of the increment dx in x. It can be shown that the variable r is itself a suitable x.

We have used an empirical form of equation (1) due to Friedlander[3], together with simplified explosive scaling laws to obtain this integral in the form

$$p(t) = \int \frac{a\sigma^n}{r} \left\{1 - \frac{t-\theta}{b\sigma^n}\right\} \exp\left\{-\frac{t-\theta}{b\sigma^n}\right\} dr \qquad (2)$$

A solution for the simple case of a uniform straight linear charge observed from a distant point on the axis produced is shown in Fig. 2 and is in qualitative agreement

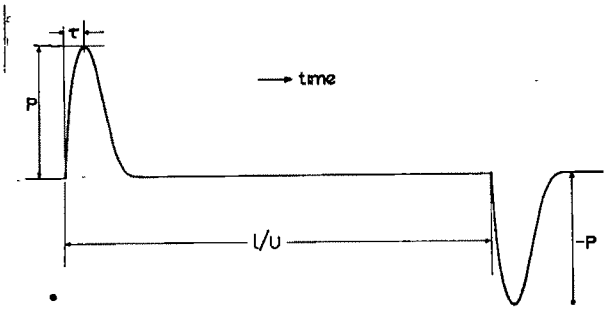

Fig. 2. Calculated pressure waveform from straight linear charge of uniform explosive linear density.

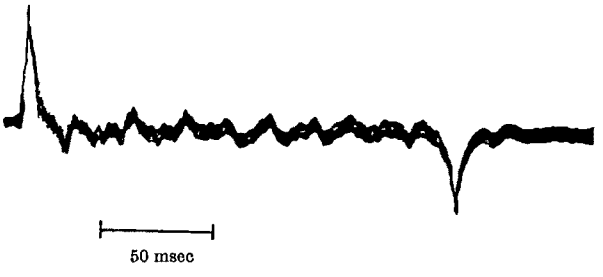

Fig. 3. Experimental pressure waveform from straight linear charge of uniform explosive linear density, length 60 m.

with the waveform observed experimentally (Fig. 3). This example is of practical interest because the only readily available distributed explosive is in this form (detonating fuse).

Many complex waveforms can be synthesized by detonating linear charges constructed from multiple strands of detonating fuse of different lengths. Fig. 4 shows schematically how sonic bang simulants (Mark I) have been developed in this way. The simulant of the sonic bang from a *Lightning* aircraft, with a duration of about 100 msec, has an explosive weight of only 1·5 kg. Fig. 5 is the experimentally determined waveform from another *N*-wave simulant, having a duration of 200 msec and a charge weight of 4·4 kg.

The waveform is dependent on the angle of observation, tending to the shape characteristic of a point source explosion at the 90° orientation, an acceptable *N*-wave being obtained within a cone of 8° semi-angle about the charge axis. Overpressures in the range 1·5 mbar–0·5 mbar are obtained at distances from the near end of the charge between 100 m and 200 m. This type of simulant sometimes shows detailed differences from actual sonic bang waveforms. A need therefore arises for some criterion with which to assess the importance of such differences in specific applications of the simulant. The criterion which we have used is the correlation between the energy spectra of the simulant and sonic bang waveforms over the frequency range in which the given "target system" responds—that is, absorbs energy. Building structures for example respond only to frequencies below about

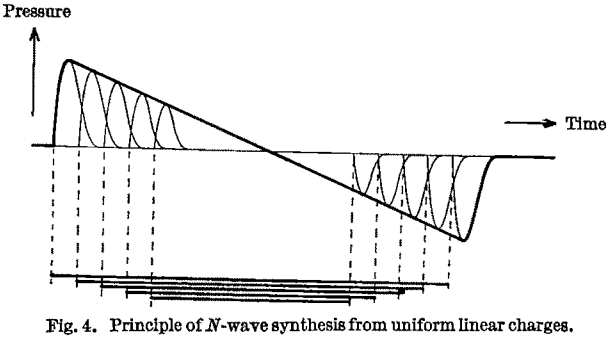

Fig. 4. Principle of *N*-wave synthesis from uniform linear charges.

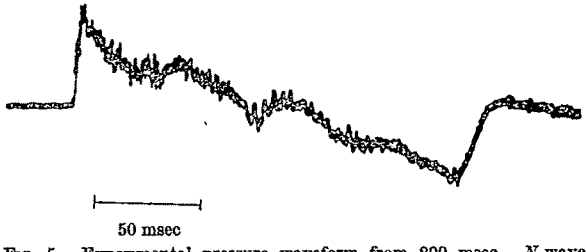

Fig. 5. Experimental pressure waveform from 200 msec. *N*-wave simulant (Mark I).

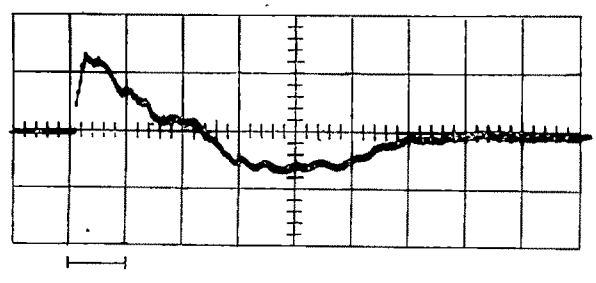

Fig. 6. Experimental pressure waveform from one half of Mark II sonic bang simulant.

50 c/s, whereas in audiometric studies the frequency range of interest lies almost wholly above this.

Energy spectra of the pressure waveforms of actual sonic bangs and explosive simulants have been obtained by digitizing the waveforms and performing the necessary Fourier analysis and summation into 1/3rd octave bands on an Elliott 503 computer. These show the Mark I simulants to be very suitable for structural studies, but in the higher frequency range divergencies appear between the spectra owing partly to the higher inherent noise level of the simulant and partly to the different pressure rise rates in its shock fronts. The extent to which these affect the suitability of Mark I for loudness studies, for example, is difficult to measure, but attempts are being made to do this using two different loudness calculating procedures.

The recent work of Zepler and Harel[4] on sonic bangs and other impulsive sounds has shown that the two most significant parameters in studies of loudness are the rate with which pressure rises and the peak overpressure. These observations together with the uncertainties already discussed concerning the Mark I simulants have led us to develop a second type of simulant which is complementary to the first type in that it simulates the energy of sonic bangs in the higher frequency range and is therefore very suitable for ear response studies. This type of simulant is composed of two identical linear charges arranged side by side and detonated consecutively with an appropriate time delay. It is designed to reproduce in amplitude and rise rate the bow and stern shocks of the sonic bang waveform—the acoustically insignificant slow linear fall in the middle of the wave is replaced in the simulant by an equally acoustically insignificant slow asymptotic return to ambient pressure; this is not possible with point source explosive charges. Fig. 6 shows the experimentally recorded waveform from one half of the Mark II simulant.

We thank Mr. M. J. Harper of this establishment for calculations of energy spectra and of loudness values.

COMPOSITION OF CRYSTALLINE SHIELD ROCKS AND FRACTIONATING EFFECTS OF REGIONAL METAMORPHISM

By K. E. EADE, W. F. FAHRIG and J. A. MAXWELL
Geological Survey of Canada, Ottawa

THERE is particular interest at present in the thermal history and chemical composition of the crust. The metamorphic facies of crustal rocks may be used to estimate temperatures that existed in parts of the crust during the early epochs and the composition of rocks of various metamorphic facies may be used to calculate the redistribution of crustal heat and heat sources that resulted from regional metamorphic events. During regional metamorphism, heat is transported by the movement of more volatile components and by the differential movement of heat-producing elements such as potassium, uranium and thorium, as well as by conduction. The data presented here represent analyses of bedrock samples from a semi-systematic array of col-

lection points in New Quebec, Canada. The analytical data for the major contributors of radiogenic heat are incomplete because thorium and uranium values are not yet available.

The rocks of New Quebec, Canada, consist in large part of weakly to strongly foliated Archaean granodioritic gneisses that are probably of metasedimentary origin. Early geological work in a part of this area[1] suggested that only rocks of amphibolite facies were present, but recent reconnaissance mapping of 200,000 square miles of the area[2–4] has revealed the widespread occurrence of rocks of the granulite facies. A large number of hand specimens was collected in the course of systematic traversing by helicopter, and chemical analyses of groups of these specimens have made possible a comparison of the composition of rocks of the granulite facies with that of adjacent rocks of the amphibolite facies. These analyses provide a unique opportunity to determine directly the composition of a large area of the surface rocks of the Canadian Shield which presumably was at one time deeply buried in the crust. Although this approach to the determination of the abundance of the constituent elements of the crust, that is, through the analysis of a large number of hand specimens, is admittedly unimaginative, it has certain real advantages over indirect techniques[5,6] that depend on a number of assumptions. This approach was made possible by the emphasis placed in recent years by the Geological Survey of Canada on the expansion of facilities for the rapid analysis of rocks.

The rocks of the granulites facies (shown in black in Fig. 1) are, at the one extreme, very coarse grained, rusty and white weathering and exhibit a faint irregular gneissosity. This rock type grades, as a result of an increase in finer grained, biotite-rich, metasedimentary material, into a strongly banded rusty and grey weathering paragneiss. Biotite is ubiquitous in all the rocks of this facies and is pleochroic from pale yellow to deep red. Plagioclase is the dominant feldspar, locally has an antiperthitic texture and its fresh surfaces are pale green or brownish green with a greasy lustre. Quartz is blue or dark grey. Hypersthene, hornblende and locally garnet and augite are common constituents.

These rocks are broadly similar in origin and composition to the common lower grade granitoid gneisses of the Canadian Shield. The banding of the gneiss and the inclusions of banded biotite-rich material suggest a derivation from predominantly sedimentary strata. The absence of notable quantities of crystalline limestone, lime silicate or highly quartzose layers suggests a greywacke-type of primary sediment. Mineralogical peculiarities, notably the presence of hypersthene, calcicplagioclase and garnet, and textural features such as large grain size, are thought to result from metamorphism under condition of high pressure and temperature. The presence of biotite and, less commonly, of dark hornblende in the association suggests the hornblende granulite subfacies. These gneisses of New Quebec may constitute one of the world's largest areas of high grade metamorphic rocks.

The rocks of the amphibolite facies (Fig. 1) are grossly similar in appearance to their neighbours of higher metamorphic grade and the structures of one facies are continuous into rocks of the other facies. The granitoid varieties of the amphibolite facies are chiefly pink or buff on a fresh surface and rocks of this facies abound in minerals such as epidote, microcline and muscovite that are considered characteristic of lower temperature-pressure conditions. Locally, the preservation of structures in rocks of the amphibolite facies allows the

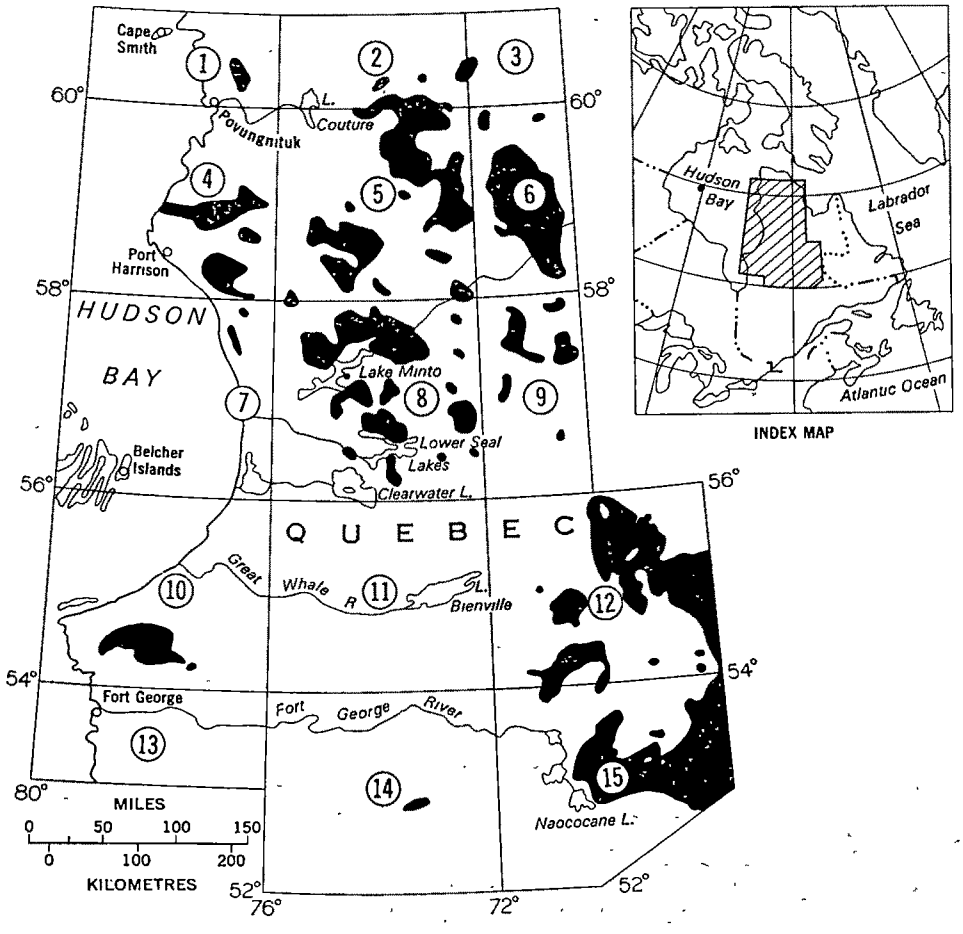

Fig 1.

identification of metasedimentary and metavolcanic rock types. For more detailed descriptions of rock varieties from both the hornblende granulite and amphibolite facies of New Quebec see Eade[2] and Stevenson[3,4].

Map-sheets constituting one quarter of primary quadrangles of the National Topographic System comprise the unit areas in this investigation. In Fig. 1 these map-sheets, or portions of them, are numbered 1 to 15 for ease of reference. The distribution of samples within one area is shown in Fig. 2 and is typical of the other areas. To prepare a sample for analysis the hand specimens of each rock unit, as determined by the geological mapping within each area, were grouped together. Approximately 20 g of each hand specimen were combined to form a composite sample for each rock unit in each area. After crushing, grinding and thorough mixing, a portion of each such area rock unit was analysed by a combination of X-ray fluorescence and chemical methods. The fifteen unit areas provided 78 rock unit samples.

From these 78 analyses the average composition of rocks of the amphibolite and granulite facies of each area studied was obtained by measuring the areas underlain by rock units of the two facies and using these measured areas to obtain a weighted average (Table 1). The average composition of all amphibolite facies rocks and of all granulite facies rocks, together with the average composition for the entire region, were obtained by weighting the data in proportion to the area occupied by each rock type (Table 2). Cratonic cover rocks were not included.

As a check on the validity of such calculated averages, a special composite sample representing areas 6, 9, 10, 11, 12, 13 and 14 was prepared by mixing portions of the area rock unit samples in proportion to the aerial extent of the rock units as measured on the geological maps. This special sample was analysed by classical chemical methods and its composition may be compared with that obtained by calculation from the rapid analyses of individual rock unit samples from the same area (Table 2).

The calculated comparative chemical analyses are shown in Table 1. There are no major differences between the chemical composition of the two facies probably because there were no primary differences in their protorocks. The values for Al_2O_3, total Fe (as FeO), P_2O_5 and, possibly, MgO, CaO and TiO_2, appear to be higher in the

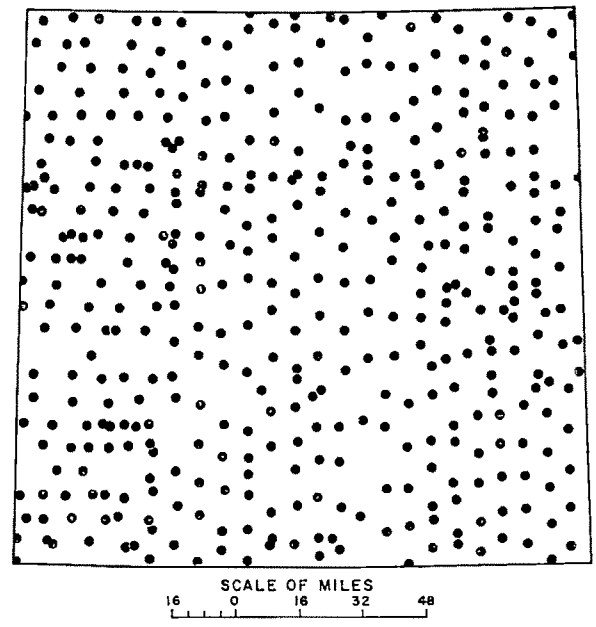

Fig. 2.

granulite facies, whereas K_2O, H_2O and, possibly, SiO_2 appear to be lower. The ferrous–ferric ratio also appears to be significantly higher in the granulite facies. These results seem to corroborate the views of Ramberg[7] and Heier and Adams[8] that high-grade gneisses tend to be more basic than low-grade gneisses. This basification of granulites results from the loss by upward movement of a mixture of more volatile constituents (K_2O, H_2O, SiO_2) in response to regional metamorphism. The loss of potassium from rocks of the granulite facies, and so presumably from deeper crustal levels during regional metamorphism, is particularly interesting as potassium is one of the chief sources of radiogenic heat. Table 1 thus gives some indication of the scale of this migration in one large area of Shield rocks.

The abundance of TiO_2 in the amphibolite facies and the corresponding granulite rocks of each of the sample areas is shown in Fig. 3 in which the values of TiO_2 in the

a, Rocks of amphibolite facies. *g*, Rocks of granulite facies. * No rocks of granulite facies were mapped in those areas.

These calculated values are based on 78 rapid rock analyses provided by the Analytical Chemistry Section of the Geological Survey of Canada. Silicon, aluminium, total iron, calcium, magnesium, potassium, titanium and manganese were determined by X-ray fluorescence using an Applied Research Laboratories X-ray spectrograph (Model *VXQ*–25,000) and a fusion method based on that of Rose *et al* (ref. 12). Sodium was determined by flame photometry, iron-21 titrimetrically, phosphorus colorimetrically and total water and carbon dioxide gravimetrically. The accuracy of the 78 analyses from which the above averages were calculated may be stated as follows, in terms of the possible maximum percentage variation in the reported value: SiO_2 (±1 2); Al_2O_3 (±0·7); Total Fe, as Fe_2O_3 (±0·5); CaO (±0 3); MgO (±1·0); K_2O (±0·1), TiO_2 (±0·05); MnO (±0 02); FeO (±0 2); Na_2O (±0 15); CO_2 (±0·1); Total H_2O (±0·1).

amphibolite facies are plotted in a sequence such that the TiO_2 increases to the right. Titanium is generally higher in the granulite rocks and has a much greater range than in the amphibolite facies. As previously noted, biotite is ubiquitous in New Quebec rocks of the granulite facies and the stability of high-temperature biotite may be the result of a concentration of titanium[9]. Titanium is so much higher in granulite rocks of some of the areas, for example, 1, 5, 9, relative to adjacent rocks of the amphibolite facies that addition of titanium to the granulites is indicated. The source of the titanium may be a deeper, higher-grade granulite in which biotite was unstable and from which titanium was expelled.

Inspection of the analyses indicates little or no regional compositional variation and hence no great variation in the primary rock types throughout the area.

The accompanying data contribute in some measure towards the solving of the problem of the bulk chemical composition of the continental crust. Specifically, of course, the data relate to the surface crystalline rocks of the continental shield. Analysis 1 of Table 2 gives the average composition determined from the sampling of some 200,000 square miles of northern Quebec, Canada. We believe that, as a result of the sampling procedure used, this average closely represents the surface composition of this part of the crystalline shield. The composition of this large cratonic area may be of particular interest because the general absence of "high level" types of igneous intrusions and the widespread occurrence of gneisses of the granulite facies suggest that it represents an area of deep continental crust.

There are small but significant differences between our average composition and the estimate of Poldervaart[6] (No. 8, Table 2) for the average composition of continental shield crystalline surface rocks. The surface crystalline rocks of New Quebec are slightly higher in aluminium and sodium and slightly lower in silicon, potassium, titanium, calcium and phosphorus than the average composition given by Poldervaart[6]. The differences are attributed in part to the migration of silicon and potassium from the present exposed level of New Quebec during high-grade regional metamorphism. Poldervaart's average may represent a composition in which high level granitic intrusions play a more dominant part.

The average composition given by Reilly[10] (No. 7, Table 2) using samples from a Geological Survey of Canada project[11] for an area of 40,000 square miles in north-western Ontario is directly comparable with our data as it is based on a rather similar sampling scheme. The value for aluminium is significantly lower, and that for silicon significantly higher, in Reilly's areas than in New Quebec. The Reilly sample area represents a higher crustal level because both "high level" granitic intrusions and greenstone belts of low metamorphic grade are present in significant amounts.

1. Average composition of the entire New Quebec sample area (Fig. 1) calculated from values given in Table 1.

2. Average composition of all amphibolite facies rocks of the sample area (Fig. 1), calculated from values in Table 1.

3 Average composition of all granulite facies rocks of the sample area (Fig. 1), calculated from values in Table 1.

4. Average composition of all rocks in areas 6, 9, 10, 11, 12, 13, and 14 (sample preparation described in the text) determined by classical chemical analysis, J. A. Maxwell, analyst, Analytical Chemistry Section, Geological Survey of Canada.

5. Average composition of all rocks in areas 6, 9, 10, 11, 12, 13 and 14 calculated from values in Table 1.

6. Average composition of the continental crust, one part basic and one part felsic rock (ref. 5).

7. Average composition of an area of 40,000 square miles of Canadian Shield of Northwestern Ontario (ref. 10).

8. Average composition of shield crystalline surface rocks (ref. 6).

* Total Fe as FeO.

Taylor[5] has used an interesting method for calculating the composition of the continental crust. The distribution of rare earth elements in sedimentary rocks was studied and related to a mixture of the two most common igneous rock types, namely, granite and basalt. His data closely fit a 1 : 1 mixture of basalt and granite (No. 6, Table 2). A possible disadvantage to the calculation is that the results are based on sediments and hence on rare earth element abundances in that part of the crust that has been exposed to weathering. If the continental crust is significantly zoned in its upper part (say, 10 km) the 1 : 1 mixture may not represent continental crustal abundances. Possibly crustal averages from crystalline shield regions of high grade regional metamorphism where "high level" intrusions are lacking are more characteristic of a greater thickness of continental crust.

The data presented here have been considered on two levels, that of the relationship between chemical composition and metamorphic grade, and the average regional composition. It is concluded that there are minor but significant differences in composition between rocks of the amphibolite and granulite metamorphic facies as a result of the removal of some constituents from the granulite zone. The potassium content of rocks of the hornblende granulite facies is lower than in adjacent rocks of the amphibolite facies, suggesting that significant fractionation of this heat-producing element occurs during deep-seated regional metamorphism. There are differences between the average composition of this area of continental shield crystalline surface rocks and previously published average compositions for surface shield rocks. Because the New Quebec area probably represents a deeper crustal level, these differences reflect a chemical zoning of the crust resulting from the transport of low temperature constituents to higher crustal levels. The average composition of New Quebec rocks may be close to the average composition of the

continental crust, or at least that part that lies above the Conrad seismic discontinuity.

THE SOLOMON ISLANDS AS AN ISLAND ARC

By DR. P. J. COLEMAN
Department of Geology, University of Western Australia, Perth

OF the various categories of island arcs which have been proposed[1], the "fractured arcs" are the least known and have received the least attention. So far as routine geological literature is concerned this category of the little known includes the Solomon Islands, a straight-line chain, but with arcuate features, which makes up some 800 miles of the border of the south-west Pacific Ocean.

The Solomon Islands are comparatively new to geology for it was not until 1950 that systematic investigations began. The islands have now been covered by general or semi-detailed reconnaissance surveys. A gravity survey of the land areas has been completed by the Geophysical and Polar Research Centre, University of Wisconsin, and sea gravity and aeromagnetic surveys are planned for the near future*. This article is based primarily on stratigraphical investigations, the results of which, however, are supported by the geophysical information so far available. It aims to give a summary of the island arc features which distinguish this island chain. It would be premature, however, to use these as a basis for interesting speculations on various aspects of the grand tectonics of the region; for this, more detailed information is required, especially on bathymetry and on the gravity picture.

Disposition and Bathymetry

The Solomon Islands lie east of New Guinea (Fig. 1). As a geological entity the Solomons probably include the Lihir group of small volcanic islands, but not the Santa Cruz group to the east which geologically is part of the New Hebrides archipelago.

The axis of the Solomon bathymetric high appears distinctly sigmoidal. Over the middle part the islands form a double chain around a rhomb-shaped basin up to 2,500 m deep. The bathymetry is confused about Malaita and San Cristoval, where there are rhomboidal, linear and small "pocket" depressions. On the Pacific side the islands Bougainville-Choiseul-Santa Ysabel-Malaita are progressively offset so that they lie *en echelon* to each other. This arrangement persists in the bathymetric lines, but is not followed by the islands on the opposite flank.

On the Australian side the Solomon high is bordered by the Solomon Trough which includes part of the Planet Deep (over 9,000 m), unnamed deeps of over 5,000 m, and the San Cristoval Trench (about 7,000 m). Somewhat sinuous in plan, it is roughly arcuate and convex towards Australia. The Solomon high is separated from the large platform of the Ontong Java Rise by minor linear deeps.

* August, 1966: the aerogeophysical survey is now nearly completed

Stratigraphy and Structure

The account which follows is based on the work of British Solomon Islands Geological Survey personnel (in particular that of J. C. Grover, Chief Geologist; R. B. Thompson, P. Pudsey-Dawson and B. D. Hackman); R. L. Stanton, University of New England; F. K. Rickwood, British Petroleum Company, and that of the writer. Unpublished information on Bougainville was supplied by J. G. Speight, Commonwealth Scientific and Industrial Research Organisation, and D. H. Blake, Bureau of Mineral Resources, Canberra. Detailed references up to 1963 are given in ref. 2.

The Solomon Islands constitute an autochthonous stratigraphical system; that is, all the rocks present have originated within the region. On the bases of rock type and structure the group can be divided into three provinces (Fig. 2): the Volcanic, Central and Pacific Provinces.

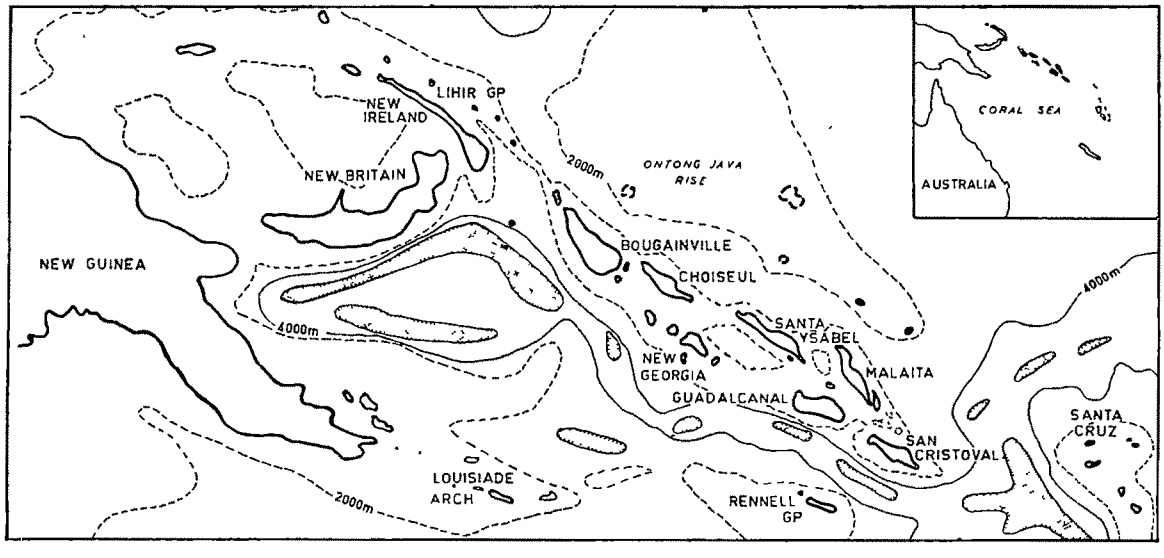

Fig. 1. Generalized locality and bathymetry map of the Solomon Islands region. As a geological entity the Solomons block probably includes the Lihir Group, but not the Santa Cruz Group

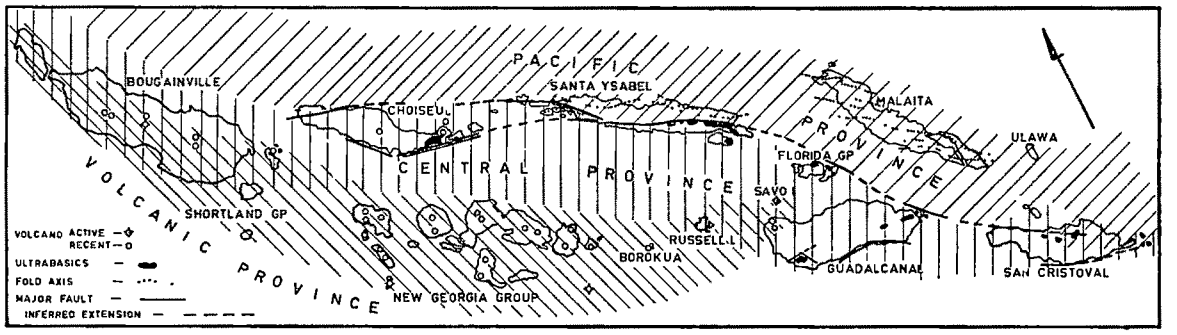

Fig. 2. Geological provinces in the Solomon Islands and the distribution of active and recent volcanoes, ultrabasic (serpentine) rocks and major structural features.

The arcuate Volcanic Province includes more than thirty well preserved recent volcanoes, but only a few are at present active. It is best exemplified by the New Georgia Group which is an assemblage of cones linked by their own extrusives and by fringing reefs. The lavas and pyroclastics are mainly andesitic and probably no older than Pliocene. Faulting is intense and many large faults are active. The three recent volcanoes on Choiseul are in an area of great fractures associated with the boundary between the Central and Pacific Provinces and may not be truly a part of the Volcanic Province. In terms of the continuing development of the Solomons, the Volcanic Province may be regarded as a youthful extension of the Central Province.

The Central Province has a Mesozoic (probably Cretaceous) igneous and metamorphic basal complex which includes chloritic and amphibolitic schists, a few patches of lightly metamorphosed pelagic sediments, and some gabbroic and granitoid rocks. Potassium–argon radiometric age determinations of the Choiseul schists indicate a Lower Eocene age of metamorphism. The results are described in detail in the accompanying paper[3].

The basal complex is intruded and covered by Upper Eocene–Oligocene lavas and occasional agglomerates, predominantly andesitic, although basaltic pillow lavas are also common. The lavas may be up to 3,000 ft. thick. They are overlain by a pile of reef-sediments, re-worked tuffs and material derived from the older lavas, which range in age from early Miocene (approximately equivalent to Aquitanian of the Lower Miocene) through Recent. The sediments accumulated in subsiding fault-bounded troughs. In one such trough on north-east Guadalcanal, there are more than 15,000 ft. of sediment, a large part of it derived from a source area, now many hundreds of feet below sea level, off the south coast. Regional dips are usually of the order of 5–15 degrees. Some Quaternary fringing reef masses have been uplifted more than 1,200 ft.

The Central Province is shaped and shattered by high-angle faults, which in plan form an irregular mesh-work, the result of the intersection of two major sets, one trending 80–100 degrees, the other 145–160 degrees. A less obvious set trends 30–50 degrees. Many faults have strong strike-slip components, but neither the lateral nor the vertical movements have acted to produce a systematic result, except on Guadalcanal which has a spine of step-faulted block mountains, asymmetric in cross-section and falling away steeply to the fault-bounded southern coastline. The south coasts of San Cristoval and east Choiseul also have tensional features.

The boundary between the Central and Pacific Provinces is marked by an apparently sigmoidal "lineament", almost certainly a major crustal fracture system, expressed emphatically by great faults in Choiseul and particularly by those running through the length of Santa Ysabel, and delineated also by a serpentine belt (Fig. 2). The first erosion products from these serpentinites appear in Lower Miocene sediments (approximately Burdigalian).

The Pacific Province contrasts markedly with the Central Province. It is demonstrated best on Malaita where basal basaltic lavas, which show evidence of submarine emplacement, are overlain in large part by about 4,000 ft. of calcareous organogenic sediments which range in age from Upper Cretaceous through Quaternary. Some of the Upper Eocene sediments show contemporaneous intrusion by younger lavas. These include types akin to alnöite and ankaratrite; it is worth noting that similar alkaline lavas occur in the Lihir Group[4]. The older sediments consist essentially of planktonic foraminifera and their clayey detritus, although radiolarian cherts are common and at least one benthonic fauna (of Upper Eocene age) is present. The Upper Miocene and younger sediments show an increasing amount of terrigenous (volcanic) material.

The whole sequence is folded with moderate intensity to give a series of rather irregular folds disposed *en echelon* to the general trend of the island. The older sediments are crumpled in cascade fashion on the limbs of the folds and show other evidence of deformation before consolidation. These folds may well be of the *Bruchfalten* type, brought about as much by movements in the faulted lava basement as by lateral compression.

The marginal areas on Santa Ysabel and San Cristoval have thinner sequences with a much higher terrigenous content than those on Malaita. So far, no basal complex of the Central Province type has been found in the Pacific Province.

Island Arc Features

Although it lacks much significant detail, the outline just given provides a minimal background for the following generalizations.

The Solomon Islands chain is an autochthonous geological system which had its origin in the Mesozoic, probably in Cretaceous time.

The Solomon block is not sharply demarcated from New Ireland nor the Ontong Java Platform, but is clearly separated from the easterly extension of New Guinea (Louisiades–Rennell Rise) by the Solomon Trough, a deep which is subarcuate and convex towards Australia.

The crustal thickness of the Solomon block has been estimated to be about 15 km, a result[5] based on the rather slender seismic evidence then available. The recent gravity work suggests a lower figure. It also suggests that the region is a gravity high with large positive and negative anomalies superimposed, having gradients as steep as any so far recorded (personal communication from T. S. Laudon, University of Wisconsin). Significantly, the positive anomalies on Guadalcanal and San Cristoval increase in magnitude (to over 200 milligals) from north to south, towards the Solomon Trough. Data from gravity, structural and stratigraphic investigations indicate that the Solomon block is in a state of isostatic imbalance, with great vertical displacement of crustal and subcrustal material, and that it is made up of elongated

rhomboidal blocks defined by fractures with preferred orientations of 80–100 degrees and 145–160 degrees (usually the long dimension). The common *en echelon* arrangement of these blocks, due to differential movement between them (as reflected by Bougainville–Choiseul–Santa Ysabel), gives rise to asymmetric flattened sawtooth lineaments, thus ⩘⩘. If the angles of such lineaments be rounded off (subjectively, by the observer) then sigmoidal lines result and this is the probable explanation of the many sigmoidal trends observed in the region[6], both large and small scale; for example, the axis of the Solomon block, the border between the Pacific and Central Provinces and the north and south coasts of Guadalcanal.

A belt of high seismicity lies between the Solomon Trough and the axis of the Solomon block, with shallow shocks greatly predominating, most of them probably tectonic. Intermediate and deep focus earthquakes are comparatively rare and tend to be concentrated at the Bougainville and San Cristoval ends. In profile, the seismic zones appear to be either vertical or steeply inclined to the Pacific, but they are neither clearly defined nor continuous, with a near-gap between 170 and 300 km depths, and finishing at 500 km.

The oldest unaltered lavas (Lower Cretaceous to Eocene) are basic, probably submarine in large part and are found on the Pacific side. The youngest (Quaternary) are on the Australian side, are predominantly andesitic and have been produced by a volcanic belt which is subarcuate and convex to Australia. The lavas of the central region are mainly of Upper Eocene–Oligocene age, and are generally andesitic.

Folded terrains are found only on the Pacific side. Folding probably began in Upper Eocene time and reached its greatest intensity in the late Miocene.

The folded Pacific Province alone has pelagic sediments in quantity, but pre-Pleistocene reefal sediments are not found.

The central region is shattered by a trellis pattern of high-angle faults which have dominated the structure and sedimentation since at least Upper Oligocene time. The faulted Central Province alone has large areas of regional metamorphic rocks and great thicknesses of terrigenous sediment. The last and possibly the only major episode of metamorphism occurred in the Lower Eocene.

The present-day proximity of the Central and Pacific Provinces, with their contrasting stratigraphies, poses a problem centred on the presence of widespread Eocene metamorphics in the Central Province and unmetamorphosed contemporaneous lavas and pelagic sediments in the Pacific Province. This problem can be resolved by postulating a past shift of the Pacific Province relative to the Central Province; that is, strike-slip movement along a fault or system of faults during the Upper Eocene–Oligocene, a time fixed by stratigraphic evidence. An obvious target here is the fracture system/serpentine belt separating the two provinces and manifestly a belt of some tectonic significance. Alternatively, the total movement involved could have resulted from the cumulative effect of small incremental shifts by a number of blocks making up the region. Neither idea is supported unambiguously by investigation of the lesser faults, many of which have strike-slip components. Regionally, the progressive off-setting of the islands on the northern flank, the trends of the largest faults and lineaments and tensional features such as the central rhomboidal bathymetric depression suggest past movement of the Solomon blocks to the north-west in the relative sense. It is conceivable that the Pacific Province either did not share this movement, or, more likely, moved at a slower rate and was, as it were, overtaken by the Central Province. The overall structure of the Solomons is consistent with Carey's Tethyan Torsion Zone[7] and the offsetting which resulted in the Melanesian Re-entrant (Solomons–Fiji–Tonga–Kermadec).

The build-up of the Volcanic Province has been accompanied by tension in, and collapse of, parts of the Central Province.

No true granite plutons have been found.

The Solomon chain can be compared most closely with the New Hebrides group (a conclusion based largely on unpublished information). Its central Province has some features in common with the Fiji group, but no relationship is suggested: Fiji remains a tectonic enigma. The Solomon chain is quite distinct from the other larger Pacific arcs, or parts thereof, including the herniated arcs of the Caribbean and Nova Scotia.

POTASSIUM–ARGON MEASUREMENTS OF THE AGE OF BASAL SCHISTS IN THE BRITISH SOLOMON ISLANDS

By Dr. J. R. RICHARDS and J. A. COOPER
Department of Geology and Geophysics, Australian National University, Canberra
A. W. WEBB
Bureau of Mineral Resources, Geology and Geophysics, Canberra
AND
Dr. P. J. COLEMAN
Department of Geology, University of Western Australia, Perth

This article reports the results of the first radiometric age determinations on basal schists from Choiseul Island in the Solomon Islands group, located east of New Guinea in the south-west Pacific Ocean. In the preceding article, Coleman summarizes the present understanding of the geology of this group. Conventional biostratigraphic methods have unravelled the basic history of the Pacific Province in these islands as far back as the Upper Cretaceous, but only to the early Miocene in the adjacent Central Province. Here, the fossiliferous Miocene sediments overlie a pile of andesitic lavas and older metamorphosed volcanics of the basal complex[1]. The time of this metamorphism, an important parameter of the tectonic history of the region, seemed to offer the best target for an exploratory venture in potassium–argon dating.

Amphibolites are widely distributed on Choiseul Island and have similar petrological characteristics. They were probably derived from rather basic lavas

(basic andesites, basalts) and their equivalent pyroclastics; a few samples show what appears to be relic bedding. From the twenty samples available from the collection of the Geology Department, University of Western Australia, three were selected. The criteria for selection were: freedom from weathering effects (this factor alone, in such a tropical terrain, barred most samples); a location removed from faults (again, an almost prohibitive condition); the sample should be "typical"; the samples should not all be from the same locality, to lessen the possibility of unsuspected contact-metamorphic effects brought about by a hidden igneous intrusion.

Sample *GA* 698 (53878) met these requirements rather better than the others, which were both about 50 ft. from faults, judged to be small ones.

The first number refers to the Australian National University geochronology collection and applies to a split of the main sample (number in parentheses) in the collection of the Department of Geology, University of Western Australia. *GA* 698 (53878): from the west coast of the northern end of a small un-named island a few hundred yards to the east of the mainland, north of Siutu Island, Eastern Choiseul. Co-ordinates on the 1,000 metre southern New Guinea Zone, British Metric Grid, Bessel Spheroid, are 3834697/1063559, eastings first.

The sample was taken at the northern end of a beach outcrop, from an unweathered ledge which was broken up to give the freshest possible sample.

GA 699 (53879): same locality as 53878, but taken from a spot about 80 ft. south.

GA 700 (53880): collected from outcrop filling small stream bed, 50 ft. from east bank of the Kolumbangara River, on upstream limb of large open hairpin bend about 6 miles from the river mouth, western Choiseul. Co-ordinates are 3750369/1103545.

The samples are similar in hand specimen and in thin section. They are dark green, fine grained, finely foliated amphibolite schists. The foliation is due to the partial segregation of the hornblende and feldspar, which are in roughly equal proportions, and together make up 95 per cent of the whole. The hornblende is a bright green pleochroic variety common to such rocks, and occurs in streams of aggregated shreds and elongated crystals; these may contain grains of apatite, clinozoisite, epidote and sphene, and wholly or partially envelop feldspar crystals. The feldspar, a plagioclase close to andesine in composition, shows crystals which are more tabular and less elongated than those of the hornblende. Epidote occurs as veinlets of tiny anhedral grains and as granular aggregates. The grains of iron ore (commonly magnetite) are dragged out into strings. The quartz is probably secondary, occurring as veins which are often distorted and faulted.

A block was cut from the centre of each sample, and crushed. Because of the small size of the grains and their original interlocking relationship, composite grains could only be avoided by separations performed on material retained on the 250 Tyler screen but passing through the 115 screen. Ten grams of hornblende and 5–10 grams of plagioclase were obtained for each sample.

Potassium was determined by flame photometry by intercomparison with standard solutions, using a lithium internal standard and a sodium buffer[2]. Argon was determined by isotope dilution, following extraction procedures very similar to those described by Evernden and Curtis[3], with the exception that acid-washing was not used.

The results are summarized in Table 1. The potassium contents of these minerals are low, but the analyses should be good to better than 2 per cent at the 95 per cent confidence level. The low potassium content, comparatively young age, and fine particle size with the consequently high surface area available for adsorption, all lead to a high proportion of air argon in the analysed gas. Thus

Table 1. CHOISEUL RESULTS

Sample No.	Mineral	per cent K	Ar^{40}/K^{40} *	Air Corr. (per cent)	Age (m.y.)
GA 698	Hornblende	0·168	$3·047 \times 10^{-3}$	91·9	51·5
(53878)	Plagioclase	0·114	$2·931 \times 10^{-3}$	90·4	49·5
GA 699	Hornblende	0·219	$2·575 \times 10^{-3}$	76·7	43·6
(53879)	Plagioclase	0·138	$2·397 \times 10^{-3}$	88·1	40·6
GA 700	Hornblende	0·233	$2·621 \times 10^{-3}$	78·2	44·3
(53880)	Plagioclase	0·1068	$1·910 \times 10^{-3}$	93·2	32·4

differences in the ages of less than 10 per cent may well not be significant[4].

The observed spread of ages is very high. On the not unreasonable assumption that metamorphism of all three samples took place at the same time (the first two came from closely related localities, the second and third yield closely similar hornblende ages), we deduced a standard deviation of $\pm 6·8$ m.y. for any one of the six ages. This gives 95 per cent confidence limits (for five degrees of freedom, $t = 2·57$) of $\pm$ 17·5 m.y., amounting to $\pm$ 40 per cent, based on the mean value of 44 m.y.

We therefore look for any special, probably geological, circumstances which may enable us to give greater credence to some results, or to reject others as of lesser significance. Previous examination of thin sections had given no cause to reject any of the three samples. Other sets of results[4] suggest that air corrections of the magnitude reported here are insufficient to account for this high scatter of ages. Next we observe a general tendency for the plagioclase to appear younger than the corresponding hornblende. This is small for the first two samples, larger for the third. As plagioclase in general responds more readily than hornblende to factors causing argon loss, we have some grounds for placing less weight on the result for *GA* 700 plagioclase. Third, and possibly most significantly, we recall that *GA* 698 was the only sample for which close proximity (less than 50 ft.) to a fault was not recorded.

Thus we conclude that the time of metamorphism of the original rocks to the amphibolite schists lay somewhere within the range 44 $\pm$ 18 m.y. (at the 95 per cent confidence level), with a preference for the figure 50 m.y. (average of *GA* 698 results). On the currently accepted time-scales[5] this implies a geological age of Lower to Middle Eocene, with bias towards Lower Eocene (Lutetian, possibly Ypresian—Evernden *et al.*[6]).

The metamorphism cannot have occurred more recently than Upper Eocene, but this younger limit, based as it is on the *GA* 700 plagioclase result, cannot be regarded seriously. These conclusions represent a good geological fit for Choiseul and, indeed, if extrapolated to the Guadalcanal schists, for the whole of the Central Province.

The fixing of a Lower–Middle Eocene time of metamorphism provides a causal connexion between the Lower Tertiary lava pile in the Central Province and the stresses which were responsible for the metamorphism of the underlying schists, and disposes of a time-gap which, on previous evidence, could have existed between the schists as such and the lavas.

Taken with the other evidence[1,7], our results remove the need to suppose that the Solomons Group began its history any earlier than the late Mesozoic (? Cretaceous) and pose the problem examined by Coleman[1], of reconciling the near-juxtaposition of two contrasting geological terrains: Eocene metamorphics in the Central Province, and unmetamorphosed Upper Cretaceous–Eocene lavas aad sediments in the Pacific Province.

IRON-55 IN MARINE ENVIRONMENT AND IN PEOPLE WHO EAT OCEAN FISH

By H. E. PALMER and T. M. BEASLEY
Battelle Memorial Institute, Pacific Northwest Laboratory, Richland, Washington
AND
DR. T. R. FOLSOM
Scripps Institution of Oceanography, La Jolla, California

THE concentrations of iron-55 in human beings and their food both in Alaska and in the State of Washington were recently reported[1]. During the course of this investigation, it was found that ocean fish had higher concentrations of this radionuclide than did the Alaskan caribou. This finding suggested that individuals whose diet contained large quantities of ocean fish could have body burdens several times higher than those of the caribou-eating Eskimos, and perhaps several orders of magnitude higher than those measured in residents of Richland, Washington. This article details the measurements that have been made on samples from the marine environment, and includes estimates of the body burdens of iron-55 of individuals who derive a major portion of their diet from ocean fish.

The concentrations of iron-55 in ocean fish have been reported previously[2,3], but the measurements were made before the last series of atmospheric nuclear tests. The concentrations in salmon and tuna fish are now 100–200 times those reported for these earlier measurements. We have analysed a number of marine samples in an attempt to (*a*) indicate the iron-55 concentrations in the various trophic levels of the marine environment and (*b*) point out the relative concentrations of iron-55 in those marine organisms which serve as foodstuffs for human beings.

Table 1. IRON-55 IN OCEAN FISH DURING THE LAST SIX MONTHS OF 1965

Type of fish (flesh)	No. of samples in average		Average stable iron content (mg/kg)	Average iron-55 content (nc./kg)
Salmon	1	Ocean at Kotzebue, Alaska	12·0	93·0
Salmon	1	Ocean at Kotzebue, Alaska	4·6	48·0
Salmon	3	Yukon River in Alaska	13·2	37·0
Salmon	1	Cook Inlet, Alaska	14·2	34·0
Salmon	1	Washington coast	5·8	14·0
Albacore tuna	1	Northern Pacific Ocean	19·1	42·0
Albacore tuna	1	Southern Pacific Ocean	16·3	1·6
Albacore tuna	1	Northern Atlantic	11·1	8·4
Albacore tuna	1	Southern Atlantic	4·5	0·78
Ocean perch	1	Pacific	1·9	0·85
Cod	1	Pacific	—	0·20
Whitefish	3	Northern Alaskan coast	11·0	0·10
Shee fish	2	Northwestern Alaskan coast	—	0·48
Sea bass	1	Washington coast	63·7	0·27
Swordfish	1	Pacific	—	0·33
Herring	2	Packed in Norway	—	20·0
Herring	3	Canadian West coast	11·2	0·79
Sardines	2	Packed in Norway	—	15·0
Sardines	2	Packed in Maine, U.S.A.	—	2·6
Smelt	2	Washington coast	18·2	0·41
Saury	(Several whole fish)	Oregon coast	52·3	106·0

Table 1 contains the results of the analysis of a variety of ocean fish using the methods previously described[1]. Several interesting points are evident from these data. First, it is seen that salmon, tuna and saury fish have the highest content of iron-55. Saury fish is processed in Japan and sold for human consumption, but only in a very small amount compared with the consumption of salmon and tuna. The saury fish that we analysed were taken in the plume of the Columbia River outlet, and some of the iron-55 in these fish probably comes from the cooling water at the Hanford nuclear reactors which empties into the river. The concentrations of iron-55 in herring and sardines canned in Norway are relatively high at about 15 nc./kg, whereas iron-55 concentrations in the same type of fish from the United States and Canada are lower by a factor of ten. We have not measured enough samples to determine if this difference is consistent or why the difference exists. Secondly, tuna caught in the northern oceans have more iron-55 than those caught in the southern oceans, and those in the Pacific Ocean have more iron-55 than those in the Atlantic Ocean. These differences in iron-55 concentrations of ocean fish from different geographical locations are consistent with the differences in concentration of caesium-137 (ref. 4), cobalt-60 and silver-110 (ref. 5); however, the interesting observation is that the iron-55 concentrations are about 1,000 times higher than the reported concentrations of the other three isotopes.

The relatively high concentrations of iron-55 in the marine species measured largely results from the low concentration of stable iron in sea-water (~ 10 μg/l.). Most of these marine species also have a lower iron content than do land animals. Furthermore, radioactive iron falling on land surfaces will be diluted by the large amount of stable iron existing there, and as a result the uptake of iron-55 by plants and animals will be greatly reduced because of this dilution. Salmon and tuna fish, on the other hand, are fast growing fish and living in a low iron environment probably take up and retain most of the iron available to them. The slower growing fish such as sea bass, perch, and whitefish contain much less iron-55. The lower ratio of iron-55 to stable iron which was measured in these fish confirms the possible lower uptake and slower growth.

Table 2 contains data on the relative concentrations of iron-55 in the liver, roe, and muscle of two chum salmon caught at Kotzebue, Alaska. The livers of these salmon contain almost 2 μc. of iron-55/kg of liver (wet weight) and represent the highest concentrations we have measured in any organism or tissue. It is also interesting to note the rather uniform labelling of the salmon as evidenced by the ratio of radioactive to stable iron in the various tissues.

Since salmon are known to feed on a variety of marine organisms (plankton, euphausiids, herring, squid, etc.), it is difficult to attribute their high iron-55 concentrations to the consumption of a specific species. Indeed, these high concentrations probably result from intake both of small fish of relatively high activity, such as herring or saury, and of organisms of lower activity such as plankton, euphausiid and squid. Table 3 lists some representative values of the iron-55 concentrations in these trophic levels. The barnacles are surface-living organisms which were taken from glass floats off the California coast, and their high iron-55 content indicates a large uptake from fresh fallout on the ocean surface. The higher availability of iron-55 at the surface may be the reason for the high concentrations in saury fish because they also live close to the surface. The sea cucumbers are mud scavengers and these samples were taken from the Columbia river plume which probably accounts for their high content of iron-55. Other marine organisms such as oysters, scallops, clams, shrimp and crab have very

Sea urchins (whole)	Oregon coast	0·48

Table 4. COMPARISON OF IRON-55 BODY BURDENS IN ALASKAN NATIVES WITH MEAT AND FISH CONSUMPTION

Alaskan village	Ratio of fish consumption*/ animal meat consumption	Average adult male body burden (nc.)
Anaktuvuk Pass	0·19 (ref. 8)	81
Allakaket (Tanana Area)	0·7 (ref. 9)	252
Southwestern Alaska (Bethel Area)	4·4 (ref. 9)	900

* The type of fish consumed is mostly salmon except at Anaktuvuk Pass where salmon are not available.

low concentrations of iron-55 (ref. 1) and probably do not contribute much to the iron-55 body burdens of either other marine species or humans.

As might be expected, these high concentrations of iron-55 in the salmon produce higher than average concentrations of iron-55 in populations who eat substantial quantities of these fish. The caribou-eating Eskimo of Anaktuvuk, Alaska, had an average iron-55 body burden of 61 nc. in January 1965 (ref. 1). In November 1965, this same group of people had an average iron-55 body burden of 81 nc., an increase of some 13 per cent. By way of comparison, adult male Eskimos from Tanana, Alaska, who eat large quantities of salmon in addition to caribou and moose meat, showed an average iron-55 body burden of 252 nc. Furthermore, recent blood samples received from natives in south-western Alaska near Bethel, Alaska, who eat more salmon than the Tanana natives show that the average body burden of iron-55 in the adult male is about 900 nc. in some villages, with one individual having a body burden of 2,300 nc. Data on fish consumption from studies of Alaskan diets are compared with these body burdens in Table 4, and these show a definite correlation between salmon consumption and body burden of iron-55.

In the analysis of the blood specimens obtained from the Bethel natives it was found that the average body burden of iron-55 in the females was twice that of the males. The opposite is true in the case of caesium-137 in the Alaskan natives where the content in women is consistently two-thirds that in the males[8] due to their lower dietary intake. Because the food intake of women is generally lower than that of men, the higher iron-55 body burdens observed in this case probably reflect the more rapid turnover of iron by females. This probably results from the loss of iron through the menstrual blood with the result that their body burdens are closer to an equilibrium with the iron-55 in their diet than are those of the males.

Despite the fact that some of the Alaskan natives have body burdens approaching 2·3 μc., which is about 100 times the average level of residents of the State of Washington, it must be emphasized that these levels are far below the maximum permissible body burden of 100 μc. for members of the general population who are not exposed to iron-55 in the course of their occupations[7]. The radiation dose to the erythrocyte fraction of the blood of a person with a constant iron-55 body burden of 1,000 nc. would be approximately 30·0 m rem per year. This is only about 30 per cent of the yearly dose to the body from natural sources such as cosmic rays and internally deposited potassium-40 and radium.

As a result of these investigations it can be predicted that populations in northern countries such as Japan and the Scandinavian countries who eat large quantities of ocean fish probably have relatively high iron-55 body burdens as do the Alaskan natives. In our present investigations we are measuring the iron-55 content in various populations of the world.

We thank R. M. Bernard and T. A. Jokela for their assistance in analysing the many samples, Dr. J. M. Aase and Dr. H. D. Miller of U.S. Public Health Service in Alaska for obtaining blood samples from Alaskan natives, and Mr. Max Brewer, director of the Arctic Research Laboratory, for support in obtaining the many Alaskan samples. This work was performed under a contract between the U.S. Atomic Energy Commission and Battelle Memorial Institute.

EFFECTS OF IRRADIATED SUCROSE ON THE CHROMOSOMES OF HUMAN LYMPHOCYTES *IN VITRO*

By DR. MARGERY W. SHAW and EMMET HAYES
Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan

EVIDENCE is available that suggests that certain food substances, or their derivatives, may be toxic and/or mutagenic if exposed to irradiation before being utilized by micro-organisms, plants and animals. Stone *et al.*[1] reported that broth irradiated with ultra-violet light is capable of inducing mutations in *Staphylococcus aureus*. Several investigators[2–4] have demonstrated an increase in mutations when *Drosophila melanogaster* are reared on irradiated food. Others have reported cytological aberrations in higher plants produced by irradiated carbohydrates[5–8]. These include chromosome stickiness, lagging anaphase fragments, nuclear disintegration, formation of micronuclei, increased chromosome breakage at the centromere region, and arrest of prophase. Toxicity to mammalian cells *in vitro*, as shown by growth inhibition produced by irradiated glucose and fructose in the culture media, was demonstrated by Berry *et al.*[9].

To our knowledge, no studies have been reported on the effects of irradiated media (or irradiated components of the media) on the chromosomes of mammalian cells. This article describes experiments concerned with the effects of irradiated sucrose on the chromosomes of human lymphocytes *in vitro*.

The test solutions used in these experiments were autoclaved sucrose solutions which had not been exposed to radiation (control) or which had received 2 Mrads (2 million rads) from a cobalt-60 source (treated). Irradiation and autoclaving were carried out several months

before the experiments, and the solutions were stored at room temperature or at 5° C. The sucrose solutions were irradiated at a concentration of 2 per cent and were evaporated for shipment to 20 per cent. Just before use, various dilutions of the test solutions were made with 0·9 per cent sterile sodium chloride solution.

Heparinized syringes were used to obtain venous blood from four healthy adult males and females. Each culture tube contained 5 ml. of culture medium with phytohaemagglutinin (Grant Island Biological Company, Medium 1*A*), 0·25 ml. whole blood, and 0·25 ml. of appropriate dilutions of the sucrose test solutions. In some experiments the sucrose was added at the beginning of the culture period, while in others it was added 24 h before collecting the cultures.

All cultures were incubated for 72 h at 37° C. Three hours before gathering them, colchicine was added to give a final concentration of 0·6 μg/ml. culture medium. The cultures were collected and slides prepared using minor modifications of the method of Moorhead *et al.*[10]. Many replicate slides of each culture were made and assigned code numbers by individuals who did not participate in the microscopic studies. Five well spread mitoses per slide were chosen under low power for the purpose of scoring the number of chromosome abnormalities : scoring was done directly with oil immersion phase microscopy.

Aberrations were classified as "breaks" only if a distinct discontinuity of the chromosome matrix was visible. If two breaks were visible in homologous regions of sister chromatids they were scored as a single isochromatid break. If a region of the chromosome appeared pale, stretched, uncoiled, or attached by a tiny thread it was scored as a "gap" but not included in the calculations of breakage rates. Single acentric fragments were counted as chromatid breaks while double fragments were included among isochromatid breaks. Exchange figures were scored separately.

The following results were obtained:

(*A*) *Seventy-two hour treatment.* Preliminary experiments suggested that when the irradiated sucrose solutions were added at the beginning of the culture period at concentrations of 0·55 per cent and more, they were extremely toxic to the lymphocytes. Mitoses were inhibited and many of the non-dividing cells appeared pycnotic and had not undergone normal "blast" transformation. Degenerated mitoses were observed and the chromosomes were grossly damaged. The chromatin material was clumped or the chromosomes appeared shattered or pulverized. In the few dividing cells where definite counts could be made the chromosomes appeared "sticky" with attenuated regions and telomere strands (Fig. 1*a*). In contrast, treatment with unirradiated sucrose for 72 h at the same concentration had no apparent effect on the mitotic rate and the chromosomes were not visibly damaged. Table 1 gives the mitotic rates for both treated and control cultures.

(*B*) *Twenty-four hour treatment.* In subsequent experiments the sucrose solutions were added 24 h before the cultures were collected. Cultures containing irradiated or unirradiated sucrose at eight different concentrations were prepared. In these cultures an adequate number of

Table 1. MITOTIC RATES AND FREQUENCIES OF CHROMOSOME BREAKS IN HUMAN LYMPHOCYTES TREATED WITH IRRADIATED AND UNIRRADIATED SUCROSE

Final concentration in culture (per cent)	Time treated (h)	Mitoses per 1,000 cells	Breaks per 100 mitoses	Percentage of mitoses with breaks

0·009	24	71	6	4

* Frequencies of breaks could not be obtained because of the poor condition of the cells and the rarity of mitotic figures. The chromosomes appeared to be "shattered".

† Many mitoses could not be scored because of the severe erosion of the chromosomes. The number of breaks given is therefore a minimum figure.

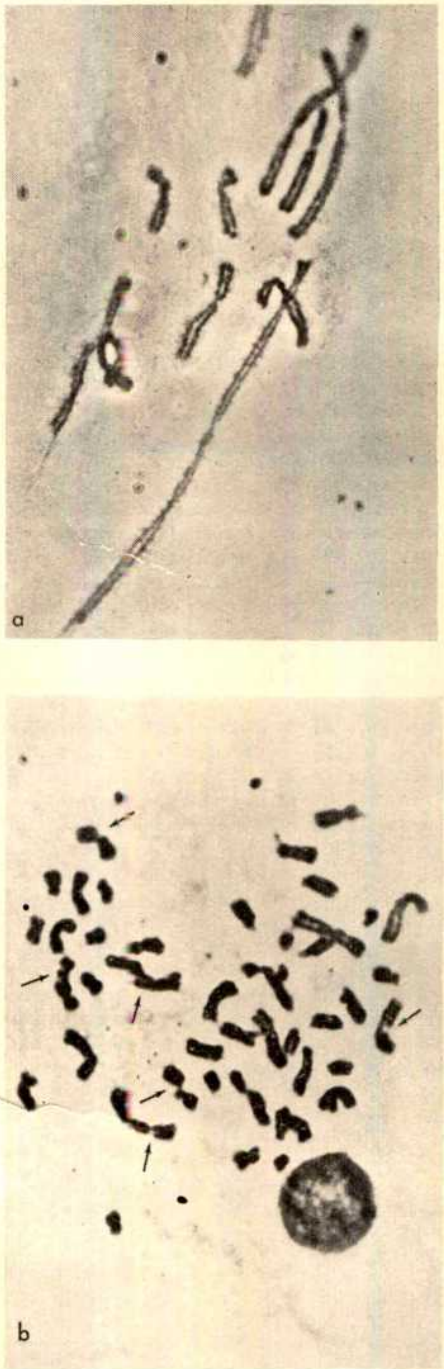

Fig. 1. Effects of irradiated sucrose solutions on the chromosomes of cultured human lymphocytes. *a*, 72-h treatment, 0·55 per cent sucrose. Note extreme attenuation of the chromatin material, the "sticky" appearance of the matrix, and the telomere strands. *b*, 24 h treatment, 0·91 per cent sucrose. Arrows point to chromatid and isochromatid breaks and gaps.

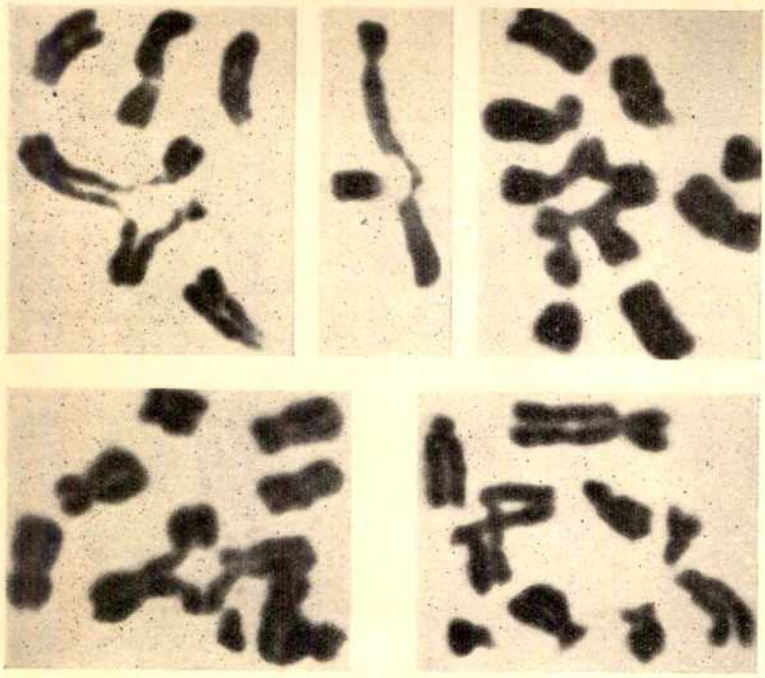

Fig. 2. Five exchange figures produced by treatment with irradiated sucrose solutions for 24 h. A complex exchange involving three chromosomes is shown in the upper right.

mitoses were present and could be scored for chromosome abnormalities. These results are also given in Table 1. At concentrations of 0·36 per cent or greater, the mitotic rate was lower in the treated cultures. At all concentrations of irradiated sucrose tested there was an increase both in the total number of breaks and in the percentage of mitoses with one or more breaks. Fig. 1*b* illustrates a metaphase from a cell which had been exposed to irradiated sucrose for 24 h. The proportion of breaks which were of the isochromatid type was much higher in the treated cells (52/234) than in the control cells (2/37). Among the treated cells there were eight double fragments and two single fragments, compared with one single fragment in the controls. Fig. 2 illustrates five of the nine exchange figures which were scored among the treated cells. Undoubtedly they were induced by the irradiated sucrose solutions because no exchanges were observed in the controls. Endoreduplication was encountered four times among treated cells when mitotic rates were being scored; this phenomenon was not seen on the control slides. Dicentric chromosomes and rings were not observed.

(*C*) *Specific effects of irradiated sucrose.* The distribution of breaks among specific chromosomes or groups of chromosomes is given in Table 2. The observed distribution agrees closely with that expected, based on random breakage per unit of chromatin length calculated from the Denver measurements[11]. Although breaks may be randomly distributed among chromosomes it does not follow that they occur within a given chromosome randomly along its length. Several regions of several chromosomes were quite frequently broken and may represent "hot spots". For example, thirty-one of forty-one breaks found in the *D*13–15 group occurred in the middle third of the long arm; seven of eleven breaks in the *F*19–20 group occurred in the proximal third of one arm; and twenty-two of thirty-nine breaks in *A*1 occurred in the middle third of one arm rather than at the paracentric secondary constriction.

Table 2. DISTRIBUTION OF CHROMATID AND ISOCHROMATID BREAKS ACCORDING TO SPECIFIC CHROMOSOMES OR GROUPS OF CHROMOSOMES

Chromosome or group	Chromatid breaks	Irradiated sucrose Isochromatid breaks	Total breaks	Expected No. of breaks*	Unirradiated sucrose Total breaks
*A*1	36	3	39	28·6	4
*A*2	24	6	30	26·7	4
*A*3	14	3	17	22·4	2

*E*16	4	0	4	10·0	0
*E*17–18	15	4	19	18·0	3
*F*19–20	9	2	11	15·0	3
*G*21–22	4	2	6	10·6	1
Y	0	0	0	2·8	0
Total	282	52	234	233·7	37

* Expected values derived from measurements given in the Denver report (ref. 11). Breaks are assumed to be random according to unit chromatin length.

Berry *et al.*[9] using a human aneuploid line (HeLa) and a mouse aneuploid line (strain *L* fibroblasts) measured the cytotoxicity of glucose and fructose solutions which had been exposed to 2·5 Mrads of cobalt-60 gamma irradiation. It is interesting to note that this radiation dose and the concentrations of irradiated carbohydrates they used are directly comparable with our experiments and their results are in agreement with our findings. Apparently there is a rather sharp threshold concentration for demonstrating toxicity of irradiated carbohydrates to mammalian cells *in vitro*.

The chromosome breaks reported in our experiments were observed in the first (or rarely, in the second) mitotic division *in vitro*. Counts were made and breaks were scored under direct observation but only a few of the 1,900 metaphases were analysed and karyotyped. Therefore, structural rearrangements would, for the most part, have gone undetected. Exchange figures, however, are immediately evident. It thus seems reasonable to conclude that permanent chromosomal rearrangements can be induced *in vitro* and passed on to daughter cells.

Our experiments have no bearing on the question of whether point mutations are produced by irradiated sucrose. Neither do they shed light on the important question of whether foods which have been preserved by irradiation and ingested by mammals produce chromosome damage *in vivo*. These questions are particularly pertinent because evidence of increased mutations in *Drosophila*[2–4] suggests that the toxic products of irradiated media can indeed pass the gastro-intestinal barrier, and mass human consumption of irradiated foods is being seriously considered. Feeding experiments with deer mice are now in progress in order to assess somatic damage to the chromosomes in bone marrow and germinal damage to chromosomes of testicular cells undergoing spermatogenesis.

We thank Prof. F. C. Steward of Cornell University for suggesting these experiments, for providing the test solutions, and for his helpful criticism of the manuscript. The radiation treatments were carried out at the Nuclear Reactor Laboratory of Cornell University, Ithaca, New York. We also thank Mrs. Martha Janzen for her technical assistance. This study was supported in part by a U.S. Public Health Service grant.

EFFECT OF FORMIC ACID ON THE STRUCTURE OF α-KERATIN

By E. G. BENDIT

Division of Textile Physics, C.S.I.R.O. Wool Research Laboratories, Ryde, Sydney

It has long been believed that the crystalline reflexions in the X-ray diffraction pattern of keratin disappear when the material is exposed to concentrated formic acid[1–5]. Some of the work referring to this[1,2] has been based on an early report by Speakman[6], in which he quotes the finding of Meyer and Mark[7] that the fibre pattern of silk disappears when the fibre is placed in formic acid; at that time Speakman considered it probable that the same effect would also be observed with wool. This view appeared to be confirmed later, when Sikorski[8] tested wool fibres immersed in 98–100 per cent formic acid and failed to detect any crystalline reflexions, although the fibre pattern was found to be present at lower acid concentrations (74 per cent). It has also been reported[3,9] that a dilute solution of monochloroacetic acid in water destroys the X-ray diffraction pattern of crystalline keratin. In view of the importance of the effect of organic acids on the structure of keratin these problems have now been re-investigated, and it has not been found possible to substantiate these claims. This article presents infra-red and X-ray diffraction evidence which establishes that at least part of the crystalline α-helix structure of keratin, though modified, is not destroyed by formic or mono-chloroacetic acids.

Earlier, on the basis of mechanical properties and the dimensions of wool in formic acid/water mixtures, it was suggested by Mason[10] that a proportion of aligned α-helices are still present in formic acid. Feughelman[11] concluded from the birefringence of wool fibres in formic acid that about half the original α-helical molecules were present in the helical form. Furthermore, values of the dielectric constant of wool in water and in formic acid indicated[12] that at least some α-helices must be stable to the acid. It is also relevant to mention here that the helix-containing soluble fraction of wool keratin (*S*-carboxymethylkerateine *A*), which is 50 per cent helical in water in dilute solution, has a helix content in formic acid which is still of the order of 15 per cent[13], although here cystine cross-links are absent and stabilization by aggregation is not likely. The helical structure is preserved even when films of this material are prepared by casting from cold or boiling formic acid or cold trifluoroacetic acid, for the infra-red spectrum[14] indicates a helix content as high as in films cast from water.

Apart from the earlier work by Sikorski[8], only one X-ray test of the effect of formic acid on keratin seems to have been reported. Skertchly[4] showed that, compared with dry keratin, the intensity of the "9·8 Å" equatorial reflexion is reduced relative to the intensity of the so-called halo near 4 Å. He concluded that the major part of this reflexion had been removed, and implied that most, if not all, of the crystallinity had disappeared. It is difficult to accept this interpretation, because the acid makes a very substantial contribution to the intensity of the halo: as the "9·8 Å" reflexion is as strong as the halo in his diagram, Skertchly's results indicate that considerable crystallinity is retained in formic acid.

The infra-red spectrum in the 6μ region of the soluble wool protein *S*-carboxymethylkerateine *A* (kindly supplied by Dr. J. M. Gillespie, C.S.I.R.O. Division of Protein Chemistry, Melbourne) is shown in Fig. 1. The spectrum of the dry film (curve *a*) exhibits the diagnostic α-helix peak at about 1,545 cm^{-1}, and that of the wet film (in the presence of saturated water vapour) is very similar (curve *b*), except for the underlying water band and a general shift to higher wave numbers. The spectrum of the film exposed to an atmosphere of 98–100 per cent formic acid vapour (curve *c*) also has a very similar shape, although somewhat modified by the presence of a strong underlying band due to the acid. Curve (*c*) is broader on the low-frequency side than curves (*a*) or (*b*), and this probably reflects the presence of additional non-crystalline material, which in dry keratin has been shown[15] to absorb near 1,520–1,525 cm^{-1}, and 5–10 cm^{-1} higher in keratin exposed to saturated water vapour.

The presence of helices is confirmed by the X-ray diffraction pattern of a horsehair immersed in formic acid (Fig. 2), which is typical of α-helical material. For this test, a short piece of horsehair of circular cross-section was placed in a tight-fitting, thin-walled glass capillary containing formic acid. This procedure was adopted in order to reduce interference from the acid; it is possible that previous tests (for example, ref. 9) with organic acids failed to detect the presence of crystalline reflexions because wool bundles were used, so that the strong halo due to acid between fibres completely swamped the X-ray diffraction pattern. Before the glass capillary was sealed and the specimen pushed into position, the specimen was placed in a wider part of the tube; in an atmosphere of dry nitrogen, acid was allowed to flow past it for 15 min. The effluent was tested and found to contain 99·5 per cent formic acid, which leaves no doubt that the X-ray pattern shown in Fig. 2 was obtained with almost pure formic acid. After sealing, the fibre was held in the acid for 15–30 min before the X-ray diffraction pattern was recorded in order to ensure proper penetration of the acid; the X-ray diffraction procedure itself took about 2 h. These times can be compared with that taken for a horse-

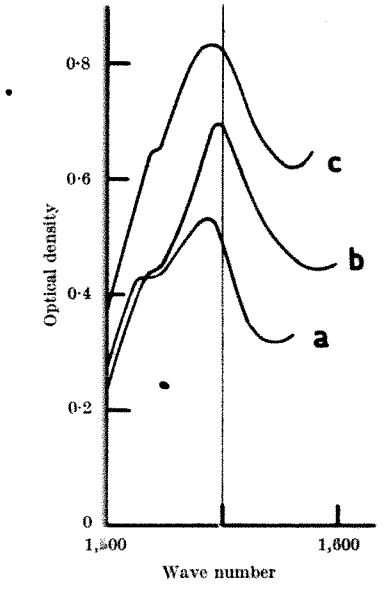

Fig. 1. Infra-red spectrum of a film of the helix-containing soluble wool fraction *S*-carboxymethylkerateine *A*. (*a*) Specimen dry; (*b*) specimen exposed to saturated water vapour; (*c*) specimen exposed to the vapour of 98–100 per cent formic acid.

hair to swell to equilibrium in formic acid, which is of the order of a few minutes.

Exposure of keratin to formic acid for extended periods weakens the X-ray fibre diffraction pattern. In one test, a horsehair specimen was kept immersed for 10 months, and both the 5·15 Å and "9·8" Å reflexions were very considerably reduced in intensity. This partial destruction of the ordered helical structure may have been one of the reasons for Sikorski's[8] failure to observe the crystalline reflexions, as his specimen had been kept immersed in formic acid for some 6 weeks before testing[16].

A single Lincoln wool fibre (60μ in diameter (dry)) was also tested in a thin-walled glass capillary containing formic acid. Once again the X-ray diffraction pattern exhibited the meridional and equatorial reflexions diagnostic of α-keratin.

Similar tests on horsehair using aqueous solutions of monochloroacetic acid (2·7 N) have shown that, contrary to previous claims[9], the crystalline X-ray diffraction pattern is again not destroyed by the reagent; the pattern is, in fact, somewhat better than that of a specimen immersed in formic acid. The halo which results from the liquid is less pronounced than for formic acid, and this reflects the degree of lateral swelling in these reagents (about 55 per cent for concentrated formic acid and about 25 per cent with 2·7 N monochloroacetic acid). A test with 22 N monochloroacetic acid (lateral swelling about 45 per cent) gave an X-ray diffraction pattern similar to that for formic acid.

Additional conclusions can be drawn from the X-ray diffraction patterns, but before considering these it is desirable to outline some aspects of keratin structure. α-Keratin is thought to consist of microfibrils, which contain the crystalline component, embedded in a non-crystalline matrix[17]. The microfibrils are many thousands of Ångströms long, about 75 Å in diameter, and have a centre-to-centre distance of 85–95 Å depending on the type of keratin. They are formed by an assembly of protofibrils, each consisting of two- or three-strand ropes of α-helices. A possible model of the distribution of α-helices in the microfibril is shown in Fig. 3. The main meridional reflexion at 5·15 Å results from the axial repeat of coiled α-helices, while the prominent equatorial reflexion near 10 Å is approximately equal to the lateral distance between α-helices within the protofibril. This equatorial reflexion exhibits a multiple structure under high resolution, owing mainly to the interference produced by the arrangement of protofibrils within the microfibril. The reflexion is usually quoted as 9·8 Å for dry keratin, but precise measurements[19] using markers indicate that it is significantly lower at 9·4–9·5 Å. It is worth noting that the shape and position of the

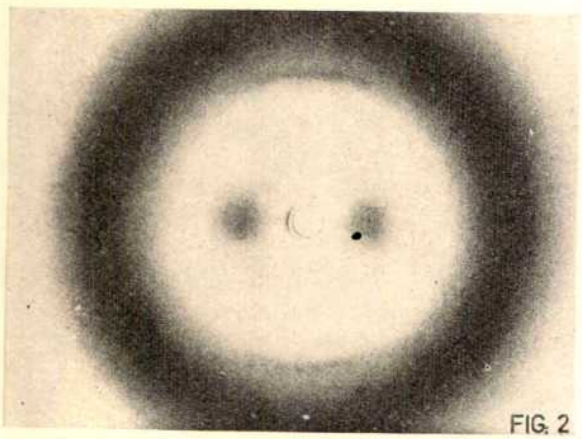

Fig. 2. X-ray diffraction pattern of horsehair (dry diameter 180μ), immersed in 99·5 per cent formic acid. Nickel filtered copper *kα* radiation from a Philips fine focus X-ray tube, lead glass collimator 300μ diameter, specimen-film distance 24·8 mm.

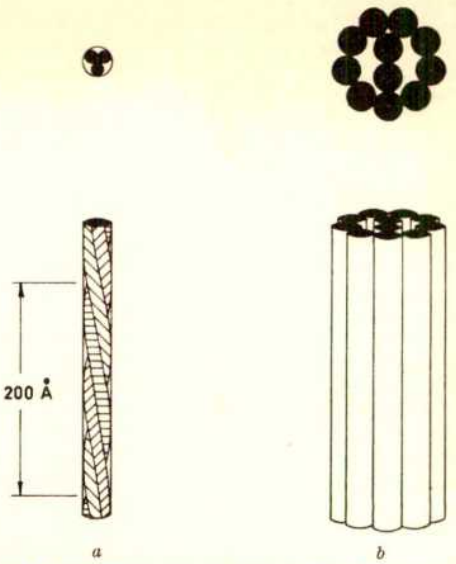

Fig. 3. Model of microfibril structure (*b*) showing the "9 + 2" arrangement of protofibrils (*a*) based on a diagram reported by Fraser *et al.* (ref. 18).

envelope of the 10 Å group of reflexions reported by Fraser *et al.*[20] for dry porcupine quill suggests that the peak under low resolution should be in the region of 9·5 Å. The microfibrils themselves give rise to three prominent reflexions in the low-angle X-ray diffraction pattern of keratin; in dry porcupine quill these occur at 83 Å, 45 Å and 28 Å.

Returning now to the X-ray pattern shown in Fig. 2 (formic acid), the spacing of the main meridional reflexion appears to be unchanged at 5·15 Å, although the precision with which this measurement can be made is limited by the broad halo due to the acid. This indicates that the configuration of those α-helices which are not destroyed by the reagent is very similar to that of the α-helix in dry keratin; however, it is possible that in formic acid the longitudinal order of the helices within the protofibrils is disturbed, as the usual[21] off-meridional reflexions near 5·15 Å do not appear to be present in Fig. 2.

For horsehair, the main lateral spacing is changed from 9·5 Å in the dry state to 11·1 Å on immersion in formic acid. This is an increase of 17 per cent, but it does not necessarily indicate a corresponding dimensional change in the protofibril or microfibril. In the parallel case of keratin fibres in water, the spacing increases by about 5 per cent[21], but it can be inferred from recent work by Fraser *et al.*[22], that only part of this increase is the result of dimensional change.

It is not clear, at this stage, whether the microfibrils retain their identity in formic acid, as the present equipment does not permit the innermost equatorial reflexions (at 83 Å and 45 Å in dry keratin) to be observed. If microfibrils are present, their diameter is likely to increase by about the same extent as the distance between helices, that is, of the order of, but less than, 17 per cent. As there is only a very small length change when a wool fibre is placed in formic acid, the volume swelling of the microfibril is less than 30 per cent. In contrast, the volume swelling of the whole fibre is about 150 per cent, and as the microfibrils in dry keratin occupy about half the space, the volume swelling of the matrix will be of the order of 250–300 per cent. Even if the microfibrils are disrupted, and if the interferences in the X-ray diffraction pattern shown in Fig. 2 result from protofibrils dispersed throughout the structure, the volume swelling of non-helical material would still be well in excess of 150 per cent. There is little doubt that the

protofibrillar arrangement of α-helices is retained in formic acid, because single dispersed helices could not account for the 5·15 Å meridional and the 11·1 Å equatorial reflexions.

This high degree of matrix swelling cannot easily be reconciled with its disulphide content, which averages about one half-cystine group per five residues. It is clear that these cystine cross-links cannot be distributed uniformly in the matrix, and it is necessary to postulate concentrations of disulphide groups (perhaps as high as 1 in 2) arranged in such a way as to permit the rest of the matrix protein to swell several times over. It is therefore tempting to regard these concentrations as clusters or sheets surrounding the microfibril. Such local concentrations, cross-linked to the microfibril in possibly only a few places, could act as "keepers" in certain sections along the microfibril and provide the viscous element opposing extension in the stiff post-yield region of wool (above 30 per cent extension), while the sections along the microfibril between the "keepers" would correspond to the easily extended yield region.

These considerations should be taken account of in discussions of keratin structure and its relationship to mechanical properties.

In summary, it has been shown that part of the helix structure in α-keratin is not destroyed by formic or monochloroacetic acids. The spacings of the X-ray diffraction patterns indicate that the helices are present in the form of protofibrils, but it is not certain whether the protofibrils remain in the microfibril arrangement or are dispersed throughout the structure. In either event, the high degree of swelling in the non-helical part of the structure can be reconciled with the high density of disulphide cross-links only by postulating local concentrations of very high cystine content. It is suggested that these concentrations may be arranged along the helices to act as "keepers", in order to provide the viscous element opposing extension in the stiff post-yield region of keratin.

SULPHYDRYL—DISULPHIDE INTERCHANGE AND THE STABILITY OF KERATIN STRUCTURE

By M. FEUGHELMAN

Division of Textile Physics, C.S.I.R.O. Wool Research Laboratories, Ryde, Sydney

WHEN a horsehair fibre was stretched in water at 20° C to 140 per cent of its normal length for 10 min, dried in the extended state, and its X-ray diffraction pattern recorded, the characteristic 5·1 Å meridional reflexion of α-keratin and the 4·7 Å equatorial reflexion of β-keratin were both present. This is in accord with previous work[1,2]. When the fibre was placed, still held extended 40 per cent, into distilled water at 100° C for 2 h, removed from the water and air dried still extended, the X-ray diffraction pattern showed a complete absence of α-keratin, and a sharper β-keratin reflexion at 4·7 Å on the equator. In another test, horsehair fibres were stretched in boiling distilled water in small steps over a period of 1·5 h to 140 per cent of their normal length and held extended a further 30 min in the boiling water. After drying them still in the extended state, they gave X-ray reflexions showing both the presence of α- and β-keratin similar to the first case. When an aqueous solution of hydrochloric acid at *p*H 2 and 100° C was substituted for the boiling distilled water, the X-ray diffraction pattern obtained showed the presence of β-keratin only. When a fibre was extended rapidly in boiling water (in less than 0·5 min) to 40 per cent extension, held extended for 2 h in the boiling water, removed from the water and air dried still stretched, the X-ray diffraction pattern obtained also showed the presence of only β-keratin. These results are summarized in Table 1.

The stability of the α-keratin structure in a keratin fibre in water will depend on the temperature and the stress on the α-keratin[5,8]. Under stress-free conditions[3,4] the α-keratin "melts", that is becomes unstable, in water at about 130° C. In the presence of stress on the structure this temperature of melt is reduced. The X-ray diffraction results obtained under the varying conditions of extension of the horsehair fibres to 40 per cent can be explained in terms of this variation of stability of the α-keratin with stress and temperature. A diagrammatic representation of this relationship is shown in Fig. 1.

In the situation corresponding to (*a*) in Table 1 the α-keratin present in the extended structure is stable. The stress level on the α-keratin is high at room temperature, but not sufficient to cause "melting" because of the low temperature. When the fibre is plunged into boiling water

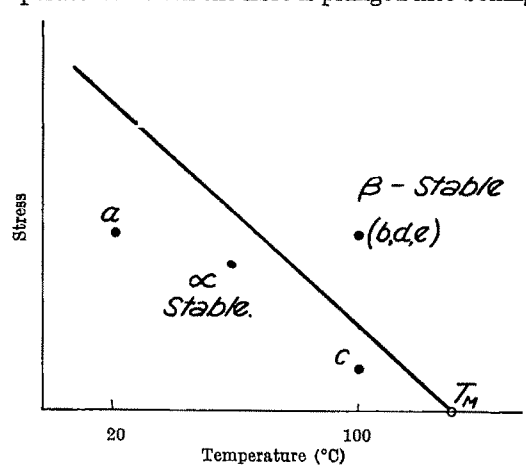

Fig. 1. Diagrammatic representation of the relationship between stress, temperature and the stability of α- and β-keratin in water. T_M is the stress-free melting temperature of the α-keratin phase. The points (*a*), (*b*), (*c*), (*d*) and (*e*) correspond to the same fibres as in Table 1.

Table 1

Conditions of extension in water to 40 per cent	Crystalline state
(*a*) Extended at 20° C	α and β
(*b*) Case (*a*) plunged still extended into water at 100° C for 2 h	β only
(*c*) Extended slowly to 40 per cent over 1·5 h at 100° C and then held 30 min at 100° C	α and β
(*d*) Extended as in (*c*) except aqueous hydrochloric acid at *p*H 2 is substituted for water	β only
(*e*) Extended rapidly in less than 0 5 min in water at 100° C and held at 100° C for 2 h	β only

the initial high stress level combined with the high temperature results in the instability of the α-keratin material present and thus "melting" occurs with a disappearance of the 5·1 Å meridional repeat for fibre (*b*). If a fibre is extended very slowly at an elevated temperature as in the conditions corresponding to fibre (*c*), the level of stress in the fibre remains very low and is insufficient to upset the stability of the α-keratin present in the extended fibre. The low stress level during slow extension in boiling water mainly results from sulphydryl-disulphide interchange eliminating bonds stressed by the extension of the fibre[6]. However, if the fibre is either extended slowly in an acid solution (*p*H 2) at 100° C or extended rapidly in water at 100° C, a high level of stress will result. In the former it will result from reduction[3] of the rate of sulphydryl-disulphide interchange at *p*H 2; in the latter it will result from the fact that insufficient time has been allowed for the interchange. Because of this high level of stress at 100° C the remaining α-keratin becomes unstable, and in both cases only the presence of β-keratin is observed in the X-ray diffraction pattern when the fibre is removed from the water and air dried while still stretched.

When a horsehair fibre which has been extended by 40 per cent in water at 20° C is released in water at 20° C the β-keratin disappears and the native α-keratin structure is returned[1]. For the fibre corresponding to (*b*), the α-keratin does not return on release in water either at 20° C or 100° C. The β-keratin appears to be quite stable. If the fibre is only held extended in the boiling water for a short time (about 0·5 min) and then released, however, the α-keratin structure returns and the β-keratin disappears[7]. From these results it seems that the major portion of the retraction force in a fibre must be present at 100° C, if the "melted" α-keratin structure is to return on release of the fibre. It has been shown[6,7] that this force of retraction rapidly relaxes in distilled water at 100° C after a few minutes because of scission of strained disulphide bonds by way of sulphydryl-disulphide interchange. From these observations it appears that once the α-keratin structure has melted it will only return so long as a sufficient force of retraction is still present, that is, a sufficient number of uninterchanged disulphide bonds are present. This non-reversal of α-keratin structure, when the disulphide interchange process has gone too far, could arise in a number of ways:

(i) The force of retraction as supplied by the presence of the disulphide bonds provides part of the "memory" directing the structure back to the native α-keratin.

(ii) Disulphide interchange may interpose new cross-links, which interfere sterically with the reformation of the helices of the native α-keratin configuration.

(iii) Reformation of disulphide bonds in equilibrium with the extended state may stabilize the β-keratin crystallites formed in the extended state, and thus prevent their return to their native configuration.

(iv) The α-keratin structure is directly dependent on disulphide bridges to provide stability to the structure, and their removal by interchange makes the α-keratin structure less stable.

In summary, the stability of the native α-keratin structure is dependent on temperature and stress. This stress arises from the straining of disulphide bonds in the structure, and is transferred to the α-keratin components of fibre by these bonds. Sulphydryl-disulphide interchange in an extended fibre interferes in a number of ways with the ability of the native α-keratin to recover its configuration, when the fibre is later released.

ANTI-VIRAL ACTIVITY OF AZATHYMIDINE AND URACIL METHYL SULPHONE

By DR. LEA SEKELY and PROF. WILLIAM H. PRUSOFF

Department of Pharmacology, Yale University School of Medicine, New Haven, Connecticut

AZATHYMIDINE, the deoxyribonucleoside of azathymine (6-methyl-*as*-triazine-3,5(2H, 4H)-dione), has been prepared by enzyme[1] as well as by chemical synthesis[2] and the biological properties of this analogue have been reviewed[3,4]. Azathymine and its deoxyriboside are competitive inhibitors of the utilization of thymine or thymidine for the growth of *Streptococcus faecalis*. Although this analogue is incorporated into the DNA of *S. faecalis*, the amount of incorporation is not related to its lethal effect. Marsh and King[5] observed that azathymidine was a competitive inhibitor of the enzyme *trans*-N-glycosidase derived from *Thermobacter acidophilus*. In mammalian cells the incorporation of formate into DNA is effectively inhibited by azathymidine, but thymidine incorporation is much less sensitive[6]. Because azathymidine appeared to be relatively non-toxic to mammalian cells, we decided to investigate its potential anti-viral activity.

6-Uracil methyl sulphone (UMS) was designed as a potential metabolic antagonist of orotic acid[7]. This analogue inhibits the reproduction of several bacteria[8] and murine lymphomata[9,10]. Metabolic investigations indicate inhibition of (*a*) the formation of orotidylate from orotate and 5-phosphoribosyl-1-pyrophosphate by a partially purified enzyme preparation from yeast[11]; (*b*) the utilization of orotate or formate but not of thymidine for the biosynthesis of DNA-thymine in Ehrlich ascites cells *in vitro*[12]; (*c*) the utilization of orotate for the formation of RNA-pyrimidines in regenerating liver slices[13]; and (*d*) the conversion of ribonucleotides to deoxyribonucleotides by mammalian cells[14]. Because UMS reacts rapidly and non-enzymatically with several sulphydryl compounds such as glutathione it was postulated that this analogue may function as an alkylating agent for a sensitive protein containing sulphydryl that is critically involved in cellular reproduction[15]. The present report includes a study of the anti-viral activity of UMS and of the inability to prevent its inhibition by various compounds that were chosen on the basis of the postulated[11–14] biochemical sites of inhibition of UMS.

A monolayer of 2-day old chick embryo fibroblasts in 3 oz. prescription bottles was prepared by the procedure described by Hsiung[16] and inoculated with 0·1 ml. of herpes simplex virus, *HF* strain (obtained from Dr. J. McCrea), having a titre of 10^6 plaque-forming units (P.F.U.)/ml. The infected cells were incubated for 1 h at 37° C, washed once with Hanks's buffered salt solution and layered with 10 ml. of Earle's maintenance medium[17]. These were examined for cytopathological changes (CPE) 24 h later.

The supernatant fractions were stored at −70° C before determination of their virus titre. The cellular debris was removed by centrifugation and serial ten-fold dilutions were made in Eagle's growth medium supplemented with 10 per cent calf serum. Chick embryo fibroblasts in 3 oz. prescription bottles were prepared as already described and inoculated in triplicate or quadruplicate. After incubation at 37° C for 1 h, the inoculated cells were washed with Hanks's buffered salt solution. Agar overlay medium (7 ml.) was added and the formed plaques were counted 5 days later.

The results shown in Table 1 show that azathymidine markedly inhibited the formation of herpes simplex virus; however, 5-iodo-2′-deoxyuridine (IUdR) was found to be seventy times more potent on a molar basis.

Because with mammalian cells a thousand-fold molar excess of azathymidine was required to inhibit the utilization of thymidine labelled with carbon-14 for the biosynthesis of DNA-thymine[2,6], the effect of thymidine on the inhibition of viral reproduction exerted by azathymidine was investigated. Thymidine added within 2 min of the addition of azathymidine completely prevented the inhibitory effect of azathymidine when the former was present in a 0·015 molar equivalent (Table 2). More than 90 per cent inhibition was achieved when the ratio of azathymidine to thymidine was 330.

An attempt was made to determine which phase of the growth cycle of herpes simplex virus was most susceptible to the inhibitory effect of azathymidine and of IUdR (Table 3). The cultures were prepared and inoculated with virus as described above and either azathymidine (2 mmoles/l.) or IUdR (0·06 mmoles/l.) was added at various intervals of time. The inoculated cultures were incubated for a total of 24 h and the virus titre determined by the plaque technique as already described.

Although both these compounds are analogues of thymidine and exerted a similar pattern of inhibition under these conditions it must not be assumed that a similar molecular mechanism of inhibition is involved.

Table 1. EFFECT OF AZATHYMIDINE ON THE REPRODUCTION OF HERPES SIMPLEX VIRUS*

* Control titre: $2{\cdot}4 \times 10^7$.

Table 4. EFFECT OF 5-URACIL METHYL SULPHONE ON THE REPRODUCTION OF HERPES SIMPLEX VIRUS*

Concentration of UMS (mmoles/l.)	Virus titre (P.F.U./ml.)
None	$2{\cdot}4 \times 10^7$
0·026	4×10^6
0·105	$1\,9 \times 10^6$
0·53	1×10^5
1·59	$5\,3 \times 10^4$
5·25	4×10^2†

* UMS was added 2 h after inoculation of a monolayer of chick embryo fibroblasts with the virus.

† On the basis of additional experiments this figure is interpreted as residual input virus.

The results shown in Table 4 indicate that UMS inhibits the formation of infective herpes simplex virus. This analogue is considerably less potent than 5-iodo-2′-deoxyuridine but approximately equal to azathymidine. UMS has no direct inactivating effect on herpes simplex virus particles *in vitro*. The virus (10^6 P.F.U.) was incubated for 1 h at 37° C in the presence or absence of UMS (2·6 mmoles/l.) and treated as already described.

Attempts to reverse or prevent the inhibitory effect of UMS (1·3–2·6 mmoles/l.) with thymidine (0·41–2·05 mmoles/l.), uridine (0·4–2·05 mmoles/l.) or orotic acid (0·64–3·2 mmoles/l.) failed. A similar failure was obtained with combinations of thymidine, uridine, cytidine and deoxycytidine (0·41–2·05 mmoles/l.) or thymidine, deoxyadenosine, deoxycytidine and deoxyguanosine (0·04–0·4 mmoles/l.).

Thus inhibition by UMS of the reproduction of herpes simplex virus is neither the result of failure to form pyrimidine nucleotides by the *de novo* pathway, nor the result of failure to inhibit the conversion of ribonucleotides to deoxyribonucleotides. UMS may be exerting a non-specific alkylation[15] of an induced or cellular sulphydryl enzyme critically involved in the formation of the infectious virus particle.

An anti-viral action of 6-uracil methyl sulphone has been demonstrated, but the failure of many "logical" metabolites either to reverse or to prevent the inhibition makes it difficult to speculate on its mechanism or site of action.

It has been shown that azathymine deoxyribonucleoside, an analogue of thymidine, is an inhibitor of the reproduction of herpes simplex virus and that this inhibition can be completely prevented by thymidine. This analogue appears to affect the formation of the infective virus particle in the same phase of growth as IUdR, but is not so potent an inhibitor. It would be of interest to determine the anti-viral activity of azathymidine under conditions *in vivo*, because it presumably has a higher therapeutic index than IUdR. The very limited availability of azathymidine, however, at present limits investigation.

We thank Mr. David Shen for his valuable technical assistance. This study was supported by research grants from the U.S. Public Health Service and the U.S. National Science Foundation.

SPECTROSCOPIC EVIDENCE OF ALLOSTERIC EFFECTS IN PHOSPHORYLASE B

By S. BRESLER, L. FIRSOV and E. GLASUNOV
U.S.S.R. Academy of Sciences, Institute of High Molecular Compounds,
Leningrad 2, Birshevoi 6, U.S.S.R.

It is generally accepted that allosteric effects in enzymes[1] are mediated by conformational changes in the tertiary structure of the protein. Few observations have yet been made, however, of the physico-chemical changes which occur in the enzyme molecule during allosteric activation or inhibition. We decided to work on the problem spectroscopically and chose phosphorylase B (ref. 2) as a suitable object molecule because its active centre is marked by a phosphopyridoxal group with a characteristic absorption band near 330 mμ (ref. 3). Measurements of absorption spectra and ultra-violet dichroism in the region 300–400 mμ showed that this absorption band has a measurable dichroic ratio (0·002) but both absorbance and dichroism are insensitive to the presence of the activator—adenosine monophosphate (AMP), and its inhibitor—adenosine triphosphate (ATP). We therefore concluded that the active form of the enzyme must be a small equilibrium fraction of the protein, even if the substrate is present in excess.

To substantiate this assumption we have made measurements with a differential spectrophotometer (*SF*–4, Milano) with a xenon lamp and a filter with a transmission band between 300 and 400 mμ. Four identical quartz cells (2 cm path) were used, two in each beam. One of the two in the first beam contained phosphorylase B (20 mg/ml.) and cysteine (0·03 M) in glycerophosphate buffer (0·03 M, *p*H 6·8). The second cell contained the allosteric activator, AMP (0·001 M), in the same buffer and 0·01 M glucose-1-phosphate. Two cells were placed in the second beam; in one of them all the components (enzyme, substrate and activator) were mixed together in equal volumes, while the second contained buffer.

We observed a new absorption band near 360 mμ and a decrease of extinction near 330 mμ (Fig. 1). Thus it would seem that some of the protein of the common form (absorption band at 330 mμ) is transformed into a new species with an absorption band at 360 mμ. We found that we could estimate the concentration of this new form

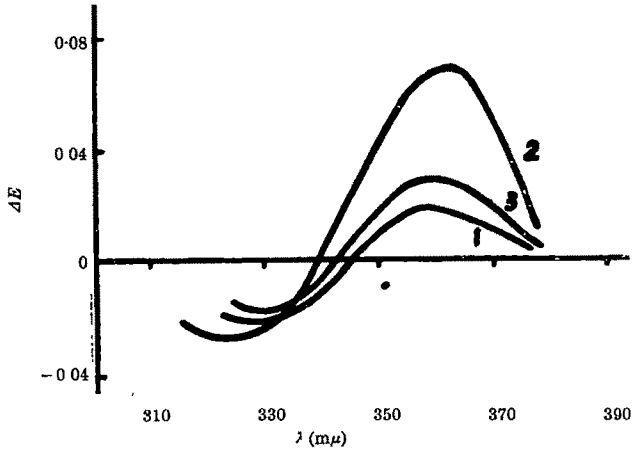

Fig. 1. Differential spectra of phosphorylase B in the presence of substrate glucose-1-phosphate (0 01 M), activator (0 001 M) and inhibitor (0 01 M). (1) Enzyme + adenosine monophosphate, (2) enzyme + adenosine monophosphate + glucose-1-phosphate, (3) enzyme + adenosine monophosphate + glucose-1-phosphate + adenosine triphosphate. The protein was dissolved in 0·03 M glycero-phosphate buffer *p*H 6 8, containing 0 03 M *L*-cysteine. The enzyme concentration was 20 mg/ml.

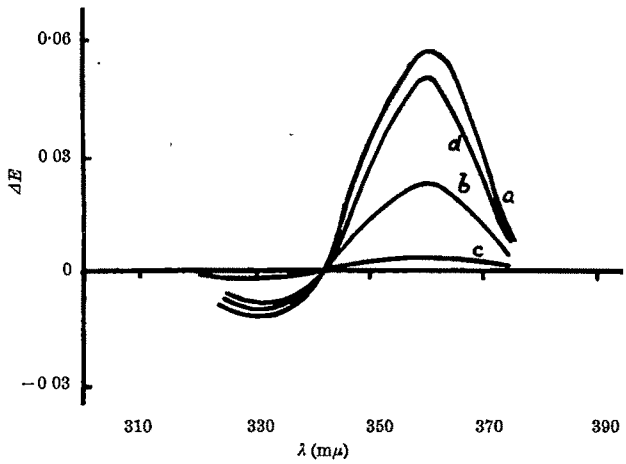
to within 2 per cent of the total amount of enzyme. Two control experiments were carried out. First, the activator, AMP, was omitted. The protein solution was treated with charcoal. Both beams were symmetrical and the spectrophotometer traced a zero-line. Second, in the absence of AMP, the substrate glucose-1-phosphate was then placed separately from the enzyme in one beam and mixed with the enzyme in the second beam. The extinction was near to the background. Next we omitted the substrate and retained the activator separate from the enzyme in one beam and mixed the two in the second beam. We observed a weak absorption at 360 mμ very near to the background. When we added both substrate and activator and varied the concentration of the protein we found that the intensity of the new absorption band increased linearly. The intensity of the band at 360 mμ does not depend on what order both reagents (substrate and activator) are added to the protein solution.

The action of ATP was found to bring about the most significant spectroscopic changes. When we added equal quantities of 0·01 M ATP to the cell containing enzyme, substrate and AMP in the first beam and to the cell without enzyme (with the AMP solution) in the second beam; we found that the intensity of the spectral band at 360 mμ was reduced 2·5 times. This is exactly what we can expect from kinetic studies[4] for the interaction between the enzyme, the activator and the inhibitor.

The experiment which resulted in the appearance of the 360 mμ band during activation and its disappearance during inhibition was repeated many times with different samples of purified crystalline phosphorylase B. Irreversible inactivation or denaturation of the enzyme causes the effect to vanish. We also found that the magnitude of the effect depends on the presence of a reducing agent (cysteine) in the enzyme solution. This point is a very characteristic feature of phosphorylase B, which loses its activity in the absence of cysteine. From these results we concluded that the band near 360 mμ must be due to a Michaelis complex of the enzyme with the first substrate. This complex cannot lead to the reaction of glucose transfer because the second substrate—glycogen—was not present. If instead of glucose-1-phosphate we took glycogen as the only substrate, we did not find any absorbance near 360 mμ.

To investigate what part of the substrate molecule is participating in the complex, we tried the substrate of the back reaction, for example orthophosphate. When we took 0·04 M phosphate as substrate in the presence of AMP, we observed a differential spectrum (Fig. 2, curve *a*) with the same characteristic band. Thus it seems that the phosphate group is involved in the bond with the pyridoxal moiety. It is well known that glucose is a competitive inhibitor of glycogen phosphorylase. We tried to add glucose (2 mg/ml.) to the mixture of enzyme, AMP and phosphate (Fig. 2, curve *b*). We observed that the 360 mμ band was strongly reduced.

The appearance of the 360 mμ band during the interaction with phosphate is sensitive to the presence of both allosteric activator and inhibitor. Without AMP we obtain a zero line in the spectrophotometer. If we add the inhibitor, ATP (0·01 M), to the same solution (containing phosphorylase, AMP and phosphate), we get the curve *c* in Fig. 2, that is, the background. If we then



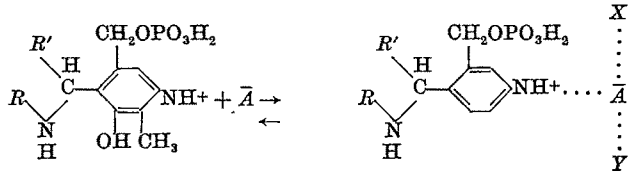


Fig. 2. Differential spectra of phosphorylase B in the presence of inorganic phosphate. (*a*) Enzyme + adenosine monophosphate + phosphate; (*b*) enzyme + adenosine monophosphate + phosphate + glucose; (*c*) enzyme + adenosine monophosphate + phosphate + adenosine triphosphate; (*d*) the same as (*c*) with additional phosphate (0·1 M).

increase the concentration of phosphate to 0·1 M the absorption band appears anew (curve *d*). This is a very characteristic property of allosteric enzymes; they can be inhibited to a certain degree but the effect is overcome by an excess of substrate.

It is well known from kinetic studies that ammonium sulphate is an inhibitor of phosphorylase B. We tried instead of substrate a solution of sulphate (0·1 M). We registered the band near 360 mμ sensitive to the presence of the activator. We suggest that the general explanation of the spectral band near 360 mμ is that a reversible equilibrium exists between the two forms of the prosthetic group (dissociated and undissociated).

Here R, R', X, Y are groups on the protein.
Here A is an anion (either sulphate, phosphate or glucose-phosphate). The undissociated form is the source of the spectral band. The attachment of the anion is specific. For instance the chloride ions do not interact with the enzyme in the presence of AMP. The undissociated compound formed by the reaction of the phosphate or sulphate ion with pyridoxal must, therefore, be stabilized by interactions with adjacent groups on the protein. The band near 350 mμ cannot be explained in terms of simple protonation of the pyridoxal ring. When the *p*H in the cell was kept at 5·5 and in the reference cell at a value of 7, we did not observe the band in question in either the presence or absence of AMP and phosphate. The band appeared at *p*H 6·1. The action of the activator and inhibitor is easily explained by supposing that deformation has occurred on the protein macromolecule, as a result of which some groups on its surface are more or less accessible to interaction with the anion.

In the case of the specific substrate (glucose-1-phosphate) we use a low concentration of the anion (5.10^{-3} – 10^{-2} M) to obtain the same amount of enzyme-anion complex, because of the existence of a special group on the protein for the attachment of the glucose moiety. If we add glucose we get inhibition because the corresponding group is occupied. Even if the anion A is simply phosphate, glucose interferes with its adsorption because of steric hindrance. From our point of view it is easy to explain the data of Hendrick and Fischer[5], who showed that pyridoxal phosphate without the protein does not catalyse the transfer of glucose to glycogen. This accords with the fact that the apoenzyme participates in the binding of glucose-1-phosphate.

In summary we can state that by means of differential spectrophotometry we successfully observed an enzyme-substrate complex with a characteristic band near 360 mμ. This complex exists only in the presence of the allosteric activator AMP and disappears when the inhibitor ATP is added. It is evident that the phosphate ion of the substrate participated in the binding with pyridoxal and we can speculate that it is a compound stabilized by additional bonding of the anion to the adjacent groups of the aboenzyme.

MIRROR-IMAGES AND THE FOREBRAIN COMMISSURES OF THE MONKEY

By JOHN NOBLE
Medical Research Council Cerebral Functions Research Group, Department of Anatomy, University College London, W.C.1

Midline section of the optic chiasma in the monkey and cat restricts the primary visual input of each eye to the hemisphere of the same side. Such a preparation, when trained monocularly to discriminate between pairs of simultaneously presented patterns or objects, shows good interocular transfer of the discrimination[1–3]. In these experiments the stimuli used were pairs of dissimilar objects or patterns, such as + and ○, or ||| and ≡. Note that each of these stimuli is bilaterally symmetrical.

This article describes the results obtained using pairs of stimuli, one of which is a mirror-image of the other, for example ⌈ and ⌉. Three monkeys (*Macaca mulatta*) were used, *M*1, *M*2 and *M*3, with their optic chiasms sectioned in the midline. Each was trained monocularly to discriminate between pairs of solid black objects, except for *M*1 which received training on black planometric stimuli. A food reinforcement was hidden underneath the "correct" object. Usually, thirty trials, twice daily, were presented for 5 days a week. The position of the objects was varied randomly from side to side by the Gellerman sequence[4]. When 90 per cent correct choices on two successive sessions of thirty trials had been reached, the other eye was tested for transfer. For these interocular tests, response to either stimulus was reinforced, except on two occasions when either the negative or the positive stimulus only was reinforced.

The results, in terms of percentage errors over successive sessions, are shown in Fig. 1, and are of transfer trials only. *M*1 was given only one problem. These stimuli were similar on one side but the other sides were mirror-images of each other (Fig. 1, *A*). *M*2 learned to solve problems of mirror-image pairs (Fig. 1, *B* and *D*) and one non-mirror-image pair (Fig. 1, *C*). *M*3 learned to discriminate three pairs of left–right mirror-image problems (Fig. 1, *E*, *G* and *H*) and one pair differing only in an up/down orientation (Fig. 1, *F*).

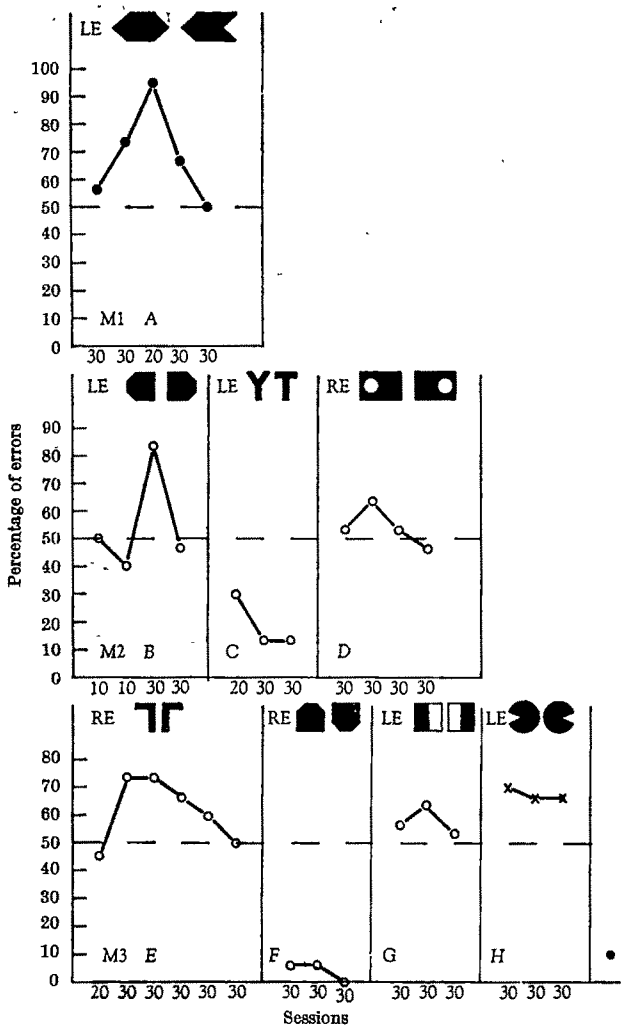

Fig. 1. Interocular transfer tests, percentage responses to the negative, incorrect stimulus, over successive sessions (the numbers refer to the number of trials on that particular session). LE and RE, in upper part of graphs, refer to left or right eye. The stimuli discriminated are shown next to the eye used. *M*1, *M*2 and *M*3 are three monkeys with optic chiasma sectioned. The horizontal dashed line indicates responses at chance level. ●, Responses when positive stimulus only rewarded; ○, responses when both stimuli rewarded; ×, responses when negative stimulus only rewarded.

As had been expected, the non-mirror problem was solved correctly by the untrained eye, although a few errors were made initially (Fig. 1, *C*). Similarly, where the problem differed only in an up/down orientation, there was positive interocular transfer (Fig. 1, *F*). There was, however, no positive transfer with left–right mirror-image pairs. After responding at chance level for twenty or thirty trials, the negative stimulus, not previously rewarded, was selected most frequently. Then after a session or two the responses dropped back to chance level.

Free use of either hand was allowed throughout, except on one occasion; on the first session of the last problem (Fig. 1, *D*) *M*2 was forced to use its non-preferred hand. The previously non-preferred hand was used spontaneously by *M*1 towards the end of the second session and throughout the third session (Fig. 1, *A*). No obvious change in the distribution of the animals' responses resulted from these changes of hand preference.

Apart from the initial chance level responding, the mirror-image of the previously reinforced stimulus was responded to most frequently. In other words, the negative stimulus was treated by the "untrained" eye as if it was the positive one. The performance of *M*1 is particularly convincing in that, on the transfer test, responses to the negative stimulus were never reinforced (Fig. 1, *A*). Yet, in one session of twenty trials only one correct choice was made. The first discrimination by *M*2 and *M*3 shows similar transfer curves but in these cases responses to both the negative and positive stimuli were reinforced (Fig. 1, *B* and *E*). The third discrimination presented to these two animals shows a similar trend, but the magnitude of the effect is less (Fig. 1, *D* and *G*). This probably occurs because the monkeys learn, because of the experience acquired since their first problem, more quickly to discriminate between the situation in which only responses to one stimulus are rewarding and the situation in which responses to both stimuli are rewarding. The latter is an extinction procedure. Compare this with the problem for *M*3, where only the negative stimulus was rewarded (Fig. 1, *H*), in an attempt to enhance the effect. Again, more responses were made to the negative stimulus and, moreover, this procedure eliminated the initial chance level responding.

The drop to chance level after the brief response to the negative stimulus in the first two mirror-image problems of *M*2 and *M*3 can be attributed to reinforcing both stimulus objects (Fig. 1, *B*+*D* and *E*+*G*). That this did not occur with non-mirror stimuli can be explained on the basis that few wrong choices were made, and so there was little opportunity for the animals to learn that both stimulus objects would be rewarding. This extinction procedure was continued for a further number of trials (not shown in Fig. 1) on these animals and responses continued to be at chance level.

It is of interest that mirror-image reversal in interocular transfer has been reported in the unoperated pigeon[5,6]. In this animal, the optic fibres from each eye cross completely in the optic chiasma and terminate in the tectum of the opposite side of the brain. In the monkey with its optic chiasma sectioned, the surviving optic nerve fibres from each eye pass only to its ipsilateral hemisphere. Apart from the hemisphere of termination, the two preparations are similar in having each eye projecting only to one hemisphere.

Midline section of the forebrain commissures in addition to section of the optic chiasma prevents interocular transfer. These commissures must therefore play a part in mirror-image reversal. Fig. 2 illustrates, diagrammatically, a possible explanation. Each primary visual area (striate

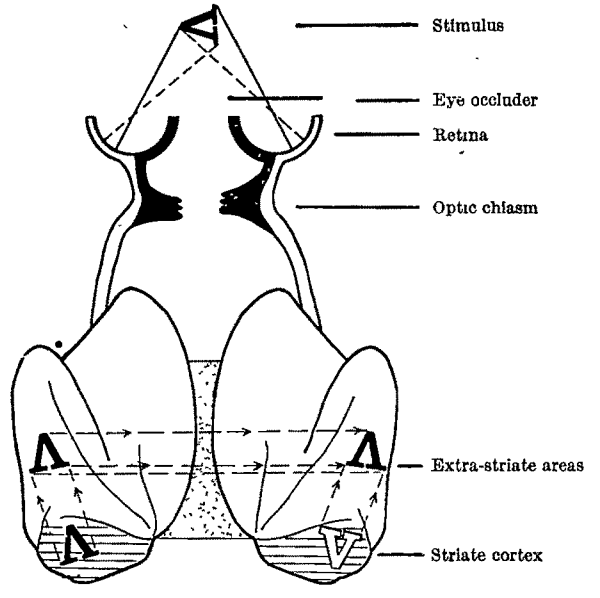

Fig. 2. Diagram to explain mirror-image reversal. With right eye occluded the input to left striate cortex is propagated to extrastriate areas (Λ) and is laterally reversed in crossing the midline via the forebrain commissures (stippled). When the left eye is occluded the input to the right striate area (V) does not match the stimulus (Λ) transposed from the left hemisphere; it does, however, match its mirror-image.

cortex) receives input from half the visual field, the right striate area from the left visual field and the left striate area from the right visual field. The projections of these half-fields are topologically organized so that the striate areas are symmetrical about the midline[7-9]. The midline of the visual field projects to the anterior border of the striate cortex. The representation of the stimulus of Fig. 2 in the striate cortex is such that in one hemisphere its open end is directed towards the anterior border whereas in the other hemisphere it is directed away from the anterior border. Apart from the striate cortex the prestriate and infero-temporal regions (extra-striate areas) are known to be important in the retention or learning of visual pattern discriminations[10,11]. There is no evidence that there are direct connexions between the two striate areas. The extra-striate areas are, however, connected in large part to homologous areas of the other hemisphere by way of the corpus callosum and the anterior commissure. The results of anatomical and physiological investigations emphasize that these connexions are between specifically symmetrical areas, that is, they are homotopic connexions[12-14]. There is some evidence that the topology inherent in the striate cortex is maintained into the extra-striate cortex, at least as far as the prestriate area[7,15]. If this is correct, the representation of a stimulus in these areas will be laterally reversed, because of the homotopic arrangement, in crossing the midline (Fig. 2).

In the monocularly trained monkey, with its optic chiasm sectioned, the stimulus is received by only one striate area and propagated to the extra-striate areas. It is not known whether or not the information passes directly to the other hemisphere or remains lateralized to the side of reception but is available at a later time for reference by the other hemisphere. In either case, if mirror-image pairs of stimuli are used, the information that crosses the midline (Fig. 2, $\wedge$) does not match that which would result from stimulation of the previously unstimulated striate area (Fig. 2, $\vee$) when this hemisphere is presented with the problem. The representation of the positive stimulus in the extra-striate areas of the untrained side matches the presentation of the negative stimulus as made through the untrained eye. Thus the animal shows a preference for the negative stimulus when made to use this representation. Bilaterally symmetrical pairs of stimuli, even though laterally reversed, maintain the same spatial arrangement, consequently the originally positive stimulus is still preferred.

This explanation does not account for the initial interocular transfer responses being at chance level, or for the fact that reinforcing the negative stimulus (Fig. 1, *H*) produces less than 100 per cent responses to the negative stimulus. This is not a regular feature in the interocular transfer of response to non-mirror image stimuli where the response is usually positive and immediate. Since normal monkeys can learn binocularly to discriminate mirror-image problems, it follows that if information crosses the midline during training it must produce a weaker increment to learning than does a direct sensory input, because such problems would never otherwise be learned. Let us assume then, that, in the initial trials of transfer testing, both hemispheres contribute to the response. In the non-mirror image problem, that is, with dissimilar bilaterally symmetrical stimuli, both hemispheres will receive the same information because lateral reversal will not alter their configuration. With mirror-image problems, because of the lateral reversal in crossing the midline, a positive sign is attached to one stimulus in one hemisphere and the opposite sign attached to it in the second hemisphere, although the latter may have a smaller value. As both stimuli will now have both positive and negative reinforcement, no discrimination is possible and chance-level responses will be made.

It has been shown that, in monkeys with unilateral occipital lobectomies, or with one optic tract sectioned, the addition of a unilateral inferotemporal lesion produces a greater deficit in the binocular learning of a visual discrimination if the inferotemporal lesion is on the side opposite the occipital or tract lesion. The more direct route from the striate area to the inferotemporal region, the one on the same side, is the most efficient one[16,17]. This might explain why the negative stimulus is preferred after the initial random responding in the present experiment. The untrained side, which is now receiving input from its own striate area, being the more efficient, becomes dominant, with the consequent preference for the mirror-image stimulus. The fact that even when responses to the negative stimulus are reinforced (Fig. 1, *H*) there are still a number of responses made to the other stimulus, suggests that the hemisphere trained initially exerts some influence for a considerable time. The same operations will apply to non-mirror-image stimuli but in this case they support the original learning.

It follows that monkeys with sectioned optic chiasmas should show positive interocular transfer when trained monocularly if dissimilar, bilaterally symmetrical stimuli are used (○ and +). Pairs of dissimilar, asymmetrical stimuli (F and Ⅎ, F and ⅁, F and ⅃) might show some initial difficulty as both stimuli will be reversed in crossing the midline. It is possible that sufficiently distinctive features will generate stimulus equivalence, for example, the curve in D may be a sufficient cue to evoke or inhibit a response. Stimuli differing only in up/down orientation (▲ and ▼) should transfer normally (as demonstrated) as they are bilaterally symmetrical, or in the case of F and Ⅎ have a distinctive feature—the horizontal line is at the top or bottom. Confusion should be evident only where exact mirror-image pairs of stimuli are used. These various categories of stimulus pairs are now being tested.

The mirror-image phenomenon, on this hypothesis, is only elicited if there is no primary visual input to the striate cortex to override the weaker trans-callosal input during training. This will happen only in animals with sectioned chiasmas. Normal monkeys should show normal, positive, interocular transfer since the primary visual input is relayed to both hemispheres from each eye. The same should apply to animals with only the forebrain commissures sectioned, leaving the optic chiasma intact, since again there is a bilateral input from either eye. A monkey with its optic tract sectioned on one side should also show positive transfer, as only one striate area is being used, irrespective of the eye open. Completely "split-brain" monkeys, with forebrain commissures and the optic chiasma sectioned, should show no interocular transfer of response to mirror-image pairs, or to any other pairs, as no visual information can cross the midline.

Experiments using two intact monkeys, two monkeys with corpus callosum section, one with additional section of the anterior commissure and one monkey with optic tract sectioned unilaterally have confirmed these predictions.

Finally, if in the normal, binocularly trained animal visual information crosses the midline during training, then both the positive and the negative representations of a mirror-image pair will receive both positive and negative reinforcement. This will not be true for non-mirror-image pairs of stimuli. Whether or not this is an explanation for the difficulty of mirror-image problems in normal animals is worth investigating. The often-reported difficulty of discriminating oblique lines (\ and /) as opposed to the ease of discriminating between a horizontal and a vertical line (— and |), where the only difference between the problems is in terms of the orientation of the lines, is a special instance of mirror-image and bilaterally symmetrical pairs[18,19]. It is predicted, from the above theory, that, in binocularly trained monkeys with forebrain commissures sectioned but optic chiasma intact, the difference in the number of trials to learn \ versus / and — versus | will be smaller than in unoperated animals.

I thank Drs. J. L. de C. Downer and B. G. Cragg for suggestions and criticism.

SULPHUR METABOLISM: THE USEFULNESS OF *N*-ETHYLMALEIMIDE

By DR. R. J. ELLIS
Department of Botany, University of Aberdeen

A SERIOUS problem encountered in the study of the metabolism of sulphur compounds is the extreme reactivity and instability of many of the intermediate compounds[1]. The reaction[2] between sulphydryl groups and *N*-ethylmaleimide (NEM) has been widely used to stabilize thiol compounds in both free[3,4] and protein-bound forms[5]. NEM is not specific for thiols but reacts also with imidazole derivatives and peptides[6]; this lack of specificity can be disregarded if sulphur-35 is used to label the NEM-thiol adducts[7,8]. NEM reacts not only with organic thiols but also with sulphite, thiosulphate, and sulphide[9–11], and the adducts can be separated by paper chromatography[9]. The potential usefulness of NEM for studying sulphur metabolism is thus greater than is generally realized. This article reports on the use of NEM to trap both the organic and inorganic intermediates in sulphate reduction by intact cells of *Escherichia coli*[12].

The scheme at present accepted for the pathway of sulphate reduction in *E. coli* can be summarized as follows[13]:

$$\text{sulphate} \rightarrow \text{sulphite} \rightarrow \text{sulphide} \rightarrow \text{cysteine} \begin{cases} \nearrow \text{glutathione} \\ \searrow \text{methionine} \end{cases}$$

This scheme relies heavily on data derived from mutant and enzyme studies. Although such investigations are valuable, they do not always yield unequivocal conclusions, and confirmatory evidence obtained from feeding experiments with intact cells is desirable[14,15]. The reactions between NEM and the postulated intermediates were therefore investigated.

The kinetics of these reactions were measured by observing the extinction of NEM at 300 mμ, since this extinction disappears when NEM is added to thiols, including sulphide[10]. Fig. 1 compares the effects of sulphite, thiosulphate, sulphide, cysteine and reduced glutathione at *p*H 7·4. The complete loss of extinction produced by equimolar cysteine and glutathione is rapid compared with the loss produced by equimolar sulphite and sulphide, but with the latter compounds the reaction is approaching completion by 5 min. Thiosulphate does not cause any loss of extinction in this time at a *p*H of either 7·4 or 4·5, or if the concentration is increased by a factor of five. The reaction of NEM with sulphite seems to be equimolar because the extinction is reduced by a factor of a half when half the molar quantity of sulphite is added; this stoichiometry suggests that the loss of extinction could be used to assay sulphite in the same way that it has been used to assay sulphydryl groups[16]. The reaction of NEM with sulphide is not equimolar, as previously noted[11]. Similar results were obtained in phosphate buffer dissolved in 70 per cent ethanol, which matches more closely the extraction conditions used in the feeding experiments.

Feeding experiments were performed with cells of *E. coli* A.T.C.C. 9723 grown on a minimal medium as previously described[17], with sulphate as the sulphur source. Cells were washed once with a simplified medium (10 mM glucose, 10 mM ammonium chloride, and 10 mM phosphate buffer, *p*H 7·4) and resuspended in the same simplified medium at a cell density of 3–5 mg dry weight/ml. A simplified medium was used rather than the original minimal medium because there were sufficient traces of sulphate in the components of the latter to reduce the incorporation of sulphur-35 to low levels. The concentrated cell suspension (9 ml.) was placed in a sparging tube and aerated at 20° C for 5 min. Carrier-free ^{35}S-sulphate (1 mc. in 1 ml.) was then added; 0·5 ml. samples of the suspension were removed into 1·5 ml. of either pure ethanol or ethanol containing 20 μmoles NEM. The cells were centrifuged down and 0·5 ml. of the supernatant placed on Whatman 3 *MM* paper. The paper was run in two dimensions as originally described[9]. Fig. 2 shows the autoradiographs obtained from extracts of cells exposed to ^{35}S-sulphate for 1 min. Chromatograms of extracts made in ethanol (Fig. 2*A*) show methionine and its sulphoxide, but those of extracts made in ethanol

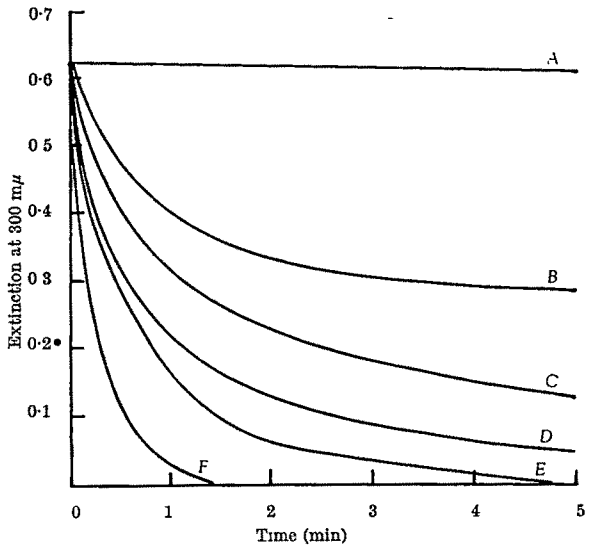

Fig. 1. Reaction of sulphur compounds with NEM. NEM (3 μmoles) was dissolved in phosphate buffer (0·1 M, *p*H 7·4) and placed in a 1 cm silica cell at 20° C. The sodium salts of the sulphur compounds were dissolved in the same buffer immediately before use and added to the cell at time zero (final volume 3 ml.). *A*, Blank cell and also cell containing 3–15 μmoles thiosulphate; *B*, 1·5 μmoles sulphite, *C*, 1 5 μmoles sulphide, *D*, 3 μmoles sulphite; *E*, 3 μmoles sulphide; *F*, 3 μmoles of either cysteine or reduced glutathione. The molar extinction coefficient of NEM at 300 mμ is 620 (ref. 10).

containing NEM show several other labelled compounds in addition (Fig. 2*B*).

The adducts of NEM with sulphite, sulphide and cysteine were identified by co-chromatography with the authentic labelled compounds, while methionine, methionine sulphoxide, and NEM-glutathione were identified by "fingerprinting" the labelled areas with the ninhydrin-positive spots produced by authentic markers. The NEM–cysteine adduct gives a negative reaction with ninhydrin because exposure to the first alkaline solvent causes cyclization to a thiazane derivative[6,18]. The identity of the NEM–sulphite spot was confirmed by two other pieces of evidence: (*a*) the radioactivity coincided with the faint red spot produced when marker NEM–sulphite was run with the extract and developed with excess NEM[9]; (*b*) chromatograms of extracts of *E. coli* mutant 8/6*G* fed with ^{35}S-sulphate revealed a heavily labelled spot in the NEM-sulphite area but no label at all in the NEM–cysteine, NEM–glutathione, or methionine areas. Mutant 8/6*G* fails to grow on sulphate because it lacks sulphite reductase[17], but it will grow on glutathione which derepresses the enzymes of sulphate reduction[13].

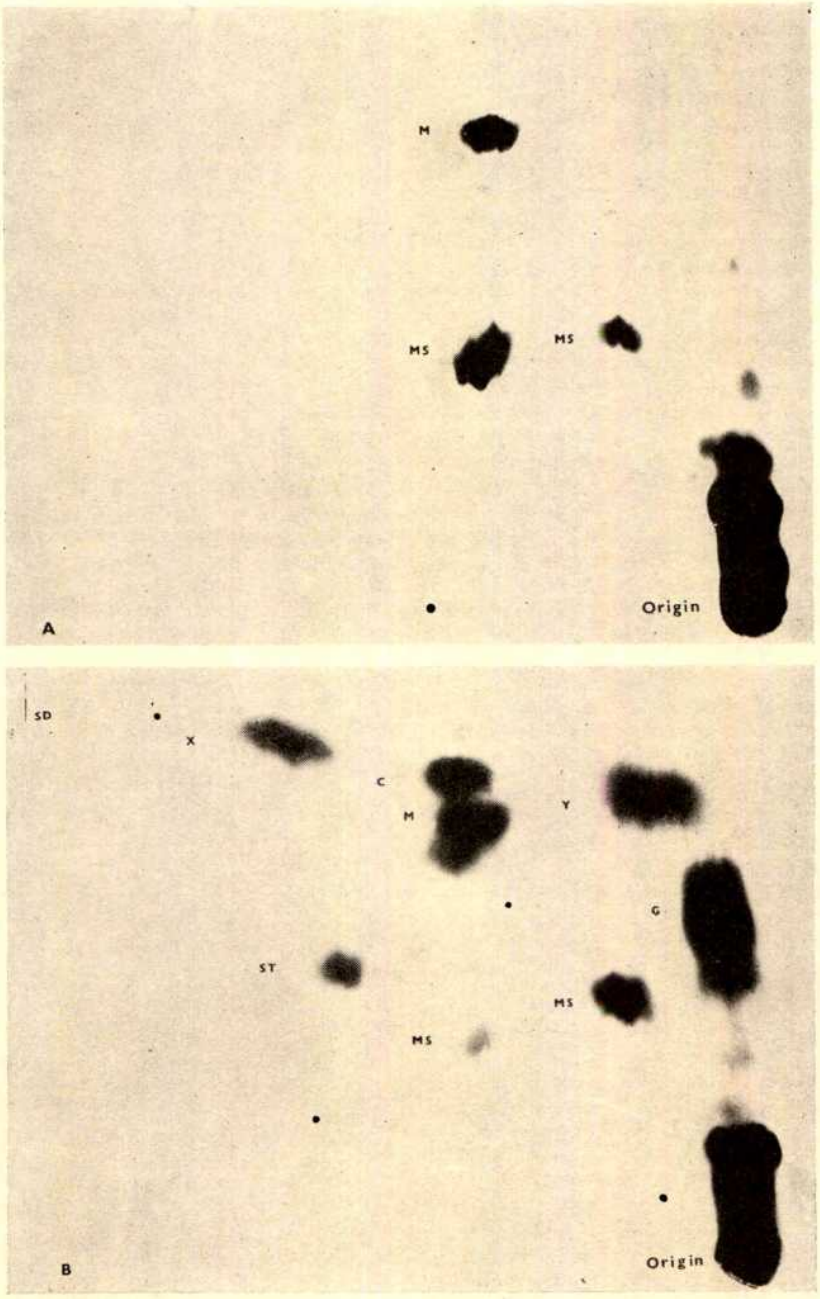

Fig. 2. Chromatography of extracts of *Escherichia coli*. A thick cell suspension of *E. coli* (4·3 mg dry weight/ml.) was fed with ^{35}S-sulphate for 1 min, as described in the text, and extracts chromatographed in ethanol–*tert*. butanol–aqueous ammonia (specific gravity 0·88) –water (300 : 100 : 4 : 75, by volume) in the first dimension (right to left), and in *tert*. butanol–formic acid–water (14 : 3 : 3, by volume) in the second dimension (bottom to top). The dried chromatograms were exposed to 'Kodirex' X-ray film for 5–10 days. *A*, Extract made in ethanol; *B*, extract made in ethanol + NEM. *M*, Methionine; *MS*, methionine sulphoxide; *C*, NEM-cysteine; *G*, NEM-glutathione; *SD*, NEM-sulphide (very faint); *ST*, NEM-sulphite; *X* and *Y*, NEM-unknowns. There are two methionine sulphoxide spots because a variable oxidation of methionine takes place during chromatography in the second solvent (ref. 9). Sulphate stays near the origin and streaks in the second solvent.

Additional evidence to support these identifications was obtained from experiments where cells were exposed to cysteine for 1 min before ^{35}S-sulphate was added. The addition of cysteine causes a rapid inhibition (more than 90 per cent) of sulphate uptake, this probably being the site of control by end-product inhibition[12]. Nevertheless some sulphate still enters the cells under these conditions and its fate can be followed by the NEM technique. Fig. 3 illustrates the chromatographic pattern observed in such experiments; radioactivity is present in the NEM-sulphite and NEM-cysteine areas but none in the methionine or NEM-glutathione areas. This is the result predicted if the above identifications are correct because the small amount of ^{35}S-sulphate taken up can be reduced to cysteine, but the subsequent metabolism of this labelled cysteine to methionine and glutathione will be masked by the large amount of unlabelled cysteine entering the cells. By the same arguments, the occurrence of label in compound NEM-*X* in Fig. 3 would suggest that it is an unknown intermediate between sulphate and cysteine; its identification is being pursued.

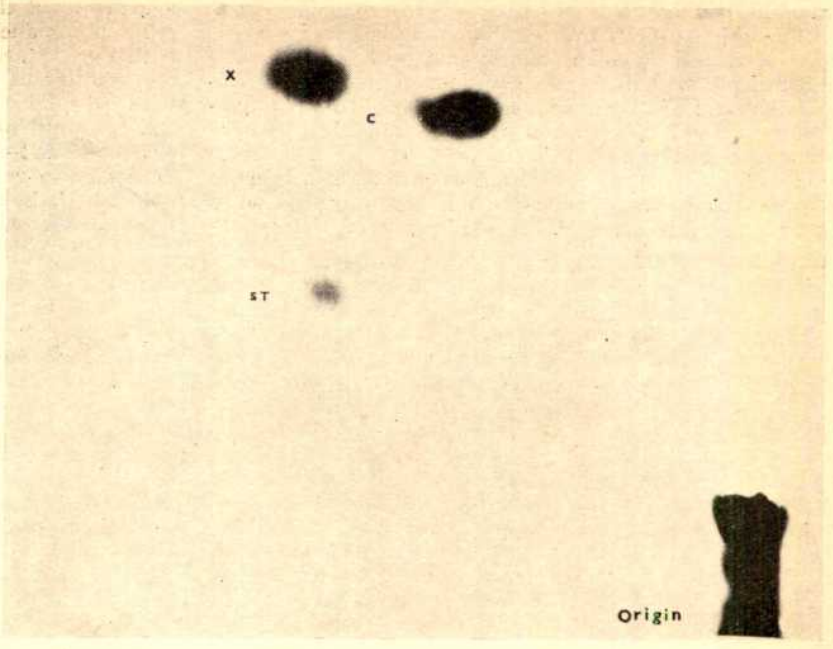

Fig. 3. Effect of cysteine on sulphate reduction. A suspension of *E. coli* was exposed to 0·5 mM L-cysteine for 1 min before a labelling experiment with ^{35}S-sulphate was carried out as described in Fig. 2. Extracts were made in ethanol + NEM 1 min after the addition of ^{35}S-sulphate. Symbols as in Fig. 2.

No radioactivity was detected in any experiment at the position on the chromatogram where NEM-thiosulphate was reported to run[9]. A similar lack of radioactivity was found when mixtures of thiosulphate and ^{14}C–NEM were chromatographed after incubation at *p*H 7·4; an absence of reaction between NEM and thiosulphate is suggested also by Fig. 1. The production of a red colour when mixtures of NEM and thiosulphate are made alkaline[11] suggests that a reaction between them does occur under these conditions, but it is clear that the present method cannot determine whether thiosulphate is an intermediate in sulphate reduction (as has been suggested for *Aspergillus nidulans*[19] but ruled out for *Salmonella typhimurium*[15]).

Table 1. TIME COURSE OF SULPHATE REDUCTION IN *Escherichia coli*

Time	Sulphite	Sulphide	Cysteine	Methionine*	Reduced glutatione	*X*
5 sec	0·24	< 0·02	0·13	0·04	0·03	0·06
10 sec	0·49	0·06	0·68	0·24	0·28	0·28
15 sec	0·58	0·09	1·11	0·51	0·63	0·58
30 sec	0·79	0·14	2·00	2·38	2·49	1·40
1 min	1·15	0·25	4·60	8·25	9·50	1·31
2 min	1·75	0·53	5·0	11·23	19·0	4·04
3 min	2·32	0·80	4·65	11·71	28·0	4·31
5 min	2·67	1·57	3·23	10·14	42·0	5·36

* Includes methionine sulphoxide.

A thick cell suspension (3·8 mg dry weight/ml.) of *E. coli* was fed with ^{35}S-sulphate as described in the text and samples placed in ethanol containing NEM at the times indicated. The figures represent the radioactivity in the various compounds as determined directly on the chromatograms with a large end-window counter, and are expressed as c.p.m. $\times 10^{-3}$.

The time course of sulphate reduction is shown in Table 1. At 5 sec sulphite is the most heavily labelled compound, followed by cysteine; methionine and glutathione are only very slightly labelled at this time. As the time of exposure to ^{35}S-sulphate increases, the radioactivity of all compounds increases. With sulphite, cysteine, methionine, and compound *X*, an approximate steady state is reached at about 2 min, whereas the amount of label in glutathione and sulphide continues to rise. After 5 min glutathione becomes far more heavily labelled than all the other products of sulphate reduction, confirming earlier findings that glutathione is the major soluble sulphur compound in this organism[20]. The data for sulphide can be reconciled with the postulated pathway if it is assumed that as well as being an intermediate between sulphite and cysteine, sulphide is also produced by the desulphurylation of cysteine. The sulphide pool is initially small in comparison with the pool sizes of the other intermediates; this is in strong contrast with the high concentration of sulphide that is required to demonstrate the conversion of sulphide to cysteine by the *in vitro* action of cysteine synthase[13].

These results demonstrate that the NEM technique can detect very small amounts of some unstable sulphur compounds; this technique should prove useful in other studies of sulphur metabolism.

EFFECT OF DISSEMINATED LUPUS ERYTHEMATOSUS SERA ON THE RESPIRATORY ACTIVITY OF GUINEA-PIG LEUCOCYTES

By A. E. FRUEHAN*, Dr. A. J. SBARRA, Dr. W. A. BARDAWIL and Dr. T. B. BAYLES

Department of Pathology and Medical Research, St. Margaret's Hospital, and Departments of Obstetrics and Gynecology, and Pathology, Tufts University School of Medicine and The Medical Service, Robert Breck Brigham Hospital, Boston, Massachusetts

Since Hargraves's original description of the lupus erythematosus (LE) cell[1] the morphological changes associated with LE cell formation have been extensively investigated. In spite of refinements in methodology and technique which have increased its usefulness as a diagnostic test[2,3] little is known about the basic cellular alterations which initiate the formation of the LE cell. Godman and Deitch[4] have described the nuclear changes which accompany the formation of LE cells, beginning with the entry of foreign protein into the nucleus of the white blood cell and the loss of ability to stain for nuclear histone. They felt that this foreign protein displaced histone from its association with nuclear DNA. This protein has been shown to be a gamma globulin, presumably LE cell factor itself[5-7]. The altered nucleus is then extruded from the cell as the LE cell body, and afterwards engulfed by viable leucocytes to form the typical LE cell[8].

It seems unlikely that such profound morphological changes could occur without alterations in the basic metabolism of the cell. Conceivably, the formation of LE cells might be initiated by metabolic changes within the cell, mediated by serum containing the LE cell factor. If a serum effect on white blood cell metabolism could be demonstrated *in vitro*, then the possibility exists that a similar mechanism might be operative *in vivo*, perhaps relating to the disease process itself.

For these reasons we have been interested in the possible changes in cellular metabolism which occur when viable white blood cells are incubated with disseminated lupus erythematosus (DLE) serum. Using leucocytes obtained from guinea-pig peritoneal exudates, we have investigated the changes in respiratory activity which occur during incubation with DLE serum, and compared these changes with those induced by normal human serum. The respiratory effects of sera from patients with other disorders of connective tissue and a variety of other illnesses have been tested for comparison, and some of the properties influencing the effect of serum on leucocyte respiration have been described.

Casein-induced peritoneal exudates were obtained by the method of Stahelin *et al.*[9] from 300–400 g guinea-pigs. These exudates contained 80–90 per cent polymorphonuclear leucocytes. The leucocyte concentration was standardized by adjusting the optical density of the leucocyte suspension (wavelength 550 mμ in a Bausch and Lomb 'Spectronic 20'). Rabbit leucocytes were obtained from 4–6 lb. rabbits by the same procedure.

Serum was obtained from patients at the Robert Breck Brigham Hospital, Children's Medical Center, and the New England Baptist Hospital. Diagnoses were established after evaluation[7] of the clinical history, laboratory results, and subsequent course of the disease. Normal human serum was obtained from healthy laboratory personnel. Guinea-pig and rabbit sera were obtained by cardiac puncture. Horse serum was obtained from the Massachusetts State Laboratories, Department of Public Health. Serum not used immediately was stored by freezing or by refrigeration for periods not exceeding 7 days.

Respiratory measurements were carried out using conventional Warburg manometry[10]. One ml. of leucocyte suspension containing 50–90 million cells was added to each Warburg flask. Unless otherwise noted, 0·6 ml. of serum was placed in the sidearm and the total volume in the flask brought to 3·0 ml. with Krebs–Ringer phosphate buffer at *p*H 7·4. 0·2 ml. of 20 per cent potassium hydroxide was placed in the centre well to absorb liberated carbon dioxide. After equilibration, serum and cells were combined and incubation continued at 37° C for 2 h. Oxygen consumption was recorded every 15 min. Two control flasks containing leucocytes in media alone (without serum) were included in each experiment to determine baseline cell respiration.

Experimental tests were carried out on LE cells according to the method of Zimmer and Hargraves[2]. Fluorescent antibody tests were performed by the indirect technique[5] on sections of unfixed human skin. Fluorescent antibody tests on leucocytes were performed after fixation of cells in absolute ethanol.

Normal serum consistently produced a marked reduction in oxygen uptake compared with leucocytes incubated in media alone. For example, after incubation for 60 min, normal serum depressed leucocytic respiration by approximately 60 per cent when compared with leucocytes respiring in the presence of media alone (Fig. 1). No such inhibition could be noted when DLE serum was substituted for normal serum and the respiratory activity of DLE exposed leucocytes was identical to the baseline respiration. This difference in the respiratory effect of DLE and normal serum remained constant over a wide range of leucocyte concentrations (16–114 million cells per flask). It should be noted that no macroscopic or microscopic differences between cells from any of the flasks could be noted after incubation for 60 min. Extended periods of incubation often resulted in macroscopic differences between the cells in the different flasks (probably because of accumulation of acids and insufficient buffering capacity). No concomitant changes in respiratory activity were noted, however. When serum volumes less than 0·6 ml. were used, normal serum showed decreased inhibition, and at 0·2 ml. or below did not depress leucocyte respiration. With serum volumes greater than 0·6 ml. both sera showed increasing ability to depress respiration, but at a given serum concentration DLE serum always caused less respiratory depression than did normal serum.

The respiratory effect of a single serum specimen was reproducible when used in the same concentration in

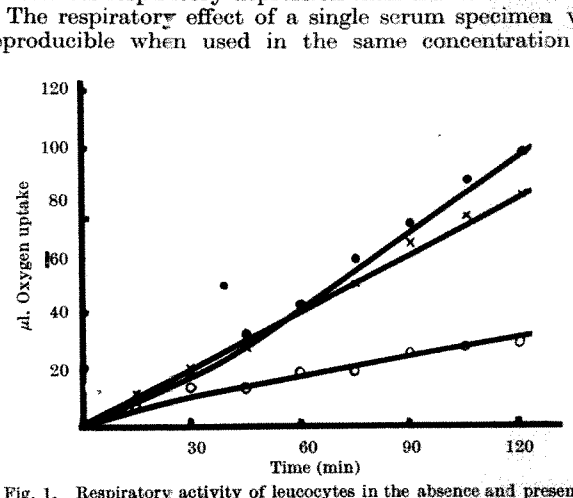

Fig. 1. Respiratory activity of leucocytes in the absence and presence of different sera. ×, Cells in absence of sera; ○, cells in presence of normal human serum; ●, cells in presence of DLE serum; serum concentration, 20 per cent; $9{\cdot}1 \times 10^6$ cells per flask. successive experiments. For example, 0·6 ml. of normal serum used in eight different experiments caused an oxygen uptake varying from 34 to 46 per cent of baseline cell respiration, with an average of 40 per cent and a standard error of 1·5.

Clinical Correlations

132 normal and pathological human sera were tested for their effect on guinea-pig leucocyte respiration. Eleven normal sera had average respirations at 40 per cent of baseline cell respiration, while sera from eighteen patients with active DLE averaged 103 per cent. Sera from patients with rheumatoid arthritis (R.A.) with a positive LE cell preparation, polyarteritis, scleroderma, ulcerative colitis and rubella arthritis have an effect on leucocyte respiration similar to that of active DLE serum.

Sera from patients with typical DLE in remission (inactive), or in patients in whom the clinical picture was atypical but who probably had either DLE or rheumatoid arthritis, or from rheumatoid patients with a negative LE cell preparation, or from patients with other types of joint diseases and, finally, from patients with liver disease, caused significantly more respiratory depression. Thirty-four patients with a variety of non-rheumatic diseases showed respiratory inhibition similar to that of normal serum. These data are shown in Tables 1 and 2.

The 132 sera tested were arbitrarily divided into two groups: those which caused depression of baseline leucocyte respiration (ninety sera, 21–89 per cent), and those which did not (forty-two sera, 90–145 per cent). These two groups were compared with respect to the patients' age and sex and to pertinent laboratory tests, and can be seen in Table 3. The forty-two sera which did not depress baseline leucocyte respiration showed a higher percentage of positive LE cell preparations and fluorescent antibody tests, but in other respects the two groups appeared comparable.

Two separate serum samples were obtained from twelve patients with active DLE, at intervals varying from 1 week to 2 years. These patients were divided into three groups, depending on the activity of the clinical disease during the interval between the first and second serum samples: four patients had no change in their clinical disease activity, four patients showed some improvement, and four patients had become essentially asymptomatic during the interval. The percentile oxygen uptakes of the first and second sera were averaged for each of these three clinical groups. No difference in respiratory activity could be demonstrated between the first and second sera when the disease activity remained unchanged or showed only moderate improvement. When the clinical disease became essentially asymptomatic during the interval, depression of leucocyte respiration appeared in the follow-up sera, a change which can be considered significant ($P < 0.05$).

The eighteen patients with active DLE were receiving many types of therapy at the time their sera were tested, including aspirin, antimalarials, large and small doses of steroids, white blood cell injections, injections of crude nucleoprotein extracts, and no medication. There was no correlation between the type of therapy received and the serum effect on leucocyte respiration.

Table 1. RESPIRATORY ACTIVITY OF LEUCOCYTES IN THE PRESENCE OF SERA FROM DIFFERENT PATIENTS WITH RHEUMATIC DISEASES

Disease	No. tested	Oxygen uptake* (μl.)	P† Normal serum	P Active LE serum

† Determined by paper strip electrophoresis.

Effects of Temperature

The specific respiratory effects of DLE and normal human serum were not altered by refrigeration at 10° C for periods up to 15 days, or by repeated freezing and thawing. When normal serum was heated to 56° C for 30 min, however, the ability to depress baseline leucocyte respiration was completely destroyed. This can be seen in Table 4. Heat did not alter the effects of DLE or guinea-pig serum on leucocyte respiration, but heating rheumatoid arthritis serum (negative LE preparation) caused complete loss of its inhibitory effect. The four heated sera showed no significant statistical differences in their effect on leucocyte respiration. When DLE and normal human serum were heated to 65° C for 30 min, results were identical to those shown for 56° C. The addition of guinea-pig complement to both heated and

Table 4. EFFECT OF HEATED SERA ON THE RESPIRATORY ACTIVITY OF GUINEA-PIG LEUCOCYTES

Addition*	Respiratory activity (%) 100†

Heated DLE serum	101

* 20 per cent serum added in all cases.
† Oxygen uptake in μl., at 90 min set at 100 per cent.
‡ Heated at 56° C for 30 min.

unheated DLE and normal serum before incubation did not change the results shown.

Heated normal serum did not depress baseline leucocyte respiration; it behaved, in effect, like DLE serum. This similarity in behaviour suggested that heated normal serum might also be capable of forming LE cells. When tested with autologous human leucocytes, however, no LE cells, rosettes, or extracellular material could be demonstrated.

Homologous and Heterologous Sera

The effect of species difference on leucocyte respiration was investigated using normal human, guinea-pig, rabbit and horse sera with both guinea-pig and rabbit leucocytes. Normal human serum caused depression of baseline leucocyte respiration with both guinea-pig and rabbit cells, but none of the other sera showed this effect.

Normal human serum caused a depression or inhibition of the oxygen consumption of guinea-pig leucocytes, while serum from patients with DLE and the other connective tissue diseases did not. This difference in respiratory effect may be explained by postulating (1) the presence of an inhibitory factor in normal serum that is absent or different in DLE serum, (2) a stimulatory factor in DLE serum that is not present in normal serum, or (3) a combination of 1 and 2. The possibility that an inhibitory factor(s) is present in normal serum which is absent, decreased or masked in DLE serum is indicated by the data presented. Certain characteristics of this inhibitory factor(s) emerge from the experimental data. It is labile to heat (destroyed by heating at 56° C for 30 min). It is stable at low temperatures, and resists repeated freezing and thawing. It is inhibitory to both guinea-pig and rabbit leucocytes, but is absent in the other animal sera tested (guinea-pig, rabbit, horse).

The possibility that the inhibitory effect of normal human serum is due simply to an agglutination of the leucocytes caused by an antibody-like substance present in normal human serum and missing in DLE serum is attractive and must be considered. The fact that no early microscopic or macroscopic differences were noted between the leucocytes incubated in the absence and presence of different sera, however, would tend to weaken this line of reasoning; also the fact that no change was found in the respiratory rate of the leucocytes in the presence of normal serum would indicate that death of the cell due to agglutination had not occurred. In addition the factor is destroyed by heating (56° C, 30 min). This would eliminate most of the conventional type of antibodies. This possibility is still attractive, however, and is at present being explored.

Merchant[11] has described the deleterious effects of normal human serum on guinea-pig peritoneal exudate cells. By observing the cells under dark field microscopy, he noted a marked reduction in the various parameters of leucocyte activity during incubation with normal human serum, compared with the effects of guinea-pig serum. Although it is attractive to attempt to correlate these observations with the inhibitory effect of normal serum on leucocyte respiration, it should be noted that Merchant also found that the reduction in leucocyte activity was not limited to human serum but was also present with other heterologous sera, and when leucocytes were incubated in inorganic media alone (Locke's solution). Washed peritoneal exudate cells were used in these experiments which may account for the difference in results with heterologous sera, since our data showed that only human serum was able to inhibit leucocyte respiration.

The respiratory effect of normal serum was simulated by sera from patients with a variety of illnesses including bacterial and viral infections, cancer, blood loss, blood dyscrasias, endocrinopathies, and cardiovascular and renal diseases. The other sera tested all showed significantly less respiratory depression, although inactive DLE, questionable DLE, questionable RA, RA with a negative LE cell preparation, other joint disease and liver disease sera caused more respiratory inhibition than did active DLE serum. RA with a positive LE cell preparation, polyarteritis, scleroderma, active dermatomyositis, apresoline lupus, ulcerative colitis and rubella arthritis all behaved similarly to active DLE serum in that they did not appreciably inhibit leucocyte respiration, and indeed sometimes showed stimulation above baseline respiration. The connective tissue diseases—disseminated lupus erythematosus, rheumatoid arthritis, polyarteritis, scleroderma and dermatomyositis—have been noted to have many common clinical, laboratory and even pathological findings, and stigmata of several of these diseases are sometimes observed in the same patient[12]. It is not surprising that a failure to inhibit leucocyte respiration is shared by serum from patients with these disorders. Apresoline lupus ulcerative colitis and rubella arthritis, although indirectly related, have been noted to show as yet poorly understood similarities to certain of the connective tissue disorders, similarities which the present investigation extends to include the effects of serum on leucocyte respiration.

Another possible mechanism for the difference in the respiratory effects demonstrated by DLE and normal serum can be suggested. The phagocytosis of inert particles is known to require an increase in glycolytic energy and is accompanied by a marked increase in oxygen consumption[13–15]. Thus, the inhibitory factor would be present in both sera, but in DLE serum a stimulatory factor, perhaps an antinuclear factor, could be present and subsequently "phagocytized" and an increased oxygen uptake could thus occur. Some evidence for this line of reasoning is seen where the serum concentration is reduced to 10 per cent. At this level, inhibition with normal serum is absent and an increase in respiration is noted with DLE serum[16]. From these data a hypothesis has been developed which relates lysosomes, aetiology, LE cell and appearance of antinuclear factor in patients with DLE[16,17]. The data presented in this paper are not inconsistent with the proposed hypothesis. In both instances, a stimulation of respiratory activity of leucocytes results when the cells are allowed to incubate in the presence of DLE sera and are compared with those respiring in the presence of normal serum. This stimulation could be "triggered" by the entry of an aetiological agent (viral, bacterial, fungal, etc.) into the cell. This would result in the activation of the lysosomal enzymes (DNase, cathepsins, etc.), which would now be free to attack nuclei and connective tissue components. The former would result in the appearance of LE cells and antinuclear antibodies and the latter would be responsible for some of the clinical manifestations often seen in DLE[16,18]. Further, the hypothesis that collagen diseases may have a basis in hypersensitivity against nucleoproteins being derived primarily from viral, bacterial or animal sources[19] also favours the proposed hypothesis and the concept that a stimulatory factor is present in DLE sera.

The failure to detect any evidence of LE cell formation in our reaction mixtures was not unexpected, as guinea-pig leucocytes from the peripheral blood are known to possess ten times the avidity for LE cell formation that is shown

by human cells[20]. Cells from guinea-pig peritoneal exudate also failed to form LE cells when tested with known positive sera by routine LE cell test procedures. Guinea-pig peritoneal exudate cells have been shown to possess a surface inhibitor substance which can prevent the phagocytosis of inert particles in the absence of serum, an inhibitor which can be removed by washing the cells[21]. Since washed cells were not used in the present experiments, this offers a possible explanation for the failure to demonstrate LE cells in the incubation mixtures.

The significance of these observations for the aetiology and pathogenesis of DLE and the other connective tissue diseases remains speculative. Nevertheless, they offer an avenue of approach to the investigation of possible metabolic abnormalities associated with these diseases.

RELATIONSHIP OF GLYCOLYTIC AND OXIDATIVE METABOLISM TO PARTICLE ENTRY AND DESTRUCTION IN PHAGOCYTOSING CELLS

By R. J. SELVARAJ and Dr. A. J. SBARRA

Department of Pathology and Medical Research, St. Margaret's Hospital and Department of Obstetrics and Gynecology, Tufts University Medical School, Boston, Massachusetts

The metabolic activities accompanying phagocytosis by polymorphonuclear neutrophils (PMN) are well known. For example, it has been shown that the uptake of particles is accompanied by a stimulation of oxygen consumption, as well as by increases in aerobic and anaerobic glycolysis, glycogenolysis, flow of glucose through the hexose monophosphate pathway (HMP), lipid turnover[1-4], and formate oxidation[5]. These metabolic alterations occur with a wide variety of particulate materials (inert matter and bacteria) and it has been thought that some of these changes represent an increased demand for energy that is required for the entry of particles. The finding that glycolytic inhibitors (that is, sodium fluoride, and iodoacetate, IAA) inhibit phagocytosis, whereas the respiratory inhibitors (that is, potassium cyanide and antimycin *A*) do not, indicates that the energy requirement for particle uptake is derived from glycolysis[2]. It is clear that phagocytosis is an active process requiring a net expenditure of energy by the phagocytosing cell.

The fate of the ingested particles, especially in relation to the alterations in the metabolism of the phagocyte after particle uptake, has also been considered by some investigators. For example, the increased release of hydrolytic enzymes and/or bactericidal agents from cytoplasmic granules of PMN after phagocytosis has been implicated in the destruction of ingested bacteria[6,7]. On the other hand, Iyer, Islam and Quastel[5] have postulated that the increased production of hydrogen peroxide by the direct oxidation of glucose during phagocytosis by PMN is responsible for the functional bactericidal action. Obviously much has been learned. It should, however, be pointed out that many of these metabolic stimulations are oxidative in nature. Since it is well known that phagocytosis occurs anaerobically[2] the question regarding the function of these oxidative changes becomes important. As yet, the significance of many of these findings and their subsequent correlation with the eventual fate of the ingested material remains unresolved.

The object of this article is to show that the increased metabolic activities associated with phagocytosis may be separated into those events which are involved with entry of the particle and those which are apparently triggered by the particle once it has entered the cell. It will further be shown that these latter events (that is, stimulated metabolic oxidative activities, such as increased oxygen uptake and increased HMP activity) are apparently not involved in particle uptake. This will explain why phagocytosis can occur equally well in aerobic and anaerobic conditions. Finally, a correlation between bactericidal activity and increased oxidative activities of the phagocytosing cells will be shown.

Polymorphonuclear neutrophils were obtained from guinea-pig peritoneal exudate by previously published procedures[2]. Respiration was measured by standard Warburg manometric techniques. Anaerobic conditions were obtained by flushing the reaction flasks for 15 min. with nitrogen. Traces of oxygen present in the commercial nitrogen used were removed by passing the gas over hot copper powder. Lactate estimations were carried out using the method of Barker and Summerson[8]. The production of carbon-14 dioxide was measured as labelled barium carbonate as described by Calvin *et al.*[9]. The bactericidal activities of the cells were measured as described in a previous publication[10]. Cultures of *Staphylococcus albus* and *Escherichia coli* were maintained and used as previously described[10].

Intact cells were incubated in Krebs–Ringer phosphate medium (KRPM). PMN homogenates were prepared by suspending the washed PMN pellet in 0·25 M sucrose and homogenizing the resulting suspension in a motor-driven Potter–Elvehjem homogenizer with a 'Teflon' pestle for 2 min. The homogenate preparations contained a negligible number of whole cells, swollen and disrupted nuclei and intact granules, as observed by phase microscopy. The reaction mixture for the incubation of homogenates consisted of 133 μmoles of sucrose, 30 μmoles of potassium phosphate buffer at *p*H 7·4, 33·3 μmoles of potassium chloride, 6·7 μmoles of magnesium sulphate,

1 μmole of adenosine-5-phosphate, 10 mμmoles of cytochrome-*c* and 40 μmoles of nicotinamide in a total volume of 1 ml. Substrates and/or inhibitors were added when desired.

For the measurement of hydrolytic enzymes, PMN suspended in Krebs–Ringer phosphate medium were incubated in small homogenizer tubes in a Dubnoff metabolic shaker. After incubation, the tubes were plunged in an ice bath and 9 ml. of ice cold medium was added. The cells were separated by light centrifugation (400*g* for 4 min) and homogenized for 1 min in 2·5 ml. of 0·25 M sucrose. An additional portion of 2·5 ml. of 0·25 M sucrose was now added and the suspension was mixed vigorously in a 'Vortex' mixer for 1 min. Portions of this homogenate were taken for the estimation of total enzyme activities and the remaining homogenate suspension was centrifuged in a 'Serval *RC*-III' centrifuge at 18,000*g* for 15 min. Portions of this supernatant were used to assay the enzyme activities in the soluble (cytoplasmic) fraction of the homogenate. The difference between the total and soluble enzyme activities has been shown to reside in the lysosomal granules[6].

Acid and alkaline phosphatase activities were measured by the rate of hydrolysis of *p*-nitrophenylphosphate[11] at two different enzyme concentrations. The incubation mixture for acid phosphatase estimation consisted of 5 μmoles of *p*-nitrophenylphosphate, 22·5 μmoles of citric acid, 2·5 μmoles of hydrochloric acid and 45 μmoles of sodium hydroxide and enzyme preparations in a total volume of 0·5 ml. The final *p*H of the reaction mixture was 4·8. For alkaline phosphatase measurement the reaction mixture consisted of 5 μmoles of *p*-nitrophenylphosphate, 25 μmoles of glycine, 0·25 μmoles of magnesium chloride, 21·3 μmoles of sodium hydroxide and enzyme preparation in a total volume of 0·5 ml. The final *p*H was 10·5. After incubation for 30 min the reaction was stopped by the addition of 2·5 ml. of 0·02 N sodium hydroxide and the yellow colour of *p*-nitrophenol was estimated in a Beckman *DB* spectrophotometer at 410 mμ. β-glucuronidase was estimated by the rate of hydrolysis of phenolphthalein-β-glucuronidate[12]. The incubation mixture consisted of 0·5 μmole of substrate, 28 μmoles of sodium acetate–acetic acid at *p*H 4·5 and enzyme preparation in a total volume of 1 ml. After incubation for 60 min, the reaction was stopped by the addition of 2·5 ml. of 0·5 M glycine–sodium chloride–sodium hydroxide buffer at *p*H 10·4. The liberated phenolphthalein was estimated spectrophotometrically in a Beckman *DB* spectrophotometer at 540 mμ.

Metabolic stimulation is shown only by intact and viable phagocytosing PMN. This is clearly shown by the results presented in Table 1. The addition of particles to PMN homogenates does not significantly change any of the metabolic activities of the homogenates. Intact cells, on the other hand, show striking stimulation of oxidative metabolism. The PMN homogenates used in these experiments possess in a functional state the necessary enzyme systems responsible for the stimulated metabolic activities. This is shown by the fact that when TPN is added to homogenates the stimulation in the oxidation of glucose-1-^{14}C is readily apparent. TPN has been shown to be the rate limiting factor for the operation of the HMP in human leucocyte homogenates[13]. In intact cells TPN does not stimulate the HMP, presumably because of a transport barrier. Finally, it has been shown that sodium fluoride will cause a marked stimulation of respiratory and HMP activities in leucocytes[2]. PMN homogenates do not show these stimulations with sodium fluoride.

It is clear that an intact cell structure is necessary to produce these metabolic changes accompanying phagocytosis. Yet it is not clear whether these changes occur at the same time as particle uptake or whether they occur as a result of an alteration in the properties of the phagocyte. However, Zatti, Rossi and Meneghelli[14] have shown that the stimulation of HMP activity occurs as early as 30 sec. after phagocytosis. In order to investigate this problem, pre-incubation experiments were undertaken using heat killed *S. albus* as a test particle. PMN were incubated with bacteria in 50 ml. glass centrifuge tubes in a Dubnoff metabolic shaker. After incubation for 15 min. the PMN were washed free of extracellular bacteria with 40 ml. of ice cold KRPM and centrifuged at 400*g* for 4 min. This procedure was repeated twice. These washed PMN (95 per cent containing more than twenty-five particles per cell, measured under a light microscope) and also homogenates prepared from them were now incubated with labelled substrates in a Warburg monometric apparatus. Table 2 shows that these washed cells, in spite of the absence of extracellular particles, showed stimulated oxidative metabolism similar to that observed with phagocytosing PMN. It is also of interest to note that homogenates prepared from washed PMN containing particles also have an increased metabolic activity.

Thus, the sustained, stimulated oxidative metabolism of phagocytosing PMN does not appear to depend on the simultaneous act of engulfment. Apparently it occurs as a consequence of particle uptake. On the other hand, it has been shown conclusively that glycolytic activity is involved in particle uptake[2]. Also, it has been suggested that the increased glycolytic activity of phagocytosing PMN causes the increased oxidation of glucose-1-^{14}C by a TPN-linked lactic dehydrogenase[15]. Further, it has

been shown that sodium fluoride will inhibit glycolysis and phagocytosis and simultaneously increase respiration and carbon-14 dioxide production from glucose-1-^{14}C and formate-^{14}C. This effect of sodium fluoride has not as yet been thoroughly investigated and explained. Experiments have now been carried out to elucidate the interrelationship of glycolysis and oxidative metabolism of PMN during phagocytosis and also to elucidate the apparently peculiar effects of sodium fluoride in PMN metabolism.

Sodium fluoride in increasing concentrations causes an increase in the respiration and glucose-1-^{14}C oxidation of PMN until a plateau is reached at about 30 mM concentration (Fig. 1). These data are similar to the results obtained when increased concentrations of particles are offered for phagocytosis[2]. Degranulation of PMN is also observed with added fluoride (Figs. 3 and 4) as has previously been observed with particles[6,7]. "Popping" of granules with fluoride has previously been alluded to in a statement by Karnovsky during a general discussion[16]. The similarities between the metabolic stimulations of fluoride and particles are further shown by the facts that fluoride does not stimulate the metabolism of PMN homogenates (Table 1) while it does stimulate the metabolic activities of intact cells and homogenates prepared from PMN pre-incubated with fluoride (Tables 1 and 2). These results are similar to those obtained with particles under identical conditions, and it is clear that fluoride stimulates the oxidative metabolism of PMN in the same way as do added particles. From our data, it would appear that this effect can be explained by the magnesium fluoro-phosphate complex formed on the addition

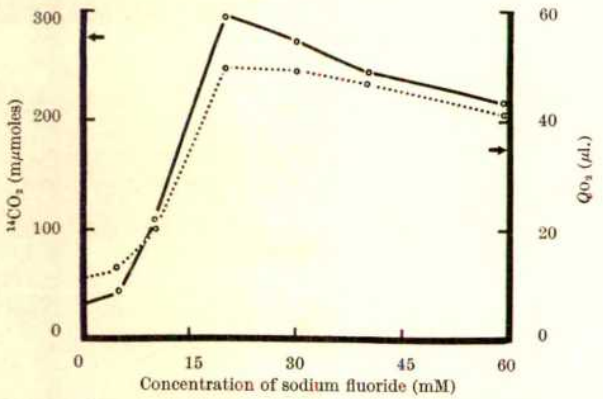

Fig. 1. Effects of sodium fluoride on respiration and glucose-1-^{14}C oxidation by PMN. Results are averages from two experiments for a 30 min. reaction period and 100 γ cellular phosphorus ($5{\cdot}5 \times 10^7$ cells). At concentrations of sodium fluoride higher than 20 mM, an equivalent amount of sodium chloride was removed from the medium to maintain isotonicity. ———, $^{14}CO_2$ produced from glucose-1-^{14}C; — — — —, oxygen consumption. Arrows indicate stimulation observed with polystyrene particles in absence of sodium fluoride.

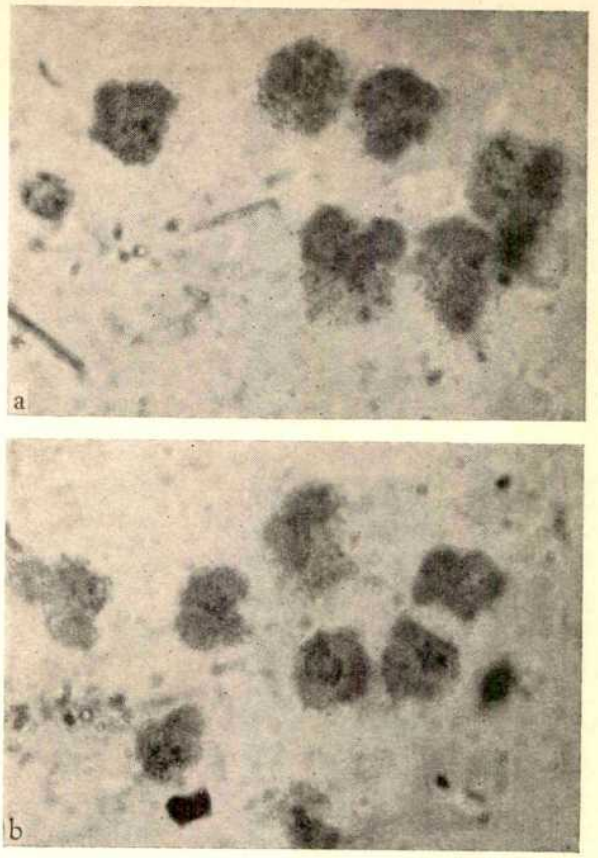

Fig. 3. Degranulation in PMN induced by sodium fluoride. *a*, Control, no fluoride; 15 min incubation period; *b*, 20 mM fluoride; 15 min incubation period.

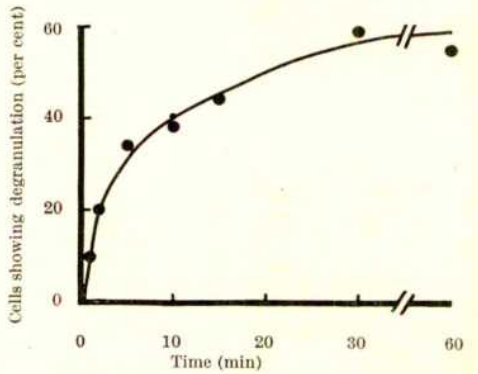

Fig. 4. Time-course investigations on degranulation induced by sodium fluoride. PMN suspensions in KRPM with and without sodium fluoride (20 mM) were incubated in test tubes held in a Dubnoff metabolic shaker at 37°C. Slides were made at the time intervals indicated and stained for 1 min with May-Grunwald (diluted 1 : 10 with 95 per cent ethanol). They were then washed with tap water and counter-stained for 6 min. with 1 : 200 Giemsa. The slides were then washed with tap water, dried in air and examined by light microscopy. Cells showing degranulation as shown in Fig. 3*b* were scored and are represented on the ordinate.

of fluoride to KRPM. The formation of this complex when fluoride is added to phosphate buffer in the presence of magnesium is well established[17]. This precipitate might therefore act as a stimulatory particle. Fluoride is also a glycolytic inhibitor, however, and depresses lactate production considerably and it effectively prevents phagocytosis. It is postulated that fluoride diffuses freely into the cell and forms magnesium fluoro-phosphate inside the cell and the resulting precipitate initiates the observed stimulated metabolic activities. If, however, sodium fluoride is added to magnesium sulphate and phosphate buffer in a test tube and the resulting precipitate is offered to PMN as a test particle, no stimulation of any of the metabolic activities usually seen with phagocytosing cells is observed. This is not unexpected as many insoluble inorganic precipitates (such as barium sulphate and manganese dioxide) have also been shown not to be phagocytosed by PMN[5].

To explore further the hypothesis that the observed increases in oxidative metabolic activities are the result of a stimulation inside the cell, pre-incubation experiments were conducted using IAA as a glycolytic inhibitor. A number of preliminary experiments were carried out by varying the time of pre-incubation and the concentration of IAA to obtain satisfactory conditions to prevent particle entry without causing an undue inhibitory effect on the metabolism of the resting cell. For these experiments, PMN were incubated with IAA in the main chambers of Warburg flasks, and glucose-1-^{14}C along with sodium fluoride or heat-killed *S. albus* were tipped from the side arm of the Warburg flask after the pre-incubation period. The results shown in Table 3 show that pre-incubation for 5 min with 0·5 mM IAA effectively prevents particle entry (as observed by light microscopy) and also inhibits significantly the metabolic stimulations observed with phagocytosis. Under identical conditions, however, sodium fluoride still stimulates respiration and oxidation of glucose-1-^{14}C. It is evident that fluoride diffuses into the cell and forms the magnesium fluoro-phosphate complex inside the cell, which then acts as a phagocytosed particle. Lactate production was inhibited considerably by fluoride, indicating that fluoride ions entered the cell, although the oxidative metabolism was stimulated.

These results not only throw light on the peculiar metabolism of PMN in the presence of fluoride, but they also allow one to draw some conclusions regarding the sequence and interrelationships of oxidative and glycolytic metabolism in phagocytosing cells. Evidence for the involvement of glycolytic energy for the engulfment of particles appears conclusive, since inhibition of the production of lactate by fluoride or IAA effectively inhibits particle entry. Convincing evidence that an increased glycolysis results in a stimulation of the flow of glucose molecules through the HMP, as has previously been suggested[15], is still lacking, however, and is inconsistent with the finding that fluoride stimulates the oxidation of glucose-1-^{14}C while lactate formation is considerably inhibited. These changes in the oxidative metabolism of phagocytosing PMN appear to be the result of changes that have already occurred in the phagocyte owing to the presence of the particle inside the cell. Although viable cells are required for the initiation of these events, neither an intact cellular structure nor simultaneous particle entry is necessary to produce these changes (Tables 1 and 2). The ingested particle might conceivably come into direct contact with the surface of the granules inside the cell, thus stimulating an increased interaction between the reduced pyridine nucleotides and their oxidases. The presence of "swollen" granules in phagocytosing cells has recently been reported by Zatti, Rossi and Meneghelli[14]. Further, these authors have also shown that this morphological change occurs during the period of stimulated metabolic activity.

Table 3. EFFECTS OF PRE-INCUBATION WITH IAA ON THE METABOLISM OF PMN

Additions	QO_2 (μl.)	Lactate (μmoles)	Glucose-1-^{14}C→$^{14}CO_2$ (mμmoles)
Control			
None	11·2	3·4	45·3
Particles	26·9	3·9	335·0
Sodium fluoride (20 mM)	42·0	0·9	296·0
IAA (0·5 mM) pre-incubated (5 min)			
None	8·9	0·5	31·3
Particles	13·0	0·5	32·1
Sodium fluoride (20 mM)	39·6	0·4	243·0

Results are averages of two experiments, for a 30 min reaction period following pre-incubation. For further details see Table 1 and text.

Since the glycolytic activity of PMN is involved in the uptake of particles and since it appears that the changes in oxidative metabolism occur as a result of this uptake, it would be of interest to examine the possible role of the stimulated oxidative changes in the digestion and destruction of phagocytosed particles. It is well known that phagocytosis occurs under anaerobic as well as aerobic conditions, although oxidative metabolism does not occur in the absence of oxygen[2,5,18]. These facts provide a basis for examining the possible relationship between the oxidative metabolic activity and the fate of the ingested material. It is evident from the results presented in Fig. 2 that the bactericidal activity of PMN against *E. coli* is significantly reduced under anaerobic conditions. Uptake of particles under anaerobic conditions was confirmed under the light microscope. Also, Table 3 shows clearly that the increased liberation of lysosomal enzymes associated with the entry of particles (increased activity in soluble fraction from phagocytosing cells) was also found to be comparable to that observed under aerobic conditions. These data would appear to indicate that the increased oxidative metabolism is associated with the higher bactericidal activity observed under aerobic conditions. Further, as lysosomal enzyme activities are increased equally under aerobic and anaerobic conditions, their role as bactericidal agents *in vivo* requires further investigation. The work of Zatti, Rossi and Meneghelli[14] is pertinent to this latter point. These authors have shown that lysosomal degradation is not related to the increased flow of glucose through the hexose monophosphate shunt nor to the increased respiratory activity associated with particle uptake. On the other hand, the increased TPNH oxidase activity associated with phagocytosis has been shown to result in increased formation of hydrogen peroxide which can be effectively prevented by anaerobiosis[5,19]. The increased bactericidal activity observed under aerobic conditions suggests that the role of hydrogen peroxide as a bactericidal agent in PMN requires further investigation. Such experiments are now in progress.

It thus appears that the metabolic activities of phagocytosing cells may be separated into those involved with actual engulfment (glycolytic) and those which are apparently triggered by the particle once it has entered the cell (oxidative). The latter activities would appear to be associated with inactivation and the eventual destruction of the phagocytosed particle.

We thank Miss C. Pilapil for technical assistance, and Mr. George Daynes for taking the photographs.

Table 4. RELEASE OF LYSOSOMAL ENZYMES BY PHAGOCYTOSING PMN UNDER AEROBIC AND ANAEROBIC CONDITIONS

	Aerobic				Anaerobic			
	Resting		Phagocytosing		Resting		Phagocytosing	
	Total	Soluble	Total	Soluble	Total	Soluble	Total	Soluble
Alkaline phosphatase	2·90 ± 0·18	0·16 ± 0·02	3·02 ± 0·05	0·40 ± 0·07	2·71 ± 0·04	0·17 ± 0·01	2·96 ± 0·02	0·39 ± 0·01
Acid phosphatase	2·74 ± 0·05	0·07 ± 0·01	2·77 ± 0·05	0·20 ± 0·04	2·71 ± 0·02	0·08 ± 0·01	2·77 ± 0·03	0·26 ± 0·02
β-Glucuronidase	0·06 ± 0·01	0·02 ± 0·01	0·07 ± 0·01	0·03 ± 0·01	0·07 ± 0·01	0·02 ± 0·01	0·07 ± 0·01	0·03 ± 0·01

Results are averages of four experiments. Enzyme activities are given as μmoles of substrate hydrolysed in 30 min by enzymes extracted from 100 cellular phosphorus (5·5 × 10^7 cells). Soluble fraction contains the enzymes released by lysed granules. For further details see text.

This investigation was supported by grants from the National Cancer Institute, U.S. Public Health Service, and the Atomic Energy Commission.

MECHANISM OF RECURRENT INHIBITION IN THE LATERAL GENICULATE NUCLEUS OF THE RAT

By DR ANN JERVIE SEFTON and DR. W. BURKE
Department of Physiology, University of Sydney

In a recent communication[1] a neuronal model was proposed to account for the deep and prolonged depression of transmission through the lateral geniculate nucleus (LGN) of the rat after a stimulus to the optic nerve[2]. This model was based on the finding of two types of cells in the LGN: *P* cells, believed to be principal cells projecting to the visual cortex, which constituted 88 per cent of the 255 cells examined; *I* cells, believed to be interneurones, constituting 12 per cent of all cells. Following the stimulus, both types of cell discharge in rhythmical bursts at intervals of about 150 msec. It was suggested that the *I* cells receive an innervation from recurrent collaterals of the *P* cells, responding to a single afferent volley with a burst of about ten action spikes, and synapse back on to the *P* cells, producing there a hyperpolarization (a summation of inhibitory postsynaptic potentials (IPSPs)). The *P* cells would be silenced during the hyperpolarization but would discharge again after about 150 msec as the hyperpolarization waned, perhaps because of an overshoot of potential beyond the resting level. The renewed *P* cell discharge would re-excite the *I* cells and the whole process would be repeated. Connexions between *P* and *I* cells appear to be diffuse. Possibly because of increasing asynchrony between the elements, the recurrent discharges do not continue indefinitely but cease after a few seconds.

The model is essentially similar to that of the spinal motor neurone–Renshaw cell loop[3] and similar models have also been proposed for several other nuclei in the central nervous system[4–8]. This article gives additional evidence in support of the model and suggestions are made concerning some still unexplained features. Recordings were made from single cells in the LGN of the rat, anaesthetized with paraldehyde or pentobarbital, using glass microcapillary electrodes filled with either 3 M potassium chloride or 2 M potassium citrate. Electrical stimuli were applied to the contralateral optic nerve or to the ipsilateral visual cortex.

Extracellular records from *P* cells in response to electrical stimulation of optic nerve show that the spike potential is usually followed by a slow negative wave. Although this is opposite in polarity to the field slow waves recorded in the ventro-basal nucleus of the thalamus by Andersen, Brooks, Eccles and Sears[9], there is little doubt that the two sorts of slow wave are homologous and accordingly, following the terminology of these authors, we refer to them as *P*-waves. The difference in polarity will be discussed later. The *P*-wave has been studied in extracellular records from forty-one *P* cells and the related intracellular potential changes in twenty-four *P* cells.

Fig. 1*A* shows a series of extracellular records from a *P* cell on successively slower time bases. The diphasic positive–negative spike potential is immediately followed by the negative *P*-wave, which commences during the negative phase of the spike. The time course of the *P*-wave is slightly longer than 100 msec and is then followed by a series of *P*-waves at intervals averaging about 150 msec and continuing for more than 1·5 sec. The later *P*-waves are always smaller than the initial wave and vary in amplitude, duration and interval. There is a rough rhythmicity in their occurrence, however, and their time course is not greatly different. An injury discharge in this cell (*A* potentials only) was suppressed during the *P*-wave.

Impalement of a cell always caused considerable damage; resting potentials were never more than 40 mV. The spike potential was usually lost within a few seconds and all responses were often lost within a few minutes; nevertheless, considerable information about the in-

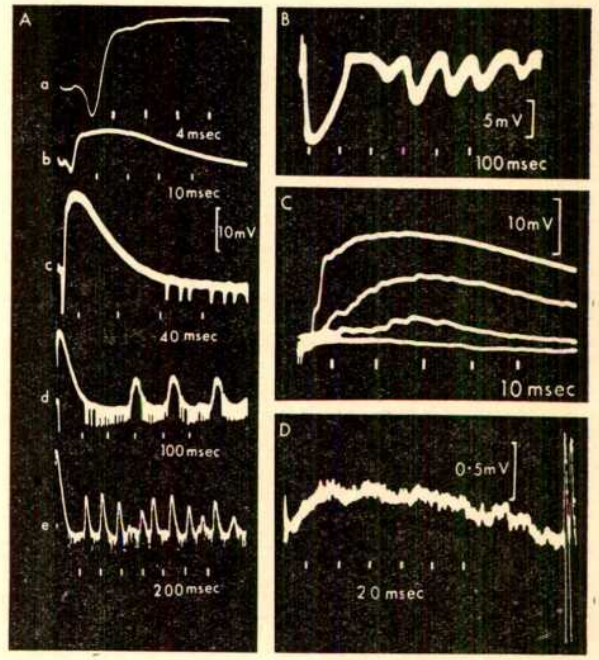

Fig. 1. Records from *P* cells in response to stimulus to optic nerve. Stimulus at commencement of each sweep. *A*, Extracellular. Negative upwards. Same strength of stimulus but successively slower sweeps. Spontaneous discharge of *A* spikes. *B*, Intracellular. Resting potential 30 mV. Positive upwards. Potassium citrate electrode. *C*, Intracellular. Resting potential at these records not recorded. Positive upwards. Superimposed successive depolarizing IPSP waves in response to a single optic nerve stimulus. Sweep for large response commences with stimulus; other sweeps are triggered by onset of IPSP wave. *D*, Extracellular. Negative upwards. Note that the negative *P*-wave is not preceded by a spike but is followed by spikes with good negative phase.

hibitory process was obtained during this time. The spike or excitatory postsynaptic potential (EPSP) is at first followed by a slow wave of hyperpolarization. This wave has a peak at about 20 msec, a duration of about 150 msec, and is followed by a series of waves of like form (Fig. 1*B*). There is no doubt that these are the intracellular counterparts of the *P*-waves and hence are referred to as IPSP waves[7]. If a potassium chloride electrode was used, the IPSP wave gradually became smaller, then reversed to give a wave of depolarization. If a citrate electrode was used there was no reversal (Fig. 1*B*). Evidently the ionic mechanisms underlying this potential change are similar to those at other postsynaptic inhibitory synapses[10]. Neither the *P*-waves nor the IPSP waves depend on the occurrence of a spike potential in the cell (Fig. 1*B–D*). Similar IPSP waves have been observed in cat LGN[11].

A similar series of slow waves may be obtained by cortical stimulation and all the other observations reported here are likewise reproducible. *I* cells can be reactivated by a second stimulus to the cortex shortly after the termination of the first discharge, that is at about 30 msec. Correspondingly, a second cortical stimulus prolongs a *P*-wave or IPSP wave. No slow waves were recorded from *I* cells. When *P* cells were tested with two cortical stimuli, in most cases they would not fire again until 130 msec or more had elapsed. The hyperpolarization is apparently sufficiently intense to prevent invasion of even the initial segment of the cell.

Fig. 2 shows the discharge of an *I* cell in response to two optic nerve stimuli (*a*, *b*). On each occasion the cell responded with nine bursts. These were recorded on moving film, each burst triggering the sweep, so that the vertical distance gives the interval between successive bursts. There is a variation in duration of burst, in pattern of discharge within the burst, and in interval between bursts. The first burst always has the highest frequency of discharge, however, and the intervals between bursts are comparable to those observed between *P*-waves or IPSP waves in a *P* cell. A high frequency of discharge and good synchronization between the first bursts of many *I* cells could account for the abrupt onset of the first *P*-wave or IPSP wave, as well as for its larger size (Fig. 1). Fig. 2 also shows that an *I* cell may discharge again after a longer interval than usual following a short discharge. Since its own short discharge would probably produce no rebound excitation in a *P* cell, the pause in the *I* cell discharge suggests a reciprocal innervation between a *P* cell and a given *I* cell. But the diffuseness of the system evidently enables one cell to pick up the rhythm from other cells and thus the discharges resume.

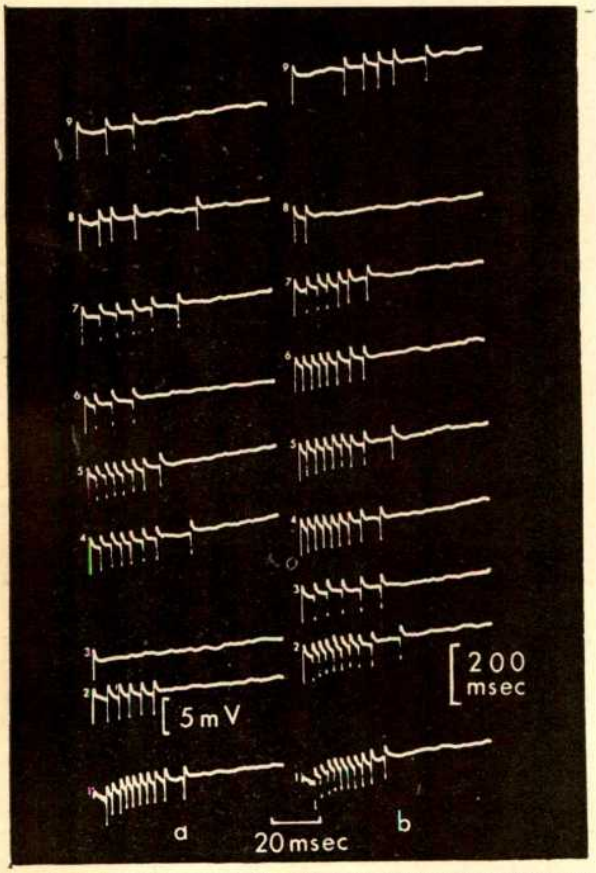

Fig. 2. Extracellular records from an *I* cell in response to two optic nerve stimuli (*a*, *b*). Each response consisted of nine bursts, photographed on slowly moving film (vertical calibration). Negative upwards. Responses commence at bottom of figure.

Rippling was observed in a few cells on the IPSP wave; the best example is shown in Fig. 1*C*. A potassium chloride electrode was used in this cell and at the time these records were obtained the IPSP wave had become depolarizing. The superimposed records are successive IPSP waves resulting from a single stimulus. The first wave (which is also the largest) commences with an EPSP of about 7 mV and is followed by an IPSP wave with a large initial step. The EPSP is absent in the later waves and the onset of the IPSP is much less abrupt.

Why is rippling not seen more frequently and why is it never seen in the LGN of the cat[11] nor in the ventro-basal nucleus of the thalamus[7] where analogous circuits apparently exist? Rippling might not be detectable if a large number of *I* cells converged on to each *P* cell and if their discharges were not precisely synchronous. In the rat LGN the amount of convergence is possibly less than in cat thalamic nuclei. In many records (such as Fig. 1*A*) there is a suggestion that the amplitudes of successive *P* waves are graded in a quantal fashion. That this is not exactly so is not surprising considering the variation in the successive discharges of an *I* cell (Fig. 2). It is not improbable, however, that the third largest wave in Fig. 1*C* results from a burst discharge of a single *I* cell; the pattern of rippling closely resembles the pattern of firing in the fifth burst in Fig. 2*a* (from another animal). The smallest wave in Fig. 1*C* seems to consist of only one IPSP such as would result from a single spike in an *I* cell (for example, the third burst in Fig. 2*a*). In the larger waves the rippling is faster and less obvious, as would be expected if more *I* cells were involved. The rippling would also be less obvious the closer the potential came towards the inhibitory equilibrium potential. Although we have insufficient data to make accurate estimates, a rough calculation will indicate the order of magnitude of the cross-innervation. It would not be unreasonable to suppose that about six *I* cells projected to one *P* cell. Since there are about eight *P* cells for every *I* cell, then each *I* cell would innervate on the average about fifty *P* cells.

An important point of difference between the rat LGN and thalamic nuclei in the cat (including the LGN) is that field slow waves are virtually absent in the rat. The *P*-waves described here are related to a single cell and disappear when the cell is lost or destroyed. In all except one of the forty-one *P* cells the extracellular slow wave was negative. This might have been because of injury by the electrode, but the same polarity was observed at a time when the diphasic spike potential also had a good negative phase (Fig. 1*D*), indicating that the electrode had not damaged the cell. Since most of the recordings are likely to be from the soma this result means that all or most of the inhibitory synapses are not on the soma, but on dendrites or possibly on the axon hillock. The single recording in which the *P*-wave was positive might have been from one of these sites. The field *P*-waves in the thalamus of the cat result from the flow of current from somas to axons and are therefore positive. These waves may very well obscure the single-cell *P*-wave. The reason for the insignificance of the field slow waves in the rat LGN may be the smallness of the structure.

OCULOMOTOR FUNCTION AND THE ALPHA ACTIVATION CYCLE

By DR. T. MULHOLLAND* and DR. C. R. EVANS
Autonomics Division, National Physical Laboratory, Teddington, Middlesex

FOR many years the electroencephalogram (EEG) has been regarded as a useful, if somewhat crude, indicator of cerebral processes occurring in humans. In the detection of tumours, for example, certain electroencephalographic atypicalities can assist the skilled diagnostician in evaluating both their site and severity. Less reliably, modification of the occipital "alpha rhythm" has been used extensively as an index of such variables as the presence or absence of "attention" on the part of the subject. Recently one of us (T. M.) has been studying the ability of individual subjects to modify their own electroencephalograms at will. This has been achieved by setting up a "closed-loop" between the EEG and the activating stimulus—the subject "intervening", as it were, within the loop. A detailed description of the EEG-stimulus loop is given elsewhere[1], but the principle may be simply summarized here. The loop is effected by supplying the subject with information as to the presence or absence of recorded alpha rhythms from his own brain—this may be done by arranging for a predetermined persistence of the alpha rhythm to switch on a light in front of the subject or to sound a tone which continues as long as "alpha", according to the agreed criterion, is present. In such circumstances many subjects can give rather dramatic demonstrations of their ability to modify their own alpha-rhythm by "switching on" the light, tone, etc., on request[2,3]. In experiments recently performed in the Autonomics Division of the National Physical Laboratory, Teddington, a number of subjects were tested in this type of situation, one of whom (R. R.) became remarkably skilful at controlling the loop. In Fig. 1 we give examples from an experiment where this subject alternated between "alert" and "relaxed" states. The task was complicated by requiring the subject to keep his eyes open throughout the experiment and by coupling a light into the loop; the light was turned on when alpha rhythms occurred on the EEG and turned off when it ceased. Despite these somewhat stringent conditions it was clear that the subject was able to alternate reliably between the two states, and was also able to remain in any one state for a number of minutes.

In other experiments, the loop was set up so that a meter pointer moved to the right when alpha rhythms occurred and to the left when no alpha rhythms were present. The subject R. R., however, learned to regulate the needle so that it moved within a narrow range around the centre position—achieved by a rapid alternation of "alpha"–"no-alpha" states—with his eyes open for the whole time. In Fig. 2 we give a sample record taken at a time when the subject, with eyes open, was attempting to keep the needle at the midpoint.

The quite unexpected efficiency of this subject and others, in modifying their own alpha rhythm "at will", raises interesting questions about the nature of the variable they were controlling. For a number of reasons it now seems likely that the voluntary regulation of the EEG in a closed visual feedback loop was accomplished by voluntary regulations of oculomotor functions. For example, the performance of subject R. R. is reminiscent of that reported by Durrup and Fessard[4]. Their subject was able alternately to increase or decrease the amount of alpha in his EEG by "shifting his attention" alternately from visual to auditory stimuli. They reported that he also controlled the occurrence of EEG alpha by regulating visual accommodation, convergence and point of fixation. Likewise, our own subject R. R. reported that when attempting to move the meter pointer to one side, he would "look into the distance" with an indefinite fixation

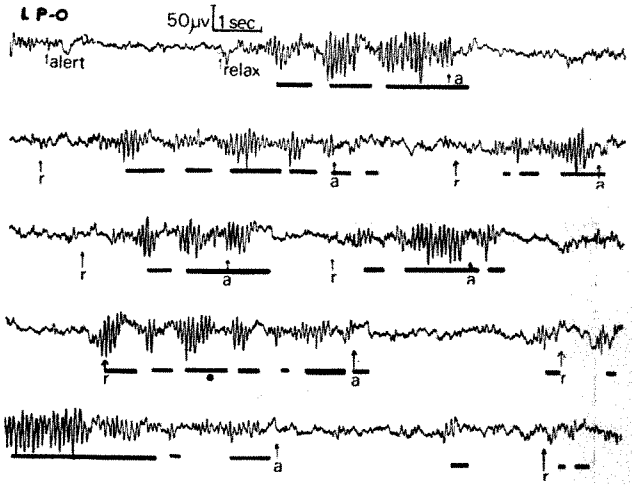

Fig. 1. Record of EEG taken when subject alternated on command between "alert" and "relaxed" states. Eyes were open throughout, and heavy bars indicate periods when the presence of alpha caused a bright light to be switched on.

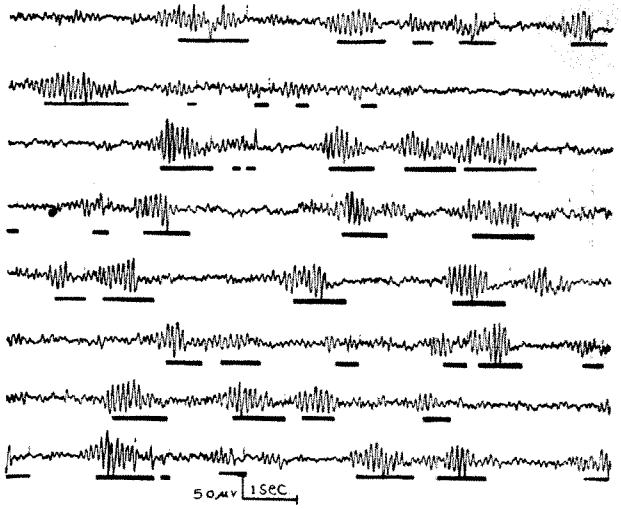

Fig. 2. Rapid alternation of "alpha–no alpha" as subject attempted to keep a meter needle at midpoint. Needle moved to right of dial when alpha occurred, and to left when alpha was not present. Heavy bars indicate periods of alpha as determined by feedback-loop analyser.

* Present address: V. A. Hospital, Bedford, Massachusetts.

point producing a blurred image of the pointer. Under these conditions, alpha rhythms were produced. To suppress alpha rhythms, he would bring the pointer into clear vision. It is evident that the concept of "attention" does not help much in understanding these results, for the subject is "attending" to his task (keeping the meter needle central) continuously.

Is the important variable the presence or absence of a clear, sharp image on the retina? In a recent paper describing tests on two subjects[5] we showed that alpha can be produced by the simple process of elevating the eyes, whether open or closed. Quite unusual bursts of alpha can be observed when these subjects roll their eyes back, and this may be sustained even when a clear pattern in the form of an after-image is present. In Fig. 3, EEG records from these two subjects are presented. Eyes were closed throughout both records. When the eyes were elevated and alpha occurred (subject T. M., top part of Fig. 3) the visual field was flooded with a homogeneous, very bright light. Despite this, alpha was abundant. In the lower part of the Fig. 3 the subject (R. R.) was observing a visual after-image with his eyes elevated (*U*) and with his eyes straight ahead (*A*). More alpha occurred during the "eyes up" condition, despite the fact that patterned stimulation was the same in each condition.

Repetition of these experiments on other subjects confirmed these earlier findings in all essentials. (There may, however, be occasional variations—for example, subjects may consistently show more alpha when eyes are elevated, and then may suddenly show a reversal of this effect.) In

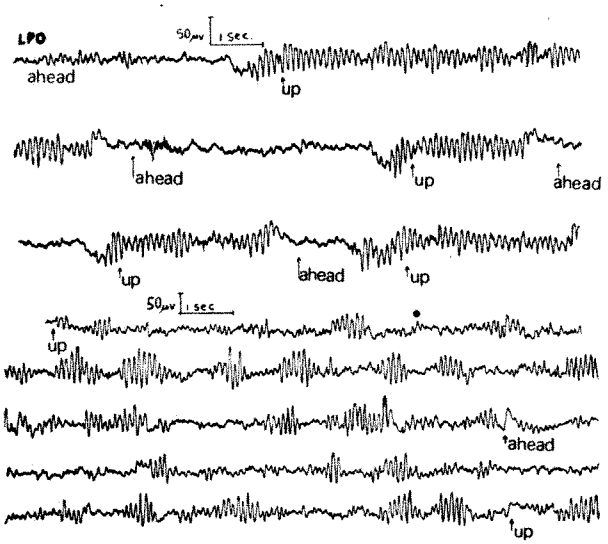

Fig. 3. Increase of occurrence of alpha with two subjects when eyes were rolled up. In top record presence of alpha switched on bright light. On lower record eyes were closed, but subject was viewing a bright patterned after-image with eyes closed.

one experiment, in which eight naïve subjects were tested, the amount of alpha rhythm was quantified by filtering the alpha component and integrating the filter output. With eyes closed, five subjects showed more alpha with eyes elevated. With eyes open, one subject only initially showed more alpha with eyes elevated, but in successive trials, the number who showed the effect with open eyes rose to five. It should be mentioned that in an early experiment, a power spectrum of the EEG was obtained from subject T. M. during two conditions; eyes closed and not elevated, and eyes open and elevated. Abundant alpha occurred during both conditions and it was found that the power spectrum obtained with eyes elevated did not differ from that obtained when eyes were not elevated.

These results show that oculomotor function may be dynamically integrated with those cortical or subcortical processes involved in the EEG alpha-activation cycle. Changing the optimum oculomotor configuration may change the response of the EEG to stimulation.

As we have stated here, the concept of "attention" in relation to the alpha-activation cycle is not particularly useful in the interpretation of these results. A search of most of the literature concerning human "attention" and the EEG does not reveal any experiment in which oculomotor functions have been excluded as a cause of the EEG phenomenon supposed to be associated with "attention". Attention, is, in fact, simply assumed to be the relevant variable. However, the results we have reported can be explained in terms of the hypothesis that the alpha-activation cycle reflects the movements, accommodation and position of the eyes. In sum, such a hypothesis would imply that the electroencephalographic and oculomotor components of the orienting reponse are not merely coincidental and independent[6], but are so dynamically linked that oculomotor processes can modify the EEG response to stimulation. From this point of view (which will need to be considered in all future experiments linking "psychological" variables with the EEG) if there is any affect of "attention", it is on oculomotor functions which in turn cause a modification of the alpha-activation cycle.

Since this article was prepared our attention has been drawn to the unusual EEG records taken from astronaut Frank Borman during the flight of the *Gemini* satellite *GT*-7. These show increases in alpha rhythm with weightlessness. This finding might be explained more simply on the basis of an oculomotor imbalance than by changes in "attention" or "arousal". We thank Dr. W. Ross Adey for allowing us to see a draft of his analysis of these results before publication.

SPERMATOPHORES AND SPERMATOPHORIC REACTION IN THE GIANT OCTOPUS OF THE NORTH PACIFIC, *Octopus dofleini martini*

By Dr. T. MANN*, Prof. A. W. MARTIN, Jun., and Dr. J. B. THIERSCH
Department of Zoology, University of Washington, Seattle

In octopus as in other cephalopod molluscs, the spermatozoa are enclosed in spermatophores before they are transferred from the male to the female. At the time of mating the males take up the sperm-packed spermatophores with their hectocotylized arm and place them in the female. In the small species, as for example *Octopus vulgaris*, the spermatophores seldom exceed in length a few centimetres, but in some of the larger species, such as *Octopus hongkongensis* or *Octopus dofleini*, they are reputed to measure a metre or more. The present study concerns the spermatophores of *Octopus dofleini*, a species which, according to Pickford[1], exists in the form of at least three subspecies, namely *O.d. dofleini* (Wülker, emend. Sasaki) in Japan, *O.d. apollyon* (Berry) in the far North Pacific, and *O.d. martini*, which inhabits the more temperate waters of the North Pacific, along the coast of Washington State. It is the latter subspecies which we have studied and on which we wish to report briefly. The males which

* Present address: Agricultural Research Council Unit of Reproductive Physiology and Biochemistry, University of Cambridge.

we examined ranged in weight from 10 to 47 kg, and were all caught in the Puget Sound—San Juan Archipelago area. Soon after an animal was taken in a trap, it was brought by seaplane to the laboratory at Seattle; there it was transferred to a large glass-panelled observation tank, filled with constantly aerated sea-water maintained at 8°–10° C. In these tanks the animals survived well for periods of many weeks or months.

To obtain a spermatophore, the animal was removed from the observation tank, and placed in a tub filled with cold sea-water where it was anaesthetized by slowly adding ethanol until a final concentration of 2 per cent was attained. When the animal became less mobile, and the muscles of the mantle more relaxed, it was possible to reach into the mantle cavity and to extract manually from the orifice of the penis a whole intact spermatophore. The animal was then either returned to the observation tank and allowed to recover, or killed if further spermatophores were required. Usually fewer than 10 spermatophores were found. In one male, however, suffering from occlusion of the terminal portion of the tract thirty-two spermatophores were present.

Male Reproductive Tract

In *Octopus dofleini* the male reproductive tract (Fig. 1) lies enclosed in a membranous capsule, the "genital bag", which occupies a large portion of the posterior region of the mantle cavity. The total weight of the reproductive tract is about 1 kg, of which one-fifth or so is taken up by the testis, a single, oval, porcelain-white gland, located in the posterior compartment of the genital bag. The remainder of the tract consists of the various accessory organs, which lie in the anterior compartment of the genital bag. In their general appearance these organs fit into the pattern described by Winkler and Ashley[2] in the animal presumed to be *Octopus apollyon* (Berry). Though much bigger and differing in shape from those of *Octopus vulgaris*, the accessory organs of *Octopus dofleini martini* tend to conform to the general distribution pattern characteristic of the common octopus[3–12].

When leaving the testis, the spermatozoa, not yet encased, pass first through the membranous, funnel-shaped ampulla into the long convoluted vas deferens proximale which in its gross appearance resembles the epididymis. Emerging from the vas the spermatozoa enter first one, and then another, system of tubular glands, each, when uncoiled, about one metre long; these two organs correspond roughly to the vesicula seminalis and prostata of the common octopus. In these two organs, perhaps best designated as the spermatophoric gland systems I and II, the spermatozoa are enfolded by the glandular mucilaginous secretions into tube-shaped membranes, and ultimately encased into the spermatophores. As it leaves these glands, each spermatophore traverses the vas deferens distale and enters the capacious spindle-shaped storage organ, known as the spermatophoric sac, or Needham's sac, so named after John Tuberville Needham[13], who in 1745 first described in detail the "milt-sac" of the "calamary" (squid). Later, the spermatophores (once called "Needhamia expulsatoria") enter singly the terminal spermatophoric duct, which penetrates the membranes of the genital bag and forms two tubes of unequal length: the longer and loop-shaped branch, named diverticulum, occupies a position closely adjacent to the genital bag, while the other shorter and straight branch, named terminal organ or "penis", hangs free outside the genital bag. During copulation a spermatophore is taken from the orifice of the "penis" and transferred to the female by the copulatory organ proper, that is the hectocotylized arm, which is the modified third right arm of the male.

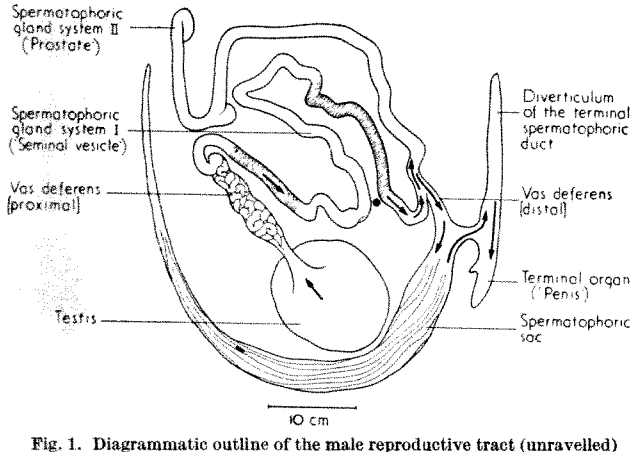

Fig. 1. Diagrammatic outline of the male reproductive tract (unravelled) of *Octopus dofleini martini*; arrows indicate the direction in which the spermatophores traverse the tract.

The Spermatophore

A complete spermatophore, freshly pulled out of the orifice of the "penis", is shown in Fig. 2. It is composed of two parts, the body and the cap thread (best seen in Fig. 3). The body, usually about a metre long, has the appearance of a slender but turgid cylinder, the turgidity being due to the tough, transparent covering tunic which is under considerable tension, so that when it is punctured the sperm contents of the spermatophore are explosively discharged. The body is much wider at one end, and consists essentially of two parts, approximately equal in length. The thicker portion, which at its round end reaches a diameter of 0·5–1 cm, emerges first from the orifice, and it might best therefore be referred to as the "proximal" portion. In terminology applied to the spermatophores of *Octopus vulgaris* and *Loligo pealii*, it would be designated as the "aboral" or "posterior" portion of the spermatophore[6,14–16]. In this part of the spermatophore is located the "sperm rope", that is the cylindrical, spirally-wound long thread consisting of a large white mass of tightly packed spermatozoa. When unwound, a thread of this kind measures about 4 m, and resembles somewhat the mammalian epididymal tubule in its general appearance. On the two occasions when spermatozoa were counted in the contents removed from such sperm ropes, we have found $1{\cdot}7 \times 10^{10}$ and $3{\cdot}7 \times 10^{10}$ spermatozoa, figures roughly equivalent to the entire sperm content of ten rams, or one hundred human semen ejaculates. On release from the sperm-rope and dilution with sea-water, the spermatozoa are immotile or only feebly motile, but their motility can be enhanced by the addition of a buffered solution of cystein or certain other amino-acids.

On the outside, the intact sperm rope is covered by 5–10 ml. of a colourless, transparent and highly viscous fluid which we propose to call the spermatophoric plasma (in analogy to the seminal plasma). The thinner half of the spermatophore, that is the "distal" portion (corresponding to "oral" or "anterior"), encloses the ejaculatory apparatus: a slender, membrane-coated rod-shaped hyaline plug, filled with yellow-coloured, markedly elastic material of rubbery consistency. The distal part of the ejaculatory apparatus is often slightly curved or even coiled, and at its tip, which is only 1–2 mm wide, the outer tunic thickens to form a firm round covering, the cap, and a fine filamentous appendage, known as the cap thread. The latter extends in two directions: proximally it runs firmly attached to the outer covering of the spermatophore, but distally it continues in a free form, as a filament about 0·5 m long (Fig. 3). The region which links the distal end of the sperm rope to the proximal end of the ejaculatory apparatus is filled with a small amount of a sperm-free, yellowish syrupy material, which in colour and consistency is quite unlike the spermatophoric plasma and therefore deserves a specific name, such perhaps as "cement liquid", without the implication,

however, that it possesses any cementing properties, nor indeed that it is analogous to the "cement body", "flacon" or "faux boyaux" in the spermatophores of other cephalopods, mentioned by Duvernoy[17], Racovitza[18,19] and Drew[9,15].

Several chemical analyses were performed on the mechanically separated components of the fresh spermatophores, namely sperm rope, spermatophoric plasma, cement liquid, outer tunic, and hyaline core of the ejaculatory apparatus.

For most determinations the sperm rope and spermatophoric plasma were collected together, by placing a ligature around the spermatophore in the region between the sperm rope and cement liquid, and emptying the entire contents of the proximal portion of the spermatophore through a cut in the outer tunic. In a few instances, the spermatophoric plasma was also obtained without the sperm, that is directly from the spermatophore, by aspiration with a syringe. The sperm and plasma were separated by centrifugation and washing. An interesting result of the chemical analyses was the identification of glycogen as a major constituent of octopus sperm. The content of glycogen in the different samples varied from 5 to 16 per cent of the dry weight. Its identity was confirmed by isolation, based on Pflüger's method of alkaline hydrolysis and ethanol precipitation, followed by acid hydrolysis and determination of glucose by means of glucose oxidase, ferricyanide reduction, and the reactions with orcinol and anthrone. The high glycogen content of the octopus sperm contrasts strikingly with the low values encountered in the sperm of mammals and echinoderms[20–22] but it recalls the elevated values reported in the sperm of oysters and certain ascidians[23,24].

In addition to glycogen some mucopolysaccharide was found in the sperm rope. Of that material, however, there was more in the spermatophoric plasma than in the spermatozoa. Most of it could be precipitated by ethanol and was composed of glucose, galactose, mannose, methylpentose and aminosugar. In addition, however, the spermatophoric plasma also contained some carbohydrate which was soluble in ethanol, including an unusually high concentration of aminosugar, up to 1 g/100 ml., and a variable quantity of free glucose (5–120 mg/100 ml.).

The cement liquid and ejaculatory apparatus, as well as the spermatophoric plasma, all showed exceptionally high dry weights (15–30 per cent), due in a large measure to the mucopolysaccharides. The outer tunic, on the other hand, was of a different composition. By stripping the tunic off the spermatophore, and then cutting it up and washing extensively with water, pieces of clean, transparent and remarkably elastic membranous material were obtained, which consisted mostly of protein, with about 10 per cent orcinol-reactive carbohydrate, and 10 per cent aminosugar. The relatively low aminosugar content shows that contrary to the views expressed by Williams[14] and other earlier investigators of molluscan spermatophores, the outer wall of the spermatophore cannot be regarded as being made up of "chitin-like material".

The Spermatophoric Reaction

In order to study the mechanics of ejaculation, that is the so-called spermatophoric reaction, *in vitro* as well as *in vivo* observations were made.

To examine the ejaculatory process *in vitro*, the spermatophores were placed in special troughs constructed of 'Perspex', 2 m long and 5 cm wide, which allowed a slow but steady flow of cold sea-water from one end to another. When a spermatophore had been placed in a trough, with the cap-thread facing in the direction of the flow, it usually took 15–30 min for the spermatophoric reaction to begin, and 1–3 h to reach completion. By tugging gently at the cap-thread it was possible to accelerate the initial, but not the later, stages of the reaction.

The first indication that the reaction is about to start comes from a change evident at the proximal end of the spermatophore. That portion, already very turgid to touch, swells owing to a rise in the volume of the spermatophoric plasma, and at the same time the sperm rope starts to uncoil and slowly moves forward, pushing before it the ejaculatory apparatus. Then, suddenly, a break occurs at the distal end of the body, that is at the point where the cap is joined on to the outer tunic, and, as the cap ruptures because of the pressure from the inside of the spermatophore, the ejaculatory apparatus immediately begins to evaginate, leaving the remnants of the cap and the cap-thread behind. As the evagination continues, the body of the spermatophore quickly increases in length by altogether about 50 per cent, so that ultimately it measures approximately 1·5 m. The next visible change associated with the spermatophoric reaction occurs in the ejaculatory apparatus. As the pressure from the spermatophoric plasma increases, and the sperm rope steadily advances, the space around

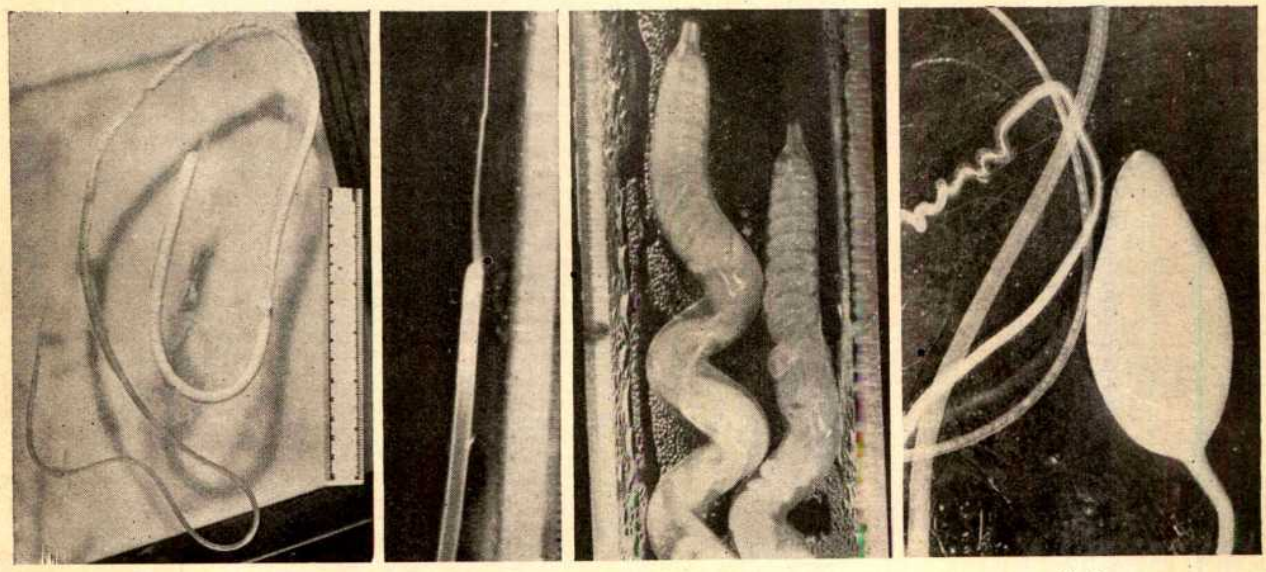

Fig. 2. Fig. 3. Fig. 4. Fig. 5.

Figs. 2–5. Spermatophores of *Octopus dofleini martini*. Fig. 2, Whole intact spermatophore. Fig. 3, Distal end of the body of the spermatophore showing the cap and cap thread. Fig. 6. Changes in the volume and content of dry weight, protein, sodium, potassium and chloride in the spermatophoric plasma of octopus during the spermatophoric reaction.

the core of the ejaculatory apparatus swells and becomes filled with fluid, while the apparatus itself undergoes a characteristic coiling (Fig. 4), followed by shortening and thickening, thereby making it possible for the sperm rope to advance still further in the direction of the distal end of the spermatophore. At this stage a definite pause occurs in the spermatophoric reaction until, again quite suddenly, the sperm rope pushes further forward and the whole of the distal portion of the spermatophore's body is blown out into a large egg-shaped bulb resembling a bladder. When completely filled with sperm, that "sperm bladder" measures roughly 8 × 4 cm. Behind it drags the remainder of the spermatophore, a long tube, still filled, though much less turgidly, with spermatophoric plasma, but more or less completely devoid of spermatozoa (Fig. 5).

Ostensibly the main purpose of the spermatophoric reaction, as observed in the giant North Pacific octopus, is to haul the whole mass of tightly encapsulated spermatozoa over a distance of about 1·5 m, from the proximal to the distal end of the spermatophore, and to provide in the form of the "bladder" a large sperm reservoir. This resembles the "reservoir spermatique de second ordre", described by Racovitza[19] in *Rossia macrosoma*, and the "sekundäre Spermabehälter" described by Marchand[8] in *Eledone moschata* and *Octopus macropus*. The two most important factors which provide the main driving force for the spermatophoric reaction as a whole, and the processes of evagination and bladder formation in particular, are evidently the elasticity of the outer tunic, and the pressure which arises from the influx of sea-water transmitted by the spermatophoric plasma to the sperm rope and the ejaculatory apparatus. This is borne out by experiments in which chemical analyses were performed on the spermatophoric plasma at different stages of the spermatophoric reaction. One such experiment is illustrated in Fig. 6. It records changes which have occurred in the volume, dry weight, and the concentration of sodium, potassium, chloride and protein of spermatophoric plasma in the course of the spermatophoric reaction, as observed in spermatophores which had been removed from the Needham's sac of an octopus, and placed in sea-water troughs. Four distinct stages were recorded: (i) at the moment of placing the spermatophore in sea-water; (ii) at 30 min, when the swelling of body and movement of sperm rope became apparent; (iii) at 60 min, coincident with the formation of the sperm bladder; (iv) at 120 min, when the sperm bladder had fully expanded. As can be seen from Fig. 6, the spermatophoric reaction was accompanied by a rapid increase in volume and sodium chloride concentration of spermatophoric plasma, owing to the influx of sea-water. Concomitantly with the uptake of sea-water the spermatophoric plasma became diluted, and consequently its dry weight, protein and potassium concentration rapidly declined. The final concentrations (at 120 min) of sodium and chlorine, respectively, were, in m.equiv./l., 386 and 433 in the spermatophoric plasma recovered from the sperm bladder; 440 and 451 in the sea-water taken from the observation trough; and 384 and 408 in a blood sample obtained from the same animal.

There is good reason to believe that events analogous to those which we have seen in octopus spermatophores undergoing a reaction *in vitro* also take place under conditions *in vivo*, during the copulation process. On three separate occasions we were able to follow the copulation of a male and female octopus placed together in an observation tank. On two of these occasions copulation was allowed to proceed to completion undisturbed: 2 and 3 h, respectively, elapsed from the moment when the male inserted the tip of its hectocotylized arm into the mantle cavity of the female, to the time when it withdrew, leaving the female not with one, but with two empty bodies of spermatophores, hanging freely from her mantle over a distance of about 0·5 m. On the next day one of these females was observed to lay eggs. On dissection, her oviduct was found to be filled with large masses of motile spermatozoa, particularly in the lumen of the oviducal gland, but there was no sign of the sperm bladder. Presumably by then it had ruptured, emptying its contents in this manner. On the third occasion, coitus was interrupted 30 min after insertion of the hectocotylus, by pulling the male away from the female. The spermatophore recovered from the hectocotylized arm of that male had the ejaculatory apparatus pointing towards the female, while the proximal portion was already exhibiting the swelling changes which are so characteristic of the early phase in the spermatophoric reaction.

The finer mechanism of the spermatophoric reaction remains to be investigated. The evidence so far obtained from both morphological and chemical observations, however, strongly favours the supposition that the main force which drives spermatozoa from one end of the long spermatophore to the other results from the tension which develops inside the spermatophore during the process of ejaculation as a result of the dilution of spermatophoric plasma with sea-water.

This investigation was supported by a grant from the U.S. National Science Foundation. We thank Mr. D. A. Rottenberg for assistance with chromatographic analysis of the mucopolysaccharide.

ASTRONOMY

Cosmological Significance of the Relation between Red-shift and Flux Density for Quasars

THE purpose of this report is to point out that recent measurements[1] of the red-shifts of quasars provide the most decisive evidence so far obtained against the steady state model of the universe. The previous evidence[2,3] consisted mainly of the anomalously[4] steep slope of the log N–log S relation for quasars (N is the number of sources with flux density greater than S). This evidence is ambiguous, however, because one could argue[5] that many of the quasars may have zero red-shifts and be situated inside our Galaxy. Their log N–log S relation would then have a purely local significance. If we can restrict the analysis to quasars of known red-shift we avoid this ambiguity, provided that we interpret the red-shift as being cosmological in origin, which in this communication we shall do.

Red-shifts are now known[1] for thirty-five quasars in the revised 3*C Catalogue*[6], which is complete down to 9 flux units at 178 Mc/s (1 flux unit is 10^{-26} W m^{-2}(c/s)$^{-1}$). To analyse the data we study not log N–log S, but the more detailed relation between red-shift z and flux density S for these sources (Fig. 1). A similar diagram was constructed by Hoyle and Burbidge[7], who claimed that the absence of a clear correlation between small S and large z shows that red-shift has nothing to do with distance. We shall see that this claim is not necessarily correct.

To test the steady state theory we draw in the diagram lines of constant intrinsic radio luminosity P evaluated at 178 Mc/s. If the sources are uniformly distributed then the steady state theory requires[8] that the number N of sources in a fixed range of P the red-shift of which is less than z should satisfy the relation

$$N \propto \ln(1+z) - \frac{z}{1+z} - \frac{z^2}{2(1+z)^2} \qquad (1)$$

P is given by

$$P = c^2\tau^2 z^2 (1+z)^{1+\alpha} S \qquad (2)$$

where τ is Hubble's constant and α is the spectral index of the source ($S \propto \nu^{-\alpha}$). The choice of α is not critical, and so we take the same value of 0·7 (K. I. Kellermann, unpublished results) for all the sources. To illustrate the analysis we draw two lines of constant P, the choice of which is also not critical.

To test the N–z relation (1) we divide the diagram into three regions of z in which we would expect to find equal numbers N of sources in any fixed range of P. Regions 1, 2, and 3 are defined by $z < 1{\cdot}02$, $1{\cdot}02 < z < 1{\cdot}55$, and $1{\cdot}55 < z < 2{\cdot}03$, respectively. We now find that there are five sources with $P > P_1$ in region 3, and because of the cut-off at 9 flux units the actual number may be greater. There is only one such source in region 2, however, and none at all in region 1. We cannot argue that we are dealing with an incomplete sample, and that the observers have a bias in favour of seeking the large red-shifts of region 3, because granted that the five sources exist at all, the corresponding sources in region 1 would have a flux density $S \gtrsim 50$ flux units, and could not have been missed. We find similarly that there are five sources with $P > P_2$ in region 3 (which is now very severely affected by the cut-off), five sources in region 2 (which is somewhat affected by the cut-off), and only two sources in region 1.

These discrepancies appear to be statistically significant and in so far as we may use relation (2) to calculate P they show that there is an intrinsic evolution of either P or N or both, with z, contrary to the predictions of the steady state theory. It is not possible to conclude from Fig. 1 that z has nothing to do with distance, because any reasonable distribution of the points could be accounted for by an appropriate rate of evolution.

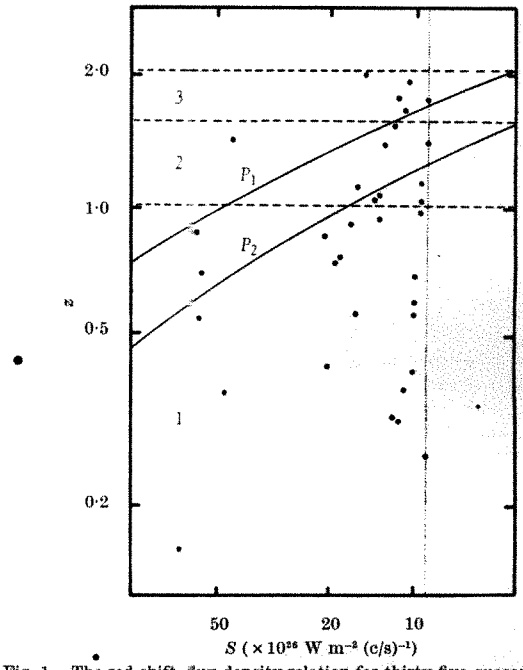

Fig. 1. The red-shift–flux density relation for thirty-five quasars in the revised 3*C Catalogue* (which cuts off at 9 flux units). The two curves are lines of constant source power according to steady state cosmology. This cosmology predicts equal numbers of sources of given power in the regions 1, 2, and 3 defined by $0 < z < 1{\cdot}02$, $1{\cdot}02 < z < 1{\cdot}55$, and $1{\cdot}55 < z < 2{\cdot}03$.

We conclude that if the red-shifts of quasars are cosmological in origin, then the present red-shift–flux density relation for quasars rules out the steady state model of the universe.

We acknowledge a helpful discussion with Mr. M. Rowan-Robinson.

A Possible Galactic Origin for Quasi-stellar Sources

THE interpretation of the observed red-shifts of "quasars" as cosmological gives rise to severe difficulties concerning both the energy output and the variation of light because these objects have then to be placed at enormous distances.

We wish to suggest the possibility that the observed red-shifts result from an inflow of matter at relativistic velocities in the gravitational field of a highly condensed white dwarf with a very large escape velocity. To establish a starting point, consider a collapsed body with mass 10^{33} g and a radius of several kilometres; these stars must exist[1] and will strongly attract interstellar matter.

The high escape velocity—a large fraction of the velocity of light—implies that nothing will escape apart from photons and neutrinos, thus there can be no net flux of matter and thus no stellar wind. If the star is a member of a binary system there will be an outward flux of matter owing to the stellar wind of the companion, but if the condensed star is isolated it must accrete interstellar matter.

The accretion process should be quite efficient. If the interstellar medium has an ambient magnetic field accreted material will bring its own field lines with it which become trapped in the star. Also the star will possess in its wake a concentrated magnetic field directed so as to guide material into the star. If the interstellar gas has a uniform motion over distances of the order of GM/v^2, where v is the relative velocity of gas and star, then under the influence of gravitation all matter will concentrate in the wake which becomes a region of high density, temperature and magnetic field. The star accretes material at the rate (capture cross-section times velocity) $G^2M^2/v^3\ \rho$, where ρ is the ambient density of the interstellar material. Taking $M = 10^{33}$ g, $v = 5 \times 10^5$ cm/sec, and $\rho = 10^{-24}$ gm/c.c., the accretion rate is 10^{11} g/sec. With an escape velocity of $\frac{1}{2}C$ the accreted material supplies energy to the object at a rate 10^{31} ergs/sec. If this energy is radiated as black-body radiation the effective temperature of the star would be a few hundred thousand degrees. Thus this star would have a luminosity one hundredth of that of the Sun. Moreover, at a distance of 100 parsecs it would have a magnitude of about 15^m, which is within the observed range of quasar apparent magnitudes; the parallax of such a star $0{\cdot}01''$ would be very difficult to observe directly.

Material moving into the wake experiences a much greater magnetic field and incoming electrons will gain energy by the betatron effect and would be expected to produce large amounts of synchrotron radiation. (Such radiation would be expected to have a maximum intensity where the material first approaches the wake because here the energy associated with transverse velocity components would be dissipated. Thus we might expect a strong source of radio emission at a distance GM/v^2. With the values already given this would be at 10^2 astronomical units from the star.) Furthermore, the optical spectrum would be produced very near the stellar surface where densities and pressures are high so that the radiation would be strongly red-shifted by almost the amount of the escape velocity; the considerable gravitational red-shift of the star itself would be added to this.

In summary, a single highly condensed star interacting with the interstellar medium should give rise to the following effects: (1) A double radio source, the two members of which would be separated by about GM/v^2. (2) Associated with one radio source is a point source with a continuum characteristic of a very hot body with superposed very broad strongly red-shifted emission lines. The red-shifts observed depend on the orientation of the star with respect to the Sun. (3) Optical radiation of the synchrotron type is associated with the other radio source. (4) Both sources should be time-variable because the density, velocity and magnetic field of the interstellar field is dependent on time. (5) The optical point source should produce soft X-rays.

The sensitive parameter is v, the relative velocity of star and interstellar medium, because the accretion rate is proportional to v^{-3} and the source separation to v^{-2}.

PLANETARY SCIENCE

Comparisons of Frequency by Long Path Very Low Frequency Transmissions

MOST of the reliable measurements of the frequency stability of very low frequency (VLF) propagation paths have been made over the North Atlantic path, and over paths of the same order of length. Pierce *et al.*[1] used atomichrons on each side of the Atlantic and found a standard deviation of 2 in 10^{11} for frequency comparisons consisting of 24 h averages for the *GBR* (Rugby, 16·0 kc/s) transmission over a path length of 5,200 km. It has been suggested by Watt and Plush[2] that the standard deviation of phase—and thus of frequency over a constant interval of time—would be proportional to the square root of path length. However, Chilton *et al.*[3] give figures suggesting that it may be proportional to the square of the path length squared.

Although the results presented here are not sufficient to resolve this question, it has been found that over very long paths there is little increase in the standard deviation above Pierce's value. Over the *GBR*–New Zealand path of 18,700 km the 24 h standard deviation of frequency is 5 in 10^{11}, and for the *WWVL* (Colorado, 20·0 kc/s)–New Zealand path of 12,200 km the corresponding figure is 3 in 10^{11}. These figures were obtained by intercomparisons between the received signals from both stations and a rubidium gas cell frequency standard. It has not been possible to determine to what extent they were affected by receiver phase shifts and they therefore represent an upper limit to the uncertainty due to purely propagation effects. The observations were made in December 1965; at this time of the year the anomalous phase effect observed at times over the *GBR*–New Zealand path does not occur[4]. National Physical Laboratory corrections were, of course, applied to the *GBR* figures, but the National Bureau of Standards corrections to *WWVL* are negligible for the present purpose.

It should be noted that the *GBR* path crosses the auroral zone and is, therefore, likely to be somewhat more disturbed than the *WWVL* path, even in the geomagnetically quiet conditions which prevailed during December 1965. The figures, therefore, give tentative support to the suggestion of Watt and Plush that a square root proportionality is in operation. Their main importance, however, lies in showing that, at least during geomagnetically quiet periods, VLF frequency comparisons over a 24 h period should, under normal conditions, be well within ± 1 in 10^{10} over the longest path lengths.

A Submarine Outcrop of Lower Carboniferous Rocks off South-East Scotland

EXAMINATION by divers of a submarine section off the coast of south-east Scotland in which are seen beds of the Scremerston Coal Group has filled in the only major gap in the exposed Lower Carboniferous succession in this area.

The Southern Uplands of Scotland separate the Carboniferous basins of northern England from those of the Midland Valley and it is well established that in the centre and west the Uplands formed a relatively positive area during Carboniferous times[1]. Towards the north-eastern end of the Uplands considerable thicknesses of Upper Old Red Sandstone and Lower Carboniferous sediments encroach increasingly on the older rocks, which they largely overlap in the east; it is a reasonable inference that a short distance offshore a continuous Carboniferous outcrop joins those of northern England and the Midland Valley. The sediments deposited over the buried continuation of the Southern Uplands occur in faulted and folded basins, the largest lying in the Tweed Valley area and a smaller one on the coast south of Dunbar (Fig. 1).

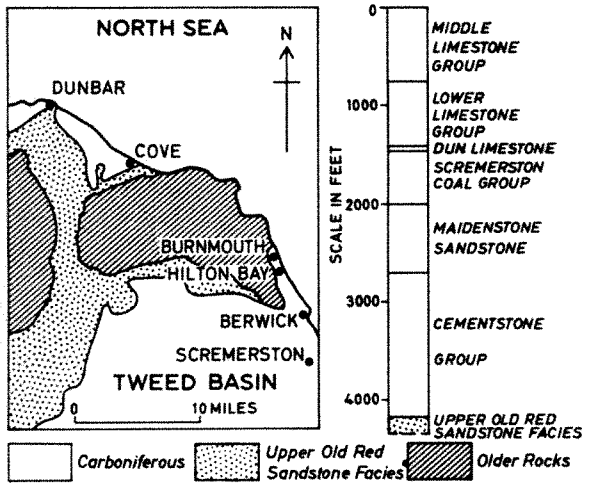

Fig. 1. Geological sketch-map of Burnmouth area, and Lower Carboniferous section between Burnmouth and Berwick.

There are excellent exposures of Carboniferous rocks on the coast of south-east Scotland, but it has not been possible to determine the total thickness of strata involved with any certainty, partly because of the presence of faults of unknown magnitude. Strike faults in Hilton Bay, a mile south of Burnmouth, and at Cove[2] farther north each cut out considerable parts of the succession.

On the foreshore at Burnmouth the base of the preserved Upper Palaeozoic section, which is faulted against older rocks, is formed by a 150 ft. bed of red sandstone with cornstones which has hitherto been classified with the Carboniferous[3]. This sandstone is indistinguishable from rocks of Upper Old Red Sandstone facies exposed near Dunbar and in the Tweed Basin so there seems no valid reason for regarding the bed as other than the topmost representative of rocks of this facies. Because the facies is, however, known to be diachronous it cannot be used for purposes of correlation over a wide area. The red sandstone is overlain by 1,500 ft. of strata of the Cementstone Group of northern England terminology, which are in turn followed by a sandstone, here called the Maidenstone Sandstone, lying approximately at the horizon of the Fell Sandstone of the area south of Berwick. At Burnmouth the Maidenstone Sandstone is seen to be at least 600 ft. thick but its top is not exposed on the foreshore. It strikes south along the coast to Hilton Bay, where the Dun Limestone, at the base of the Lower Limestone Group of northern England, is faulted against beds near the top of the sandstone. The fault in Hilton Bay thus cuts out the Scremerston Coal Group, but in the cliffs and foreshore between here and the Tweed a nearly continuous section is to be seen from about 250 ft. below the Dun Limestone to the top of the Lower Carboniferous.

Near low water mark at Burnmouth the Maidenstone Sandstone dips seaward at 75 degrees. Offshore the succession has now been shown to continue upwards through a further 75 ft. of this sandstone into 590 ft. of Scremerston Coal Group strata overlain by the Dun Limestone, and then into the Lower Limestone Group of northern England. The key horizon in the offshore section is the Dun Limestone, which consists of 4 ft. of exceedingly hard, dark grey, crinoidal limestone with productoid fragments. It is identified by comparison of the lithological sequence of which it forms part with that on the shore three-quarters of a mile to the south, beyond the fault in Hilton Bay. In each place the limestone is succeeded by a thick bed of dark mudstone passing up into banded siltstone which in turn is overlain by coarse-grained, current-bedded, red sandstone, seen to be at least 150 ft. thick in both the coastal and the submarine sections.

The only persistent marine limestones recorded at comparable stratigraphical horizons in the northern part of the Tweed Basin are in upward order—the Duddo, the Dun and the Woodend limestones. All three are believed to be represented on the coast between Hilton Bay and the River Tweed, but the probable equivalents of both the Duddo and the Woodend deteriorate northwards and neither is associated with overlying lithological sequences comparable with that above the Dun.

The measured thickness of 590 ft. for the Scremerston Coal Group compares with about 1,000 ft. for beds of the same facies 9 miles to the south at Scremerston[4], suggesting a marked change towards the northern margin of the Tweed Basin where the group encroaches on to the concealed continuation of the Southern Uplands.

It is to be noted that these measures are reported to thin out in a comparable fashion at the south[5] and west[6] margins of the Tweed Basin and that the base of the Scremerston Coal Group as at present mapped may be diachronous because it is not defined palaeontologically. The total thickness of accessible and measured Lower Carboniferous rocks between Burnmouth and the Tweed is now known to be 4,020 ft., compared with a calculated 10,000 ft. near Edinburgh[7] and at least 7,000 ft. without reaching the base just north of Brampton in the Northumbrian Trough.

The underwater section at Burnmouth was measured by examining a primary line along 900 ft. of permanent marked and buoyed rope laid downdip at right angles to the coast. Rock exposure on the line chosen is about 75 per cent complete and the consistently steep dip means that the sea-floor outcrop approximates to a vertical section of the strata. The rope was in independent 100 ft. sections in order to minimize the effects of snagging by fishing boats. With the resources available, work was most effectively undertaken by a team of three free-swimming 'Aqualung' divers, comprising a geologist who recorded the profile and indicated points for sampling, a collector and an attendant who carried samples and equipment. Depth of water varied from about 35 ft. to 80 ft. Underwater visibility was about 25 ft., but after periods of onshore gales or heavy swell it was so reduced as to be inadequate for the work; this happened frequently during winter months. Tidal currents did not normally provide a serious problem because near the irregular rocky sea-floor these are greatly reduced.

The Dun Limestone proved difficult to sample underwater because of its hardness and because it is deeply bored by modern molluscs, but specimens of most other rocks were easily collected with hammer and chisel. Below the *Laminaria* Zone, which here extends to about 25 ft. below low water, the rocks are not greatly obscured

by marine growth and even comparatively soft rocks, such as seatearths and coals, in places form ridges on the sea-floor. All samples of argillaceous rocks collected are bored by molluscs but otherwise little decomposed, and the fossils which they contain have not been affected by weathering.

This investigation arose from our duties with the Geological Survey. The offshore work was carried out by the Edinburgh Branch of the British Sub-Aqua Club, which is continuing detailed examination of the sequence.

Depositional Environment of the Cleveland Ironstone Series

DR. HALLAM has recently restated some of the problems involved in an understanding of the oolitic ironstones of the British Lias, and has emphasized the importance of a close examination of their facies relationships[1].

In spite of Strakhov's observations[2] that ancient ironstone and deltaic deposits are antipathetic, the weight of recent evidence seems to imply that many oolitic ironstones are spacially related to deltas. Pattinson has described the occurrence of three sideritic chamosite oolites in a cyclothemic succession of silty shales, siltstones and fluviatile sandstones, in the Upper Limestone Group (Namurian E_1) of Weardale, County Durham[3]. This occurrence is reminiscent of the kaolinized oolites found in the roofs of three coal seams in the Coal Measures near Bradford and Leeds[4]. A similar association is known from the Liassic succession in Scania (Sweden), where sandstones, shales, coals and oolitic iron ores are cyclicly related[5]. Another important discovery has been that of fluviatile and deltaic lacustrine oolitic ores in Kazakhstan (Russia)[6,7]. The shoestring nature of the latter together with the occurrence of freshwater molluscs is incontrovertible evidence of their origin. Here the ooliths are largely limonitic, but chlorite appears as a constituent of the matrix and is also occasionally present in the ooliths. According to Giresse, goethite ooliths are forming at the present day in shallow water on the continental platform west of Cap Lopez (Gaboon, West Africa) at the mouth of the Ogooué delta[8].

These examples serve to illustrate a connexion between the already well known continental iron oxide accumulations of the high latitudes and the more problematic iron ores. All share evidence of association with a fluvio-deltaic environment, of a warm to tropical climate, and of heavy vegetation cover on land.

The Cleveland Ironstone Series of north-east Yorkshire was probably laid down in warm waters (oxygen-16/oxygen-18 ratios determined from belemnites from the Grey Shales, Upper Lias, Yorkshire, indicate a temperature of about 20° C)[9] and a heavy vegetation is suggested by the abundance of plant debris which is present throughout. The possibility of a nearby river delta was postulated by Dunham[10] and seems quite plausible. No direct evidence of an impinging delta, however, exists in the present outcrops. Hallam's supposition that the reworked shales and siltstones of the Middle Lias are distal pro-delta deposits can only be tentative at present.

The question of the derivation of these sediments is a difficult one. A Pennine landmass may be speculative but the extension of a delta complex from Scandinavia is even more so. The evidence at present available from the Middle Jurassic Deltaic Series suggests "a river or system of rivers entering the area approximately from the N.N.W.", which is compatible with a North Pennine landmass during this period[11].

A close examination of all the available sections of the Cleveland Ironstone Series reveals the following details. First, that a lateral passage from shales into silty shales and siltstones must not be over-emphasized. It rests in part[10,12] on the observations of Fox-Strangways *et al.*[13] of the incoming of siltstones along the western escarpments of the Cleveland Hills, which resulted from the correlation of the Ironstone Series with the underlying Sandy Series. Moreover, the presence of silty shales at the horizon of the Main Seam at Hawsker Bottoms[1] cannot be used to support the idea of a higher terriginous sedimentation rate to the south-east. In the North Sea basin it is well known that much of the sediment is derived from the basin itself. In the Wadden Sea, for example, it has been shown that mixed sand, silt and clay fractions are not derived from the land but from the North Sea[14].

The Main Seam and *Pecten* Seam were economically the most important ore horizons in the Ironstone Series. They appear to have been laid down on a south-easterly sloping sea bed eroded at the beginning of *spinatum* times. Fig. 1 shows the details of a section drawn in a north-west–south-east direction approximately along the line of the present coast. The *spinatum* beds thicken south-eastwards owing to a slight angular disconformity between F_1 and F_2, and also to the wedging of the *hawskerense* beds (E), which appear to be absent in the north-west part of the section as a result of a non-sequence. The chamosite oolite shoals of the Main Seam (A and $B_{1,2}$) apparently

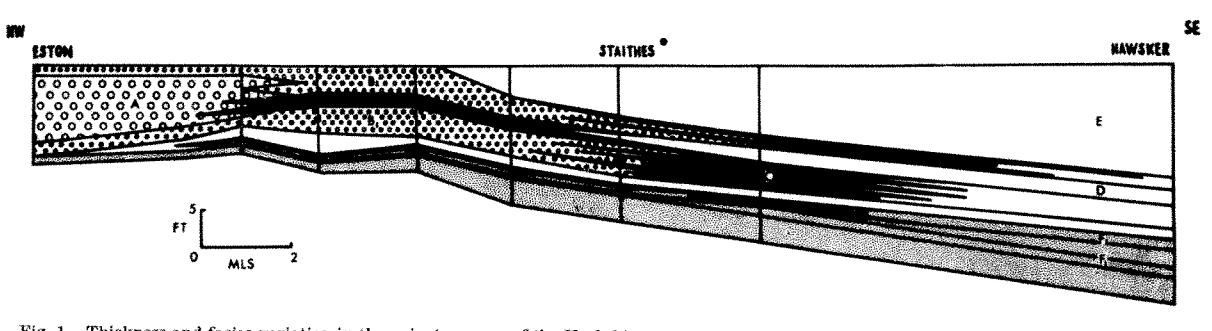

Fig. 1. Thickness and facies variation in the *spinatum* zone of the Yorkshire coast. *A–D*, Main Seam. *A*, Intraclastic chamosite oolite facies; *B*, chamosite oolite facies 2; Top Block; 1, Bottom Block and "Black Hard"; *C*, siderite mudstone and related facies; *D*, shale and siderite mudstone nodule facies. *E*, *Hawskerense* Beds (pars.), shales and siltstones with siderite mudstone nodules. $F_{1,2}$, *Pecten* Seam, siderite mudstones, and shales with siderite mudstone nodules. The top of the section is drawn at the "Sulphur Band" and its offshoal equivalent.

encroached on the basin from the north-west, thus derived fragments from the intraclastic oolite *A* are found in $B_{1,2}$, but there is no evidence of erosion in $B_{1,2}$ to provide the intraclasts for *A*. Offshoal the chamosite oolites pass into siderite mudstones (*C*) and eventually into shales (*D*). The oolitic facies of the *Pecten* Seam ($F_{1,2}$) are not preserved but a lateral passage from siderite mudstone into shale can be observed.

A diagnostic feature of the siderite mudstone facies (*C*) is the occurrence of cored siderite grains. It is tentatively suggested that the siderite mudstone facies may be diagenetically derived by the replacement of a limonitic silt and clay facies, the cloudy siderite cores representing replaced limonitic clay aggregates. Much of the iron may have been carried into the basin of deposition as a ferric coating on the surface of clay micelles as postulated by Carroll[15]. The dominantly kaolinitic nature of the shales of the Ironstone Series, as determined by X-ray diffraction, would support such a hypothesis.

Although evidence of a nearby shoreline is disputable with the Cleveland Ironstone Series, there are many instances in the literature of the association of oolitic ironstones with littoral facies. The repeated appearance of oolitic ironstones around the London–Ardennes landmass and the Morvan in the Jurassic is but one example[16].

On the basis of the evidence at present available it seems most plausible that iron reached the basin of deposition in north-east Yorkshire from a low lying, well vegetated landmass lying to the north-west. It may well have been carried by a river draining a north Pennine landmass.

THE SOLID STATE

Thermal Decomposition of Irradiated Orthorhombic Ammonium Perchlorate

Isothermal decomposition kinetics of certain solids are markedly affected by previous exposure to ionizing radiation. The observed effects are usually interpreted as a change in the nuclei formation rate and, in the following stage, enhanced propagation of the reaction through the solid. For example, the effect of pre-irradiation by 1·2 and 1·3 MeV cobalt-60 gamma-rays on the subsequent thermal decomposition of the alkaline earth azides[1], or the permanganates of sodium, potassium, rubidium, caesium and silver[2], is to shorten the induction period and to accelerate the reaction. The solids studied so far all contain a metallic cation, thus it would be interesting to investigate the effect of pre-irradiation on compounds such as ammonium perchlorate which contain a non-metallic cation.

Investigations of Bircumshaw and Newman[3] on the isothermal decomposition of whole crystals of orthorhombic ammonium perchlorate show the following effects. The decomposition comprises an induction period, followed by an acceleratory period where the pressure versus time curves were fitted equally well by the Prout–Tompkins relationship

$$\log_{10}[p/(p_f-p)] = k_1t + c_1 \quad (1)$$

or the relation

$$p = k_2t^n = k_2t^6 \quad (2)$$

where p is the pressure at time t, p_f the final pressure and all c_1 and k_1 are constants. This stage was followed by a decay stage where the decomposition followed the unimolecular law

$$\log_{10}(p_f-p) = k_3t + c_3 \quad (3)$$

or, equally well, the expression

$$\tau\exp(-E/RT) = k_4 \quad (4)$$

where τ is the time to a fixed amount of decomposition. They obtained an activation energy of 27·8 kcal. mole^{-1} for all three stages.

Contradictory results were obtained by Galwey and Jacobs[5], who concluded that for whole crystals the acceleratory and decay periods were best described by the Avrami–Erofeyev equation[6]

$$-\log_{10}(1-\alpha) = k_5t^n \quad (5)$$

where $\alpha = p/p_f$ and n is equal to 4 for the acceleratory and 3 for the decay period. In both these studies only the non-condensable gases were measured (using McLeod gauges) and the effects of pre-irradiation were not investigated.

For this study, transparent crystals of ammonium perchlorate were prepared by the method of Galwey and Jacobs[5]. Only uniform crystals, approximately 1 × 1 × 1 mm obtained by careful selection, were used. The decomposition measurements were made in a grease-free, 'Pyrex' system using Dekker[7] valves for isolation. Gas pressures were measured with a fused quartz spiral gauge (Texas Instruments Corp., Houston). To effect a measurement of only those gases which would not be condensed at approximately −95° C, a trap at melting toluene temperature was inserted between the decomposition chamber and the spiral gauge. Irradiations with cobalt-60 gamma-rays were carried out at room temperature in air. The gamma-ray dose rate was $2{\cdot}05 \times 10^5$ rad h^{-1}.

Typical curves of α versus time for both unirradiated crystals and crystals subjected to a $9{\cdot}8 \times 10^6$ rad gamma-ray irradiation before decomposition are shown in Fig. 1. The irradiated salt is opaque and milky-white in colour. For equal masses of ammonium perchlorate, both unirra-

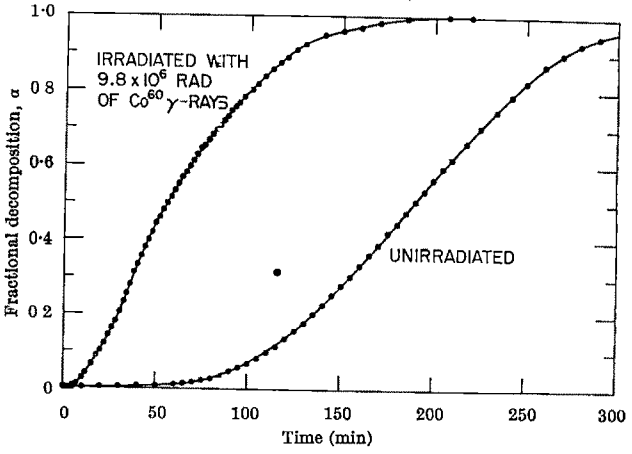

Fig. 1. Fractional decomposition, $\alpha = p(t)/p_f$, versus time for unirradiated and irradiated whole crystals of orthorhombic ammonium perchlorate thermally decomposed at 227° C. The samples weighed 20·0 mg and the same final pressure, p_f = 0·501 mm mercury, was obtained for both. The irradiated sample was exposed to $9{\cdot}8 \times 10^6$ rad of cobalt-60 γ-rays in air at room temperature.

diated and subjected to the $9{\cdot}8 \times 10^6$ rad dose, the final gas pressure is the same to within experimental error. This shows that, at this dose, any gases that may have been produced during irradiation remain trapped in the crystals. Neither the unirradiated crystals nor the irradiated ones appear to break up during decomposition.

The data from unirradiated crystals cannot be fitted by the Prout–Tompkins equation (1), or its modified form[8], nor does the unimolecular decay law (3) adequately describe the decay period. Curves from unirradiated material were successfully fitted to the Avrami–Erofeyev equation (5), with $n=4$ for the acceleratory period and $n=3$ for the decay period (Fig. 2). Preceding the acceleratory period is a linear induction period describable by the equation

$$\alpha = k_7 t + c_7 \qquad (6)$$

The curves of pressure versus time obtained from the irradiated material can also be fitted to the Avrami–Erofeyev equation (5), as is shown in Fig. 2. For a typical acceleratory stage curve (at 227° C), when $n=4$ in equation (5), a good fit is obtained only over the limited range $0{\cdot}07 < \alpha < 0{\cdot}25$. In the decay stage, when $n=3$ in equation (5), the fit is excellent over the unusually large range of $0{\cdot}40 < \alpha < 0{\cdot}98$.

From measurements made on unirradiated, whole crystals between 238° C and 217° C the rate constants, k_5 (acceleratory), k_6 (decay), and k_7 (induction period), were computed. Fig. 3 is a plot of $\log_{10} k_{5,6,7}$ versus $1/T$(°K). From this plot activation energies of 29·8, 26·9, and 24·6 kcal. mole^{-1} ($\pm 2{\cdot}5$ kcal. mole^{-1}) were found for the induction, acceleratory and decay periods respectively.

The nature of the decomposition in unirradiated, orthorhombic crystals has been attributed by Galwey and Jacobs[5] to a reaction occurring principally on mosaic boundaries after initiation by defects. The reaction proceeds three-dimensionally until the boundary material is all consumed. Assuming this mechanism to be correct, the effects of the $9{\cdot}8 \times 10^6$ rad gamma-ray irradiation appear to be a shortening of the induction period and an increase in the rate of three-dimensional growth during the acceleratory period, until a coherent interface is built up on the material between the mosaic blocks. At 227° C, the rate constant k_5 increases from $0{\cdot}39 \times 10^{-2}$ min^{-1} for unirradiated crystals to $1{\cdot}05 \times 10^{-2}$ min^{-1} for the irradiated crystals. The induction period is correspondingly shortened from 62 min to about 5 min. The increase in the rate constant during the acceleratory period might be attributed to an increase in the number of decomposition nuclei present.

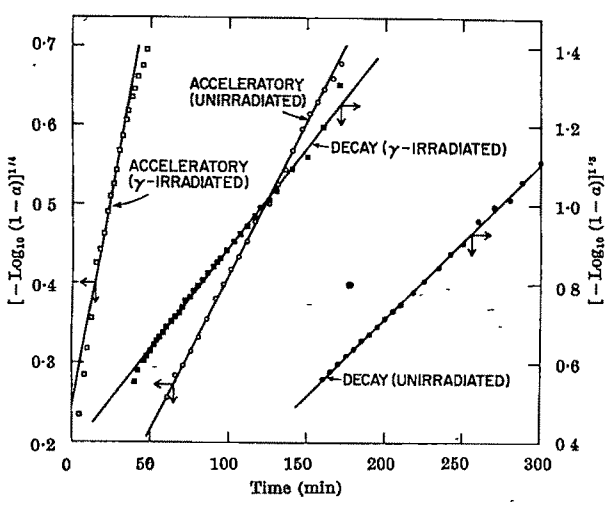

Fig. 2. Avrami–Erofeyev analysis of the data shown in Fig. 1. This demonstrates the applicability of this equation to both experimental curves. γ-ray irradiation decreases the range of fit of the acceleratory equation and greatly extends the range of the decay equation.

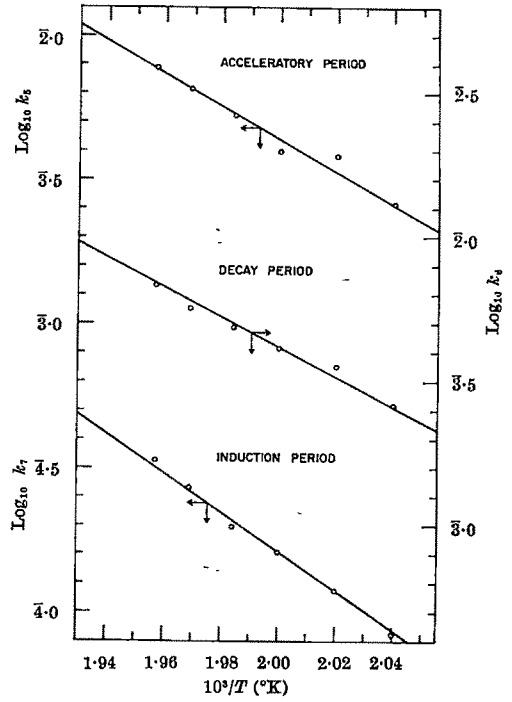

Fig. 3. Plots of $\log_{10}$ (rate constant) versus $1/T$ (°K) for the induction, acceleratory and decay periods of the thermal decomposition of whole crystals of unirradiated orthorhombic ammonium perchlorate.

This work was performed primarily at Brookhaven National Laboratory and supported jointly by Picatinny Arsenal, the Defense Atomic Support Agency and the U.S. Atomic Energy Commission.

A Method of growing Anhydrous Single Crystals of Barium Azide

THE salts of hydrazoic acid are of military interest owing to the fact that many of them are explosive. They range in sensitivity from sodium azide, which is stable, to the heavy metal azides, such as lead and gold azides, which are highly explosive. Intermediate in its explosive character is barium azide, which is sufficiently safe to be handled conveniently, yet can be made to explode. Solid state studies of this material have been hindered by the lack of suitable single crystal specimens. In particular, in order to study the photolysis of barium azide by electron spin resonance, crystals with a minimum size of about 5 × 2 × 1 mm are required. Although crystals of barium azide monohydrate are relatively easy to grow[1], it was felt that anhydrous crystals would offer a

more simple system for study by electron spin resonance. This work was undertaken to develop a method of growing such crystals.

The primary difficulty was that of finding a suitable solvent. The only two liquids in which barium azide was found to have appreciable solubility were water and dimethyl sulphoxide. Water solutions, of course, yielded only unwanted hydrate crystals, while crystals grown from dimethyl sulphoxide were found by mass spectrometric analysis to contain excessive quantities of sulphur. Results of previous work[1] suggested that the proper mixture of water and some other solvent such as acetone might be made to yield anhydrous crystals. Three solvent pairs were tested: water–acetone, water–ethanol and water–methanol.

Growing solutions were prepared for test by mixing a known volume of saturated aqueous solution with a known volume of acetone (or ethanol or methanol). The precipitated azide was filtered off, and the saturated filtrate used as the growing solution. The actual amounts of water, acetone and azide in unit volume of the resultant growing solution are not yet known, but are at present being determined by radioisotope techniques. A knowledge of this is not necessary for growing the crystals, however, and in the following discussion growing solutions will be identified by stating the volume ratio of aqueous solution to acetone (or ethanol or methanol) used in their preparation.

The following method was used to test the growing solutions. Taking the water–acetone solvent pair as an example, a small test-tube filled with the saturated growing solution to be tested was placed inside a larger screw-cap test-tube containing pure acetone. When the large tube was capped, acetone vapour diffused into the growing solution in the small tube, thereby lowering the solubility of the azide. Crystals as long as 2 mm are obtained within a week. These were found to be anhydrous if the growing solution was prepared from 20 per cent (or less) aqueous solution and 80 per cent (or more) acetone. The corresponding percentages for the water–ethanol system were found to be 30 per cent aqueous solution to 70 per cent ethanol; and for the water–methanol system, 40 per cent aqueous solution to 60 per cent methanol. It is seen that the water–methanol system can contain a higher proportion of water while yielding anhydrous crystals than either the water–acetone or water–ethanol systems. This higher water content results in higher solubility of the azide. It was therefore decided to use the water–methanol system in an attempt to grow larger crystals by slow cooling,

A water bath was constructed, the temperature of which was regulated by a mercury thermoregulator through an electronic relay. A 1/12 r.p.h. synchronous motor was arranged to decrease slowly the setting of the thermoregulator. Varying the percentage of time during which the motor was switched on provided a means of adjusting the cooling rate.

Growing solutions were prepared as before, except that the aqueous solution and the methanol were mixed at 40° C. This temperature was chosen as the starting point for the cooling experiment because it was feared that a higher temperature would cause decomposition of the azide. Three mixtures were tested in the slow cooling experiment: these were prepared by mixing 30, 35 and 40 per cent aqueous solution with 70, 65 and 60 per cent methanol, respectively. The solutions were then transferred to 50 ml. test tubes. These were of a screw-cap design, with caps lined with 'Teflon', to prevent the methanol (which boils at 65° C) from escaping and thus changing the composition of the growing solution. The neck of each tube was plugged with a foam polyethylene plug, into which was inserted a 90 mm long melting point capillary. To the end of this was glued a seed cyrstal grown in a previous experiment, with a glue prepared by dissolving polystyrene in toluene. The tubes were capped and placed in the water bath, and cooling was begun at the rate of 1·2° C/day. When the temperature had reached 20° C, the experiment was terminated, and the crystals were removed and washed with methanol.

The largest crystals (up to 2 cm in length) were found to have been produced in the growing solution prepared from 40 per cent aqueous solution and 60 per cent methanol. The clearest ones, however, were found in the solution prepared from 35 per cent aqueous solution and 65 per cent methanol. Almost no growth was observed in the solution prepared from 30 per cent aqueous solution and 70 per cent methanol. In some cases crystallization occurred on the test-tube walls, as well as on the seeds, which indicates that a slower cooling rate is desirable.

No attempt has been made to grow larger crystals, since the crystals obtained in this experiment were of sufficient size for electron spin resonance studies. Work is at present being carried out to determine the amount of methanol included in the crystals, and to determine their lattice parameters.

I thank Dr. Tillman A. E. Richter for many helpful discussions and Mr. Ralph P. Manno for the preparation of the barium azide powder used in growing the crystals.

CHEMISTRY

Far Infra-red Studies of Hydrogen Bonding in Gaseous Mixtures

RECENTLY, there have been a number of reports on infra-red spectroscopic studies of hydrogen bonding in gaseous mixtures. These studies, chiefly by D. J. Millen and his colleagues, have included amine-alcohol[1], ether–nitric acid[2] and ether–hydrogen chloride[3] complexes. These workers have measured the infra-red spectra of these gaseous, hydrogen bonded complexes in the region of the O—H stretching frequency. After complexing, they found for all the systems a strong central band with a subsidiary band on both the high and low frequency sides. The central band has been assigned to the hydrogen bonded O—H stretching vibration and the side bands have been interpreted as sum and difference combinations of the O—H stretching vibration with the hydrogen bond stretching vibration. This interpretation has been offered as a general explanation for the broadening of the O—H stretching band on hydrogen bonding and has allowed a prediction of the hydrogen bond stretching frequency in these complexes.

It is claimed that these conclusions have been substantiated by the far infra-red study of the gaseous trimethylamine–methanol complex by Ginn and Wood[4]. In their work, a band which could be attributed to the complex was observed at 142 cm^{-1}; this is within experimental error of the value predicted by Millen and Zabicky[1] for the hydrogen bond stretching frequency.

We have studied three of these systems in the far infra-red in an attempt to observe additional hydrogen bond frequencies directly. For the nitric acid–dimethyl ether complex, a band at 175 cm^{-1} is attributed to the O—H - - - O stretching mode and not 340 cm^{-1} as predicted by Millen and Samsonov. In the case of the hydrogen chloride–dimethyl ether mixture, no evidence for complex formation could be found. For the methanol–trimethylamine mixture, the 142 cm^{-1} band reported by Ginn and Wood was found to be a methanol band shifted to higher frequencies by pressure and not the hydrogen bond frequency.

Far infra-red spectra (33–400 cm^{-1}) were obtained on a Beckman *IR*-11 spectrophotometer. Conventional 10 cm gas cells equipped with high density polyethylene windows were used. Differential spectra were obtained by running a 10 cm cell containing the complex against two tandem 5 cm cells containing equivalent amounts of the unmixed components placed in the reference beam. All complexes were prepared by mixing the components in the gas phase.

Far infra-red spectra for the nitric acid–dimethyl ether system are shown in Fig. 1. Only the relatively weak 175 cm^{-1} band appeared in the spectrum on complexing even though the entire 33–400 cm^{-1} region was carefully studied. Millen and Samsonov, using the sum and difference band interpretation to explain their results in the 3,200 cm^{-1} region, have predicted the O—H - - - O stretching frequency at 340 cm^{-1} although they questioned this value when it appeared to undergo a large shift with DNO_3. We have found no indication of a band at 340 cm^{-1} and conclude that the hydrogen bond stretching frequency for the gaseous ether–nitric acid complex is at 175 cm^{-1}.

Infra-red spectra in the 120–150 cm^{-1} region pertaining to the gaseous methanol–trimethylamine system together with conditions under which the spectra were obtained are given in Fig. 2. Millen and Zabicky have studied this system in the O—H stretching region[1]. Their work has shown: (*a*) methanol and trimethylamine form a 1 : 1 complex; (*b*) only about 3 per cent of the amine is present in the complexed form; (*c*) weak satellites at ± 145 cm^{-1} from the main hydrogen bonded OH peak may be sum and difference bands involving the hydrogen bond stretching frequency at 145 cm^{-1}. The work of Ginn and Wood[4] which reports the direct observation of a band at 142 cm^{-1} for this complex has added considerable support to the conclusions reached by Millen and Zabicky.

We feel that our work on the amine–methanol system does not support the observation of a hydrogen bond frequency at 142 cm^{-1}. The spectrum of methanol vapour shown in Fig. 1 has a weak doublet at 139 cm^{-1}. On addition of trimethylamine to the methanol this band becomes more intense and shifts to 141 cm^{-1}. This is in agreement with the observation of Ginn and Wood. Exactly the same result is obtained, however, when nitrogen or argon is added to the methanol, and in addition the intensity of the 141 cm^{-1} band increases with increasing

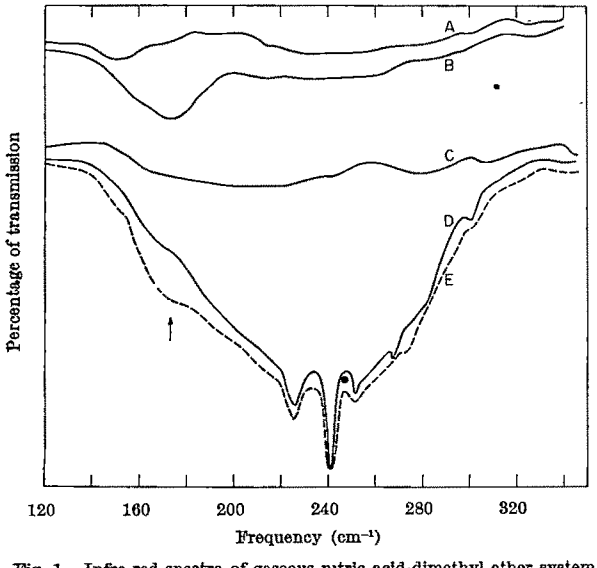

Fig. 1. Infra-red spectra of gaseous nitric acid-dimethyl ether system. *A* is spectrum of 150 mm ether in sample beam against 150 mm ether in reference beam, and *B* is differential spectrum after addition of 40 mm nitric acid to sample cell. *C* is spectrum of 45 mm nitric acid, *D* is spectrum of 400 mm ether, and *E* is mixture of 400 mm ether and 45 mm nitric acid. All spectra refer to 10 cm path length.

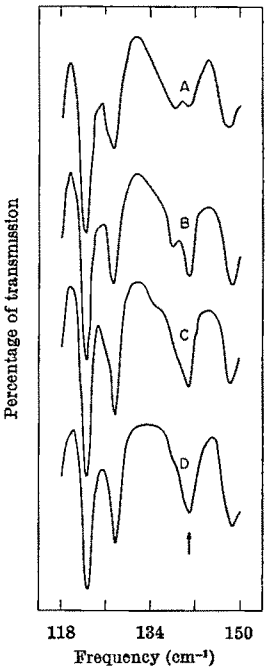

Fig. 2. Spectrum *A* is that of methanol vapour at 90 mm pressure, *B* and *C* are 90 mm methanol to which has been added 150 mm and 300 mm nitrogen respectively, and *D* is 90 mm methanol to which has been added 300 mm trimethylamine. Path length was 10 cm in all cases and spectral slit width was about 2 cm^{-1}.

partial pressure of nitrogen just as Ginn and Wood reported for trimethylamine. We therefore believe that Ginn and Wood's 142 cm^{-1} hydrogen bond frequency is the same band we have observed at 141 cm^{-1} and have shown is really a pressure enhanced methanol band. In fact, no evidence of complex formation could be found in the 33–400 cm^{-1} region, which is perhaps not surprising considering that only 3 per cent of the trimethylamine molecules are involved in complex formation.

Far infra-red spectra were also obtained on mixtures of 20 torr dimethyl ether and 30 torr hydrogen chloride. Addition of the ether produced no observable change in the position or intensity of the hydrogen chloride pure rotational lines. The differential spectrum of the gaseous mixture against equivalent amounts of the components in the divided reference cell showed no bands which could be attributed to a complex. Although Arnold, Bertie and Millen[3] have predicted from infra-red studies in the 2,500 cm^{-1} H—Cl stretching region an ←O - - - H—Cl→ frequency at 110 cm^{-1}, we could not confirm this. Apparently so little of the hydrogen chloride is involved in hydrogen bonding, as evidenced by the observation that the addition of ether caused no perturbation of the hydrogen chloride rotational lines, that any bands due to the complex are not detectable in the far infra-red.

It is concluded that with the ether–hydrogen chloride and trimethylamine–methanol systems, far infra-red studies offer no evidence for or against Millen's predictions based on measurements in the O—H stretching region. In both these systems the amount of hydrogen bonded complex formed is probably too small to be detected in the far infra-red region. We have shown, however, that a previously reported band at 142 cm^{-1} for the amine–methanol complex is not a hydrogen bond frequency. With the nitric acid–dimethyl ether complex, the observed hydrogen bond stretch at 175 cm^{-1} differs considerably from the 340 cm^{-1} value predicted by Millen and Samsonov, although there may be some significance in the fact that the observed frequency is almost exactly at half the predicted value. This could mean that the shoulders observed by Millen at ± 340 cm^{-1} from the O—H stretching band result from the ternary combinations, $\nu_{O-H} \pm$

$2\nu_{O-O}$, and that the corresponding binary combinations are not resolved from the strong central maximum. This work was supported by the National Institutes of Health.

Band-broadening in Infra-red Spectra of Gaseous Hydrogen-bonded Complexes

AN infra-red investigation of hydrogen bonding in various gaseous mixtures showed the band arising from the hydrogen stretching vibration to be unusually broad even for gaseous complexes[1–3]. In favourable cases the structure of the broad absorption contour was clear, consisting of a central band with a subsidiary band on both the low and high frequency sides. An assignment was suggested of the central band to the hydrogen stretching frequency and of the side bands to sum and difference bands of this frequency and the stretching frequency of the hydrogen bond. The pattern of results for the complexes of hydrogen chloride and fluoride with ethers, and of methanol with amines, was found to accord with this view. On the other hand, the band structure found for mixtures of nitric acid and ethers had some unexpected features. The frequency of the hydrogen bond stretching frequency inferred from the sum and difference band interpretation was unexpectedly high by comparison with the other complexes, and the change in band structure found on transferring to deutero-nitric acid was also anomalous. Accordingly, we have made a further investigation of systems of nitric acid and ether. We are prompted to report briefly on this by the comments of Carlson, Witkowski and Fateley[4] on the far infra-red spectrum of this and other related gaseous systems.

Our new investigation leads to the conclusion that the side bands are displaced by about 185 cm^{-1} from the central peak. This value has been reached as a result of a systematic investigation, in which great care has been taken to avoid contamination by impurities. It will be sufficient here to quote one particular piece of evidence from which the conclusion can be reached directly. Fig. 1 shows the band structure observed for a mixture of hexadeutero dimethyl ether and nitric acid. The spectrum of the deuteroether, which is also included in Fig. 1, shows only a weak absorption in this region so that the material has distinct advantages over the light ether for this work. Mixtures were contained in a specially constructed infra-red cell. The inter or surface of the cell was gold-plated and silver chloride windows were fitted with 'Teflon' *O*-rings.

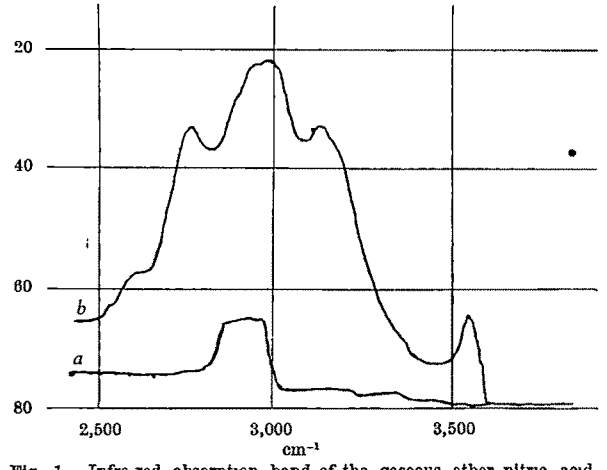

Fig. 1. Infra-red absorption band of the gaseous ether–nitric acid hydrogen-bonded complex. *a*, Spectrum of deutero dimethyl ether, *b*, spectrum of mixture of deutero dimethyl ether and nitric acid.

The spectrum in Fig. 1 shows a central peak at 2,950 cm^{-1} with subsidiary bands at approximately 3,125 and 2,760 cm^{-1}, and with a weaker shoulder at approximately 2,600 cm^{-1}. The high frequency band is displaced by about 175 cm^{-1}, and the low frequency band by 190 cm^{-1}, from the central peak. The weak shoulder is displaced by about 350 cm^{-1}.

Carlson, Witkowski and Fateley have observed a band in the far infra-red spectra of mixtures of nitric acid and dimethyl ether at 175 cm^{-1} and suggest assigning it to the stretching vibration of the hydrogen bond. Comparison can now be made with the sum and difference band interpretation of the infra-red structure of the band centred at 2950 cm^{-1}. The sum and difference band displacements are in fact not far removed from the suggested hydrogen bond stretching frequency. Agreement would be expected to be best for the difference band, but the accuracy of measurement is not high, as can be seen from Fig. 1, because of the broadening of the individual bands which make up the structure; this is particularly noticeable for the central band. The shapes of these constituent bands, like the origin of their breadth, is unknown. These could conceivably influence the observed separation between the maxima and lead to some discrepancy.

The far infra-red investigation of the hydrogen chloride–ether systems and of methanol–trimethylamine revealed no band which could be attributed to the hydrogen bond stretching vibration[2]. It is perhaps understandable that of the systems investigated only the nitric acid–ether system showed such a band, for the infra-red study of the hydrogen stretching bands indicates that the concentration of complex is most favourable in this case.

We thank Drs. Fateley, Carlson and Witkowski for sending us a copy of their paper[4] before publication, and the Gulbenkian Foundation for the award of a studentship (L. A.).

Oxygen Reduction on Titanium Nitride in Alkaline Electrolyte

THE nitrides and carbides of the metals in groups IV*B* and V*B* of the Periodic Table have been studied during the course of investigations with a view to developing fuel cell catalysts for oxygen (O_2) reduction in alkaline electrolyte. In general, the carbides show considerably more oxygen reduction activity than do the pure metals. By simple atomic consideration this can be attributed to the presence of carbon, which *per se* is a good catalyst for the reduction of oxygen to hydrogen peroxide. The nitrides exhibit more activity than does the pure metal, but to a lesser degree than the carbides. Of special interest is the nitride of titanium, which shows considerably more activity for oxygen reduction than does pure titanium. In contrast to other metals titanium nitride is more active than titanium carbide.

For these experiments the potentiostatic current-potential measurements were made on rotating disk electrodes at 75° C in 2 M potassium hydroxide saturated with nitrogen or oxygen. Each specimen, after mounting

and polishing, was introduced into a solution of potassium hydroxide saturated with nitrogen at a preset 1,200 mV and rotated at a constant 600 r.p.m. throughout the tests. (All potentials were measured against a reversible hydrogen electrode in the same solution.) A potential sweep was initiated immediately at a rate 50 mV/min scanning from 1,200 mV to 0 mV and back again to 1,200 mV. This curve indicated the corrosion behaviour of the electrode. The oxygen reduction activity was studied by repolishing the electrode and repeating the potential scan in a solution saturated with oxygen.

The $i(E)$ curves obtained for titanium (Fig. 1*a*) show detectable corrosion in the whole range of potentials; oxygen reduction begins only at less than $E = 300$ mV. Although this potential seems to be very low (900 mV overvoltage), the activity of titanium for oxygen reduction is higher than that of zirconium or hafnium, which in the range of potentials studied show no appreciable activity under similar conditions.

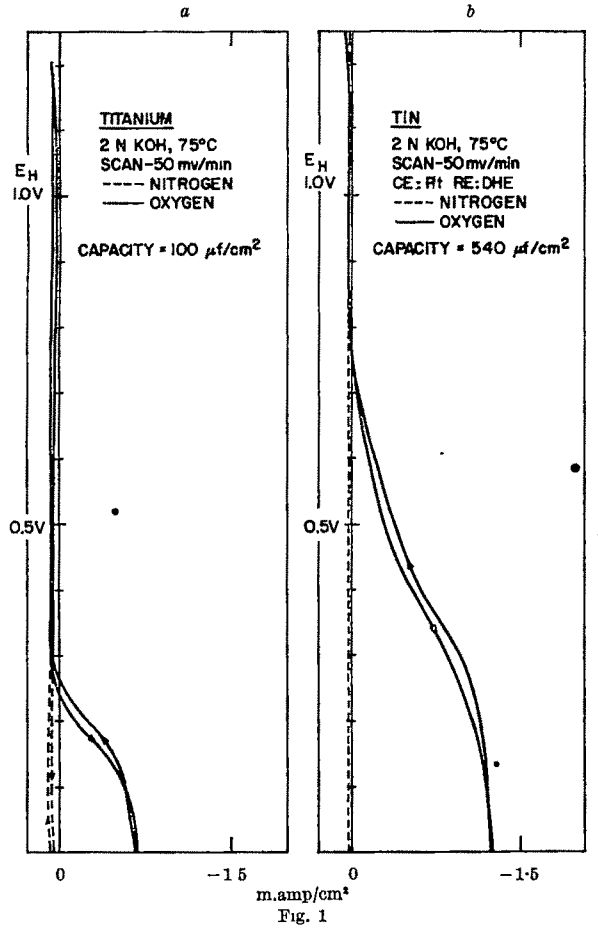

Fig. 1

The $i(E)$ curves for titanium nitride (Fig. 1*b*) show appreciably less corrosion than those of pure titanium but, on the other hand, considerably higher activity for oxygen reduction. As already mentioned, no current for oxygen reduction was observed above $E = 300$ mV with titanium, while titanium nitride showed oxygen reduction in the vicinity of 800 mV. In addition, the observed limiting current for titanium nitride is almost twice that of titanium, possibly indicating a higher efficiency for oxygen reduction (less hydrogen peroxide formation). Double layer capacity measurements show that the surface of the titanium nitride electrode is five times larger than that of the titanium electrode. Because the corrosion current is higher with titanium than with titanium nitride, however, it seems unlikely that the increase in oxygen activity is solely an effect of increased surface. Also, a five-fold increase in the surface area does not adequately account for a potential shift of 500 mV in the oxygen reduction potential.

A more plausible explanation is the reduction, by nitridation, of the rate of electrochemical oxidation and thus of the thickness of the oxide layer on titanium. This would mean that oxygen is reduced on titanium oxide and that a decrease in the thickness and/or the composition of this oxide by nitridation causes an increase in activity for oxygen reduction. (Oxynitrides of titanium are known[1].)

The increase in oxygen reduction activity on titanium nitride is of considerable interest because it could not be anticipated from atomic considerations as with titanium carbide (titanium carbide, as well as carbides of the other metals of the group, approaches graphite in activity for oxygen reduction). The results obtained with titanium nitride suggest that nitridation of such metals as iron, nickel, and cobalt—which have limitations similar to titanium for oxygen reduction—may help to increase their activity. In consequence, experiments with the nitrides and carbides of iron, cobalt, titanium and nickel are now in progress.

This work was sponsored by the National Aeronautics and Space Administration. We thank Mr. E. M. Cohn for directing our attention to nitrides and carbides as possible oxygen electrodes.

Synthesis of Substituted Phenyl-β-D-xylopyranosides (II)

IN a recent communication we reported the synthesis of a series of mono-substituted phenyl-β-D-xylosideacetates through the Helferich condensation and that of the corresponding β-D-xylosides by catalytic deacetylation with sodium methoxide[1].

This communication reports on the preparation of a further series of these β-D-xylosides by the same method.

Tetra-*O*-acetyl-β-D-xylose was prepared according to Vogel[2]. The purity of the products was tested by thin-layer chromatography on silica gel using acetic acid–water–ethylacetate (1/1/3; v/v) for xylosides, and ethylacetate–benzene (3/7; v/v) for the acetates. The spray reagent used was 5 per cent sulphuric acid in ethanol (10 min at 120° C). The xylosetetraacetate (0·1 mole) and the appropriate phenol (0·4 mole) were fused together and the molten mixture then treated with a solution of *para*-toluenesulphonic acid (0·6 g) in a mixture of acetic anhydride–acetic acid (5/95; v/v) (50 ml.). The melt was heated under reduced pressure at 100° C for 1 h. After cooling, the resulting syrup was dissolved in chloroform (200 ml.), thoroughly washed with ice cold N sodium hydroxide and water, dried (using sodium sulphate) and evaporated *in vacuo*. When necessary, solutions of benzene were run through a column of alumina and eluted with more benzene in order to remove dark condensation products which were insoluble in alkali. The resulting syrup was then crystallized from the appropriate solvent to constant melting point and optical rotation.

Table 1. ACETYLATED β-D-XYLOPYRANOSIDES

Interpretation of Electrolyte Invasion Data for Ion-exchange Polymers

IN recent years two quite independent theories have been developed to account for the observed electrolyte invasion properties of ion-exchange polymers. Scatchard and Freeman[1] suggest that in the application of the Donnan law (1), deviations are best interpreted in terms of the mean activity coefficient of the electrolyte in the exchanger phase, $\bar{\gamma}_\pm$.

$$(\nu_c.\bar{m})^{\nu c}\,(M + \bar{m}.\nu_g)^{\nu_g \nu c}\bar{\gamma}_\pm^{\nu} = k(\nu_c.m)^{\nu c}\,(\nu_g.m)^{\nu_g.\nu}\gamma_\pm^{\nu} \qquad (1)$$

where ν_c is the number of co-ions in a molecule of electrolyte; ν_g is the number of counter or gegen ions in a molecule of electrolyte, $\nu = \nu_c + \nu_g$; M is the observed counter-ion concentration; m, the concentration of external electrolyte; $\bar{m}$, the concentration of imbibed electrolyte; k, a constant; $\bar{\gamma}_\pm$ and $\gamma_\pm$ are the mean internal and external activity coefficients of the electrolyte, respectively. In accordance with the theory of specific ion interactions[2], an expression has been derived (2), in which a and b are constants, to account for variations in $\bar{\gamma}_\pm$ for ion-exchangers based on styrene-divinylbenzene copolymers. This relationship has also been applied to polymethacrylic acid ion-exchangers[3].

$$\log \bar{\gamma}_\pm = a + b\,\bar{m} \qquad (2)$$

It is assumed in this treatment that any deviations resulting from non-uniformity of the exchanger matrix are either negligible or can be eliminated by a small correction to the observed results.

The alternative view is that proposed by Glueckauf[4], in which departures from the ideal law are explained in terms of the heterogeneity of the ion-exchange matrix. A modified power law (3) for invasion by 1 : 1 electrolytes is introduced, on the assumption that the ratio $\bar{\gamma}_\pm/\gamma_\pm$ is approximately constant and that $M \gg \bar{m}$. The parameter z is characteristic of the heterogeneity of the ion-exchanger. This approach has also been applied to a series of solvent modified styrene-divinyl-benzene resins, with a wide range of heterogeneity[5].

$$\bar{m} = k'\,m^{(2-z)}, \text{ where } 0 > z > 1 \qquad (3)$$

Interpretation of electrolyte invasion results is particularly difficult as most investigations have been over short ranges of concentration and therefore do not provide an adequate test of these theories. Notable exceptions are the diffusion studies of invasion in ion-exchange membranes by Glueckauf, Watts and Crabtree[6,7], and more recently the work of Freeman, Patel and Buchanan[8], in which the resin and external aqueous phases are not separated. This report is concerned particularly with the interpretation of the data obtained in the latter investigation, which the authors have treated exclusively in terms of the mean activity coefficient in the exchanger phase, $\bar{\gamma}_\pm$. The results from this work are plotted as log m against log $\bar{m}$ in Fig. 1. Applying the Donnan law (1) to the three systems considered, the appropriate power law relationships are as follows:

for the system (*a*) $\bar{R}$-K^+, K^+Cl^-, H_2O, $\bar{m} = k_1.m^2$

(*b*) $2\bar{R}$-Mg^{2+} $Mg^{2+}2Cl^-$, H_2O $\bar{m} = k_2.m^{1.5}$

(*c*) $\bar{R}^+Cl^-$, $Mg^{2+}2Cl^-$, H_2O $\bar{m} = k_3.m^3$.

The materials used in this study were $AG50W \times 2$ (cation) and $AG1 \times 2$ (anion) exchangers supplied by Biorad Laboratories. Present-day theories on styrene-divinylbenzene copolymerization[9] suggest that resins of this type, with low divinylbenzene contents, will be very evenly cross-linked and therefore provide ion-exchangers of low heterogeneity. In consequence, if the heterogeneity theory is correct, much smaller deviations would be expected for these resins than those observed with materials of higher divinylbenzene content. From the plot for system (*a*) two significant factors are apparent: (1) with decreasing external concentration m, the gradient increases; (2) in the region $m < 10^{-1}$ molar the gradient is a very reasonable approximation to the value of two required by the ideal law. Both these effects were predicted by the heterogeneity theory. The results for the other systems, involving the magnesium ion, are somewhat ambiguous. System (*c*), for which the Donnan law requires an exponent of three, also has a gradient of about two and therefore would appear to support the conclusion of Glueckauf, from his work[7] with the lanthanum ion, La^{3+}, that equation (3) is generally applicable, immaterial of the valencies of the ions involved. The gradient for system (*b*) shows a similar increase with decreasing external concentration m, but even for $m < 10^{-2}$ molar the value is only 1·5; from which it might be concluded that it is approaching the exponent required by the ideal law and not the value of two expected for a homogeneous ion-exchanger from

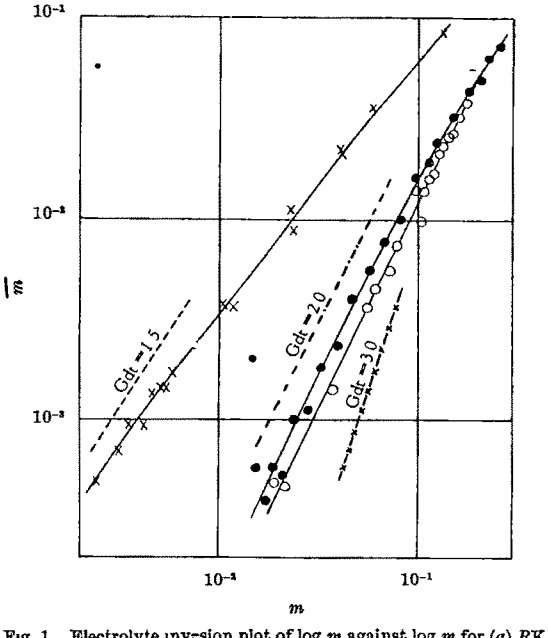

Fig. 1. Electrolyte invasion plot of log m against log m for (*a*) $\bar{R}K$, K^+ (●); (*b*) $\bar{R}_2Mg$, $MgCl_2$ (×); (*c*) $\bar{R}Cl$, $MgCl_2$ (○).

equation (3). From equation (3) for systems (*a*) and (*c*) the parameter $z \simeq 0$, but for the system (*b*) $z \simeq 0{\cdot}5$. On this basis the results for (*a*) and (*b*) do not give a consistent measure of the heterogeneity of the cation-exchanger $AG50W \times 2$.

In conclusion, the results for system (*a*) are clearly consistent with a theory based on heterogeneity. The results for systems (*b*) and (*c*) raise doubts as to the applicability of equation (3) to systems involving polyvalent ions, although in this case there is still a need for a comprehensive study.

Role of Neutral Salts on the Denaturation Temperature of Biopolymers

IN recent years, a great deal of attention has been devoted to the study of the effect of salts on the denaturation of biopolymers, both in the bulk state (for example, shrinkage of fibrous collagen) and in dilute solutions (for example, helix-coil transitions)[1,2]. Recent work in this laboratory[3] has demonstrated that two main factors must be considered in describing the effects of both salt type and salt concentration on the shrinkage of collagen at neutral *p*H (when polyelectrolyte effects are absent). These are: the diluent and the specific effect. The former effect is predominant for salting-out agents, such as potassium chloride and magnesium sulphate, whereas the latter occurs with salting-in agents, such as potassium thiocyanate and lithium bromide. The diluent effect is satisfactorily described by the conventional melting point depression theory developed for binary polymer-diluent systems

$$\frac{1}{T_m} - \frac{1}{T_m^0} = \frac{R}{\Delta H_u}\,(V_u/V_1)\,(\zeta_1 - \chi_1\zeta_1^2) \qquad (1)$$

where T_m is the melting temperature of the polymer in the presence of the diluent, T_m^0 the melting temperature of the undiluted polymer, ΔH_u is the heat of fusion per mole of repeating unit, V_u the molar volume of the repeating unit, V_1 the molar volume of the diluent, ζ_1 the volume fraction of diluent, and χ_1 represents a polymer–diluent interaction parameter which can be interpreted[3] in terms of conventional salting-out theories[4].

Considerably more debatable is the nature of the specific effect. One possible way to explain it is to consider a disproportion of the salt–water mixture resulting in ion binding to the protein[1,3]. As in the classical case of melting point depression, accompanied by the formation of a complex in the amorphous state[5], the large salting-in suggests that binding occurs mainly in the denatured state. Assuming that binding occurs only in the latter state, Schellmann, Flory and Mandelkern[1] have shown that an additional term should be added to the right-hand side of equation (1). This is

$$(RN_a/\Delta H_u)\ln(1 + kA_s)$$

where N_a is the mole fraction of available sites, k is the binding constant, and A_s denotes the activity of the salt. An alternative way of describing the specific effect is to postulate an indirect interaction by which the salt solutions affect the protein stability. This indirect mechanism could be related to such properties of the solution as its degree of ice-likeness[2].

Although present evidence favours the ion binding hypothesis[3], the critical experiment of determining whether a binding of salt actually occurs for salting-in agents, particularly at the denaturation temperature, has not previously been reported. Here we shall describe some preliminary results which unequivocally demonstrate that a removal of ions from solution does accompany the thermal shrinkage of fibrous collagen in potassium thiocyanate solutions.

We have equilibrated initially dry collagen tendons, cross-linked with *p*-benzoquinone[3], in a solution of carbon-14 labelled potassium thiocyanate of known thiocyanate concentration, C_s^i, and determined the thiocyanate concentration, C_s^f, after equilibration with the collagen[6], both below and above the shrinkage temperature (72° C for these samples in pure water). The *p*H of the solution was about 7, which is within the isoelectric plateau of the protein[3] (the isoionic *p*H of the solubilized tendons at 40° C was found to be 7·1). Concentrations of thiocyanate solutions were determined by liquid scintillation counting of equal portions of the solution in toluene–ethanol–2,5-diphenyl oxazole–1,4-*bis*-2-(5-phenyloxazolyl)-benzene scintillator using a Packard 314X liquid scintillation spectrometer. In Fig. 1*A* and *B* is shown the change in length and volume, respectively, which occurs during the shrinkage[7], and *C* shows the corresponding changes in the difference between C_s^i and C_s^f. The increase in C_s^i–C_s^f which corresponds to the

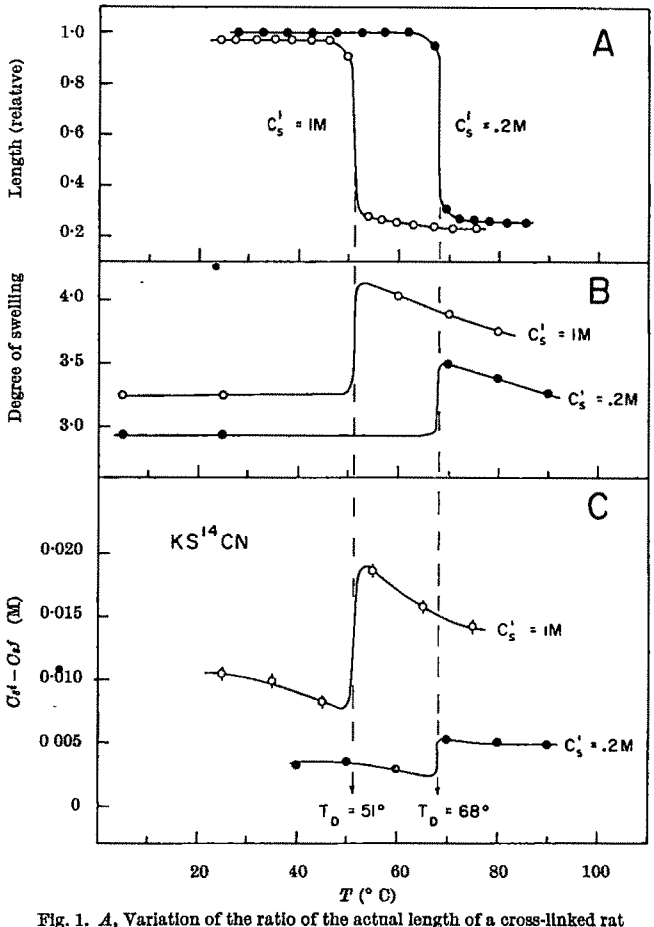

Fig. 1. *A*, Variation of the ratio of the actual length of a cross-linked rat tail tendon to the length in the native swollen state, with temperature (ref. 7). Tendons immersed in potassium thiocyanate solutions of the indicated concentrations. *B*, Corresponding variations of the ratio of the actual volume of tendons to the volume in the native, dry state, with temperature (ref. 7). *C*, Apparent uptake of carbon-14 labelled potassium thiocyanate by initially dry, cross-linked tendons as a function of temperature. Collagen concentration is about 25 mg/ml.

shrinkage temperature, T_D, indicates that shrinkage or denaturation can indeed be associated with an increase in the degree of binding.

The fact that $C_3'-C_3^I$ is greater than zero below T_D shows that some binding does occur even for the native protein. Because X-ray diffraction[7] does not reveal any alteration of the lattice spacings for native collagen in equilibrium with potassium thiocyanate solutions below T_D, it is likely that binding in the native state occurs mainly within regions of poor structural organization.

At present we are unable to define explicitly the type of association between the ions and the protein. Considerations reported elsewhere[3] indicate that an interaction of the ions with the dipoles of the peptide bond is involved, and that some difference exists between the binding behaviour of anions and that of cations. Furthermore, the binding of ions is competitive with the binding of water, and this leads to an expression which is even more complex than equation (1) with the Schellmann–Flory–Mandelkern term[8].

We are now repeating these experiments using various salts at several concentrations in order to determine both the apparent binding constants and the number of binding sites along the chain backbone.

Isotopic Exchange Chromatographic Separation applied to an Equilibrium Strontium-90 and Yttrium-90 Mixture

ANALYTICAL techniques based on precipitation, volatility, electrolysis, ion exchange, solvent extraction, chromatography, etc., with or without carrier, have been used to separate individual radionuclides and to separate groups of radionuclides. Less attention has been paid to radiochemical separation or determination involving isotopic or displacement exchange reactions. The amalgam exchange procedures[1-6] introduced by Meinke and collaborators appear to be unique and will find wider use in radiochemical separations. Isotopic exchange has also been applied to the separation of radiosilver[7] and of iodine-131 (ref. 8) by Sunderman and Meinke, and adaptation of isotopic exchange to the determination of mercury in a solvent extraction system has been worked out by Handley[9]. A displacement method for the separation of radio-iodide on a column of silver chloride granules has been reported by Arnott and Wells-Cole[10]. Americium has been separated from curium and other trivalent actinides and lanthanides with a column of calcium fluoride[11], and this column has also been used for the removal of radioactive actinides and lanthanides from aqueous solutions[12].

The exchange of strontium ions between a precipitate of strontium sulphate and a solution of strontium salt is very rapidly completed. Because of the low solubility of strontium sulphate, at equilibrium there is a very favourable ratio between strontium atoms in the precipitate and in the solution. In the work to be reported here, this fact has been used to develop a rapid chromatographic method, involving only a single step and based on isotopic exchange for the separation of carrier-free Y-90 from its parent Sr-90.

Commercially available crystal powder of strontium sulphate was treated with boiling 0·5 N sulphuric acid solution for 5 min, and the crystals thus activated were transferred with small amounts of 0·5 N sulphuric acid to a conventional chromatographic column, 1·1 cm in diameter and 5 cm in height, pulled to a tip at the outlet to facilitate the collection of the eluate. The crystals were supported by a sintered glass plate attached to the lower end of the column; the crystal bed was usually 1·3 cm long. About 20 μl. of an equilibrium mixture of Sr-90 and Y-90, converted to sulphate form and adjusted to 0·5 N in sulphuric acid, was applied to the top of the column. By means of a slight over-pressure, the strontium was allowed to pass down the column. The column was filled with 0·5 N sulphuric acid, and the pressure regulated so that the flow amounted to one drop (~0·05 ml.) per 15 sec. Every two drops of eluate were collected on counting trays and evaporated to dryness with an infra-red lamp. The radioactivity of the eluate was measured with a conventional end-window GM counter.

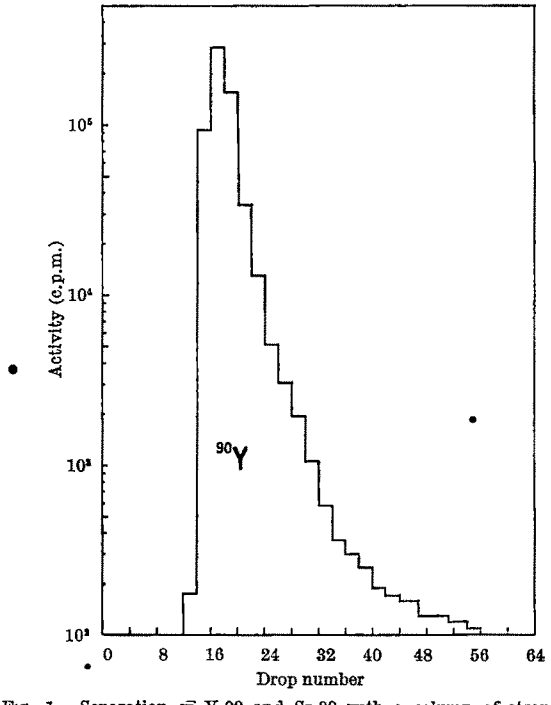

Fig. 1. Separation of Y-90 and Sr-90 with a column of strontium sulphate. Y-90 eluted with 0·5 N sulphuric acid. Strontium sulphate bed 1·3 cm long, Φ 1·1 cm (2·5 g).

A typical elution profile curve is illustrated in Fig. 1. No activity was found in the first twelve drops of the eluate. In later fractions, activity appeared rapidly, reaching a maximum at 16 drops, and then decreased rather gradually. It is apparent that there is a slight retention of the yttrium on the crystal column. This may be considered to be due partly to the similarity in ionic radius and electronegativity between Sr^{2+} and Y^{3+} ions, as indicated here:

	Sr^{2+}	Y^{3+}
Ionic radius (Å)	1·13	0·93
Electronegativity	125	160

The ionic radii are taken from Pauling (ref. 13) and the electronegativities from Povarennykh (ref. 14).

Several fractions, covering the entire elution profile, were used for decay rate measurement and γ-ray spectrometry. The decay curves consisted of two components corresponding to a β-activity with a half-life of 64·5 h and a long-lived nuclide emitting γ-rays. No sign of break-

through of Sr-90 was observed in the eluate. (A γ-ray spectrum of the long-lived activity revealed the presence of Cs-137 with a half-life of 30 yr deriving as impurity from the original Sr-90 and Y-90 mixture.) In this way the carrier-free Y-90 can be rapidly separated in only about 15 min from carrier-free parent Sr-90.

The same principle would be applicable to radiochemical separations, provided that insoluble salts exist and that exchange between the salt and its ions is rapid. Thus the separation of carrier-free Ce-144 and Pr-144 can be carried out on a short column of cerium (IV) iodate crystals. The bed was 0·8 cm long and was first treated with 6 N nitric acid. Pr-144 was recovered within 7 min, in the first 20 drops, by elution with 6 N nitric acid, but because of the increased solubility in elution with nitric acid, the contamination was rather high and averaged approximately 3 per cent.

BIOCHEMISTRY

Examination of Isoenzymes of Several Dehydrogenases in Pure Cell Lines

MANY workers have demonstrated that lactic acid dehydrogenase (LDH) and malic acid dehydrogenase (MDH) exist in several isoenzyme forms[1–5]. Bands of different electrophoretic mobility have also been reported for 6-phosphogluconate dehydrogenase (6-PGDH) (ref. 6), but the kinetic properties of these isoenzymes have not been as clearly defined.

This report describes some preliminary results obtained on the characterization of several pure cell lines (as opposed to tissues) with respect to the isoenzymes of these three dehydrogenases. To do this, homogenate supernatants of the cells were fractionated by zone electrophoresis on starch gel, the isoenzymes being located as distinct blue formazan bands on the gel.

The following cell lines were examined:

(1) *L*5178*Y* lymphoblasts[7]: (*a*) obtained directly from *DBA*/2 mice with transplanted ascites tumour; (*b*) *radioresistant* and *radiosensitive* diploid and tetraploid cells carried through seventy-two generations *in vitro*[8]. Isoenzyme bands from *DBA*/2 mouse kidney and liver extracts were used as markers for cells which originate from mouse and hamster tissues. (Mobility of isoenzymes in the hamster is similar to that observed in the mouse.)

(2) Hamster kidney fibroblasts: (*a*) *BHK-C*13 normal[9] cells carried through fifty generations *in vitro*; (*b*) *BHK-TCY*[9] cells transformed with polyoma virus and carried through twenty-five generations *in vitro*.

(3) Rat sarcoma cells (induced by benzpyrene): (*a*) primary sarcoma tissue taken from a freshly killed hooded rat; (*b*) four clones of sarcoma cells grown *in vitro* for 8 months (about 500 generations), *S*6/1, *S*6/2, *S*6/3 and *S*6/4. Isoenzyme bands from rat kidney extracts were used as a marker.

(4) N_2 cells[10]—normal adult subcutaneous fibroblasts from *C3H* mice, grown *in vitro*.

The tissues were ground in 0·25 M 'Mannitol' (containing 0·1 mg/ml. ethylenediamine tetraacetic acid) *p*H 7·4 with a 'Teflon' pestle in a Potter–Elvehjem homogenizer, tough fibrous material being broken up first by grinding for 10 sec with an 'Ultra-Turrax': the final concentration was 150–200 mg/ml. Cells were washed twice with 'Mannitol' solution, resuspended to give a cell count of 20–25 × 10^6 cells/ml, and then broken up with the homogenizer. All homogenates were centrifuged for 30 min at 144,000*g*; the supernatants were used for the isoenzyme studies. A temperature of 0°–4° C was maintained throughout these procedures.

80–120 μl. of supernatant was applied to the gel with 2–3 pieces Whatman 3 *MM* paper (1·4 mm × 1 mm). The electrophoresis was performed at *p*H 7·0 using a phosphate citrate buffer[11] at 4° C, by applying a potential of 6 V/cm across the gel for 4 h. After electrophoresis, the gel was sliced into three longitudinal layers (9 × 16 × 3 mm), each layer being stained for a different dehydrogenase. The isoenzymes were visualized directly on the gel by coupling the reduction of dimethyl-thiazolyl diphenyl tetrazolium bromide (MTT) with reduction of coenzyme (in the presence of appropriate substrates) by using phenazonium methosulphate as an electron transporter. For LDH isoenzyme a slice of gel was incubated with 10 ml. of a 1 per cent agar overlay containing 8·8 ml. 0·1 M *tris*-hydrochloric acid (*p*H 8·0); 0·5 ml. 2 M D,L-lithium lactate (*p*H 8·0); 2·0 mg MTT; 0·1 ml. phenazonium methosulphate (5 mg/ml.); 0·6 ml. nicotinamide adenine dinucleotide (10 mg/ml.) for 15 min at 37° C in the dark. For MDH a similar medium was used except that 1 ml. 2 M D,L-sodium malate (*p*H 8·0) was substituted for lithium lactate, and the incubation time was lengthened to 30 min. For 6-PGDH, 2 mg nicotinamide adenine dinucleotide phosphate replaced the nicotinamide adenine dinucleotide, and 1 ml. 6-phosphogluconate (10 mg/ml.) was used as substrate instead of lactate. The incubation time here was 30 min. On all occasions the reaction was terminated by soaking the gel slice in a methanol/acetic acid/water (5 : 1 : 5) mixture, for 10 min.

Fig. 1 is a diagrammatic representation of the patterns observed. Column 3 illustrates the distribution of LDH, MDH and 6-PGDH obtained with all the various *L*5178*Y* cells examined. These results demonstrate the stability of the isoenzyme patterns during long term culturing and also the uniformity of the isoenzyme patterns in the three *L*5178*Y* mutants studied. Although mouse lymphoblasts and hamster kidney fibroblasts show a single LDH band, N_2 and sarcoma cells contain several. The M_4 LDH band was the most commonly observed isoenzyme; however, the N_2 cells exhibited a pattern which was distinct from that of the other cultured specimens. Only one band for MDH and 6PGDH was noted with the cell cultures, except for sarcoma cells (column 6) which displayed two bands for 6PGDH. The tissues appear to display several bands of each enzyme, under the conditions used here.

With rat sarcoma, cells grown *in vitro* show a different distribution in all three enzymes from that observed with the primary sarcoma.

Identical enzyme patterns were obtained with a normal and polyoma virus infected hamster kidney fibroblast. Caution should be exercised in the interpretation of these results. It is not known whether the difference observed between the cultured and *in vivo* cells (for example, sarcoma) results from a lack of cellular homogeneity of the fresh tissue or the result of culturing[12,13]. In addi-

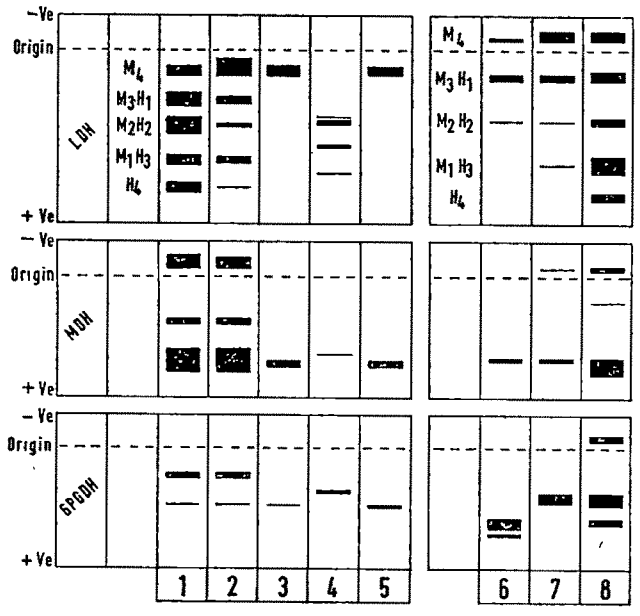

Fig. 1. Summary of the isoenzyme patterns obtained with tissue extracts and cultured cells: (1) *DBA*/2 mouse kidney; (2) *DBA*/2 mouse liver; (3) lymphoblasts directly from a tumour-bearing *DBA*/2 mouse, *radioresistant* and *radiosensitive* diploid lymphoblasts examined after forty-four, fifty-eight and seventy-two generations *in vitro*, and tetraploid cells after seventy-two generations *in vitro*; (4) N_2 cells *in vitro*; (5) *BHK-C*13 and *BHK-TCY* hamster kidney fibroblasts examined after fifty generations *in vitro*, (6) *S6*/1, *S6*/2, *S6*/3 and *S6*/4 sarcoma cells examined after 500 generations *in vitro*, (7) primary sarcoma directly from a hooded rat; (8) hooded rat kidney.

tion, periodic assessments of enzyme distribution during culture should be carried out with the kidney hamster cells, because it is possible that changes may be initially produced by infection with polyoma virus which are lost during culturing.

To ascertain whether enzyme patterns observed are an inherent characteristic of the cell, further investigations should be carried out to determine both the influence of long term culturing and tissue culture media used on the isoenzyme patterns of cells.

Interactions of Protein (Antibodies) with the Deoxyribonucleic Acid Molecule

IN view of the current hypothesis on the protein nature of genetic repressors it is of prime importance to know whether certain proteins exist capable of "recognizing" and interacting with regions of the DNA molecule differing in base composition or configuration.

Antibodies to DNA were first discovered by Seligman[1] in 1957 in the serum of patients with systemic lupus erythematodes (SLE). Unexpectedly, however, it was found that these antibodies interacted similarly with DNAs of various origins and which differed significantly in their base composition. Levine *et al.*[2] have demonstrated that antibodies to DNA found in serum of patients with systemic lupus erythematodes react preferentially with denatured DNA. Using the method of passive haemagglutination—one of the most sensitive immunological reactions—we have found that antibodies to DNA occur fairly frequently. The presence of these antibodies was demonstrated in the blood serum of 60 per cent of the healthy individuals investigated and in various experimental animals[3].

The purpose of this investigation was to study the ability of antibodies present in different sera to interact with apurine and apyrimidine DNAs and DNA lacking a secondary structure. By this means we hoped to obtain some information on the nature of the regions of the DNA molecule with which the antibodies could interact.

In order to follow the interaction of antibodies with different preparations of DNA the antibody neutralization reaction based on passive haemagglutination was used. The details of both methods have been published elsewhere[4]. The reaction was carried out utilizing ram erythrocytes treated with formalin and tannin and sensitized at *p*H 5·5 with denatured DNA. By means of an antibody neutralization reaction we determined the minimal amount of DNA required to neutralize the antibodies contained in a given volume of various sera. The following preparations of DNA were used for neutralization : (1) native DNA ; (2) denatured DNA (obtained by heating DNA for 10 min at 100° C); (3) DNA denatured in the presence of formaldehyde (DNA solution (400 μg/ml.) was heated for 10 min at 100° C in a 1·3 per cent solution of formaldehyde). As was shown by Grossman[5] formaldehyde prevents the formation of helices in separated strands of DNA; (4) apurinic DNA obtained by the method of Tamm *et al.*[6] ; (5) apyrimidinic DNA, obtained by hydrazinolysis according to Habermann's[7] technique. The absence of purine or pyrimidine bases in these preparations was demonstrated by paper chromatography.

The results of the antibody neutralization reactions using different sera and preparations of DNA are summarized in Table I.

The analysis of the data given in Table 1 shows that different amounts of the diverse preparations of DNA are necessary for the neutralization of antibodies present in different sera. Three groups of antibodies may be differentiated on the basis of their ability to interact with different preparations of DNA. The first group are the antibodies which mainly interact with single-stranded (DNA which had been treated with formalin). To neutralize this type of antibody very much more denatured DNA (60–250×) is required. These antibodies are found in guinea-pigs, in some patients (sera 6 to 8) and in a patient with systemic lupus erythematodes during the early stages of the disease (serum 5, duration of disease 4 months). The second group comprises the antibodies which interact mainly with single-stranded DNA. Furthermore, their affinity for denatured DNA is much higher in that of the first group of antibodies because the amount of denatured DNA required for their neutralization is four to fifteen times as great as the amount of formalin treated DNA for the same purpose. Antibodies of this kind were found in the serum of most patients with

Abbreviations. SLE, systemic lupus erythematodes; nDNA, native DNA; dDNA, denatured DNA; fDNA, formalin-treated DNA; apurDNA, apurinic DNA; apyrDNA, apyrimidinic DNA.
* One serum unit is the minimal amount of serum containing antibodies capable of agglutinating 0·05 ml. of a 2 5 per cent suspension of DNA-sensibilized erythrocytes.
No*, not neutralized by dose of 1 mg.

systemic lupus erythematodes (sera 9 to 21). The fact that different amounts of denatured DNA are required to neutralize the antibodies from different sera suggests that the length of the region of the single-stranded molecule of DNA with which the antibodies of the second group can interact is less than the corresponding region of polynucleotide chain which will interact with antibodies of the first group. The third group is composed of those antibodies which are equally capable of interacting with native, denatured and formalin-treated DNAs (sera 22 to 25). These antibodies were found in patients suffering from a severe form of systemic lupus erythematodes (three of the patients died shortly afterwards). It should be noted that it is this type of antibody which is able to inhibit the activity of DNA as primer in the RNA polymerase reaction and furthermore influences DNA translating activity[8]. Prolonged storage of sera containing these antibodies results in a considerable reduction in their ability to interact with single-stranded and denatured DNA.

Recently, it was shown that the antinuclear factors present in the blood serum of different people may exhibit variable properties. Thus Bardawil *et al.*[9] have found that the antinuclear factor present in the blood serum of normal people interacts with deoxyribonucleoprotein at low ionic strengths only. On the other hand, the antinuclear factor from serum of patients with severe forms of systemic lupus erythematodes can react with deoxyribonucleoprotein at higher salt concentrations.

Data presented in Table 1 show that apurinic acid is also able to interact with antibodies, the amounts of this DNA required to neutralize the antibodies being variable and depending on the serum under test. These values are, however, always higher than that for the amount of single-stranded DNA necessary for the neutralization of the same quantity of antibody. This finding suggests that purines may be an important constituent of the sites of interaction in the DNA molecule. There is another explanation which is also plausible ; treatment of DNA with hydrochloric acid—used for the preparation of apyrinic DNA—is known to degrade DNA and it is possible that this may also lead to a significant degradation of the site of antibody interaction in the DNA molecule. In fact we found that the incubation of DNA with DNase considerably decreased the ability of the DNA to interact with antibodies.

In contrast with apurinic DNA, DNA lacking the pyrimidine bases is usually unable to interact with antibodies. Thus pyrimidine bases may be directly involved in the formation of the sites in the DNA molecule which will interact with the antibodies.

Electrophoretic Determination of Albumin/Globulin Ratios in Mice

INFORMATION on the serum protein patterns of normal mice is necessary if these animals are to be used for studies in cellular immunity. However, except for Albritton's report[1], in which no indication was made of the animal's age, sex and strain, such published data are not available. This communication, therefore, provides some of this essential information; we have found that there are differences in serum protein patterns in different groups of mice, and that these patterns are related to age and sex.

All mice, with the exception of the pathogen-free ones, were outbred Swiss–Webster supplied by the University vivarium. They were housed at 22° ± 1° C under conditions calculated to minimize infection by microbes. They were fed a diet of 'Purina' rat chow and were given as much water as they wanted to drink. The following groups of mice were studied. (1) Normal: these were of known sex and age and at no time appeared ill or debilitated. (2) Immune: normal males, 10 weeks of age at the start of our injection schedule, received 1·0 mg intraperitoneally of bovine plasma albumin three times a week. They were bled 3 days after the seventh injection.

(3) Hyperimmune: normal males, 9 weeks old, received three subcutaneous injections of 2·0 mg of alum precipitated bovine serum albumin (BSA) which caused them to become immunologically paralysed. Once an anti-BSA haemagglutinin titre could be demonstrated, indicating an escape from paralysis, the animals were immediately bled. (4) Pathogen-free: 9-week-old males were obtained from the Charles River Mouse Farms. They had been maintained under aseptic conditions and were found to be serologically negative for common mouse viral and bacterial infections. They were bled immediately on receipt to ensure that their stipulated pathogen-free condition prevailed. (5) Newborn: 2-day-old suckling mice were bled and immediately killed (and hence were of undetermined sex). (6) Infected: normal 9-week-old females were injected intraperitoneally with approximately 1×10^7 coagulase positive *Staphylococcus aureus*.

All mice were bled from the retrobulbar plexus into sterile capillary tubes. Each serum was separated from the clotted blood by centrifugation and electrophoresed immediately, as poor reproducibility was obtained when frozen sera were used. A human control serum accompanied each series of test sera. In studies requiring frequent bleeding of the same mouse, we alternated plexus on successive bleedings.

All electrophoretic analyses were carried out with a microzone electrophoresis cell (Model *R*-101, Beckman Instruments, Inc.). The only changes from that procedure were: (1) that the time of electrophoresis was increased from 20 to 30 min, thus effecting better separation of serum proteins; and (2) that the *B*-2 buffer was changed after the second analysis rather than after the fourth, thus preventing precipitation of the buffer at the electrodes. When electrophoresis was completed, the cellulose acetate membranes were developed, dried, and scanned in a Beckman model *RB* 'Analytrol' with model *R*-102 'Microzone' scanning attachment.

Fig. 1 shows the wide range of albumin/globulin (A/G) ratios observed in the various groups of normal and experimental mice. The serum protein patterns of normal males differed greatly from those of females, as can be seen in Fig. 2. The male A/G ratios were not only less variable, but also displayed smaller standard deviations. The alterations of A/G ratios which occur temporarily in infected mice are shown in Fig. 3. Bacteriaemias persisted for 25–27 days, but blood samples analysed after 28 days were negative.

Our interpretation of these results is that the serum protein pattern of 13-week-old male mice remain more

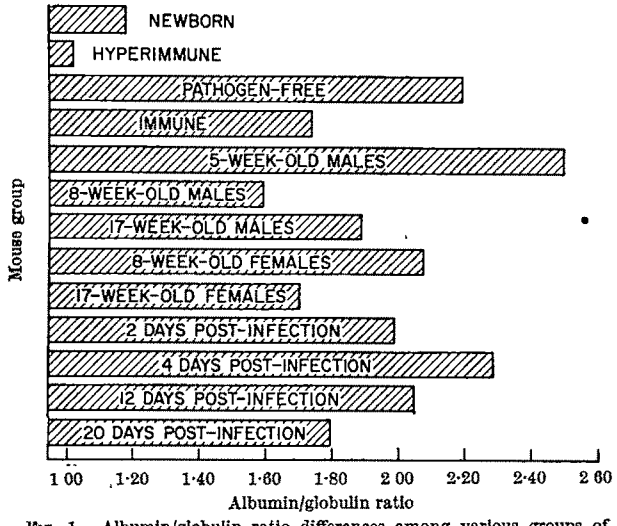

Fig. 1. Albumin/globulin ratio differences among various groups of mice. The infected animals were 8-week-old females at the time of infection. All groups except for the hyperimmune mice (four animals) contained at least ten animals.

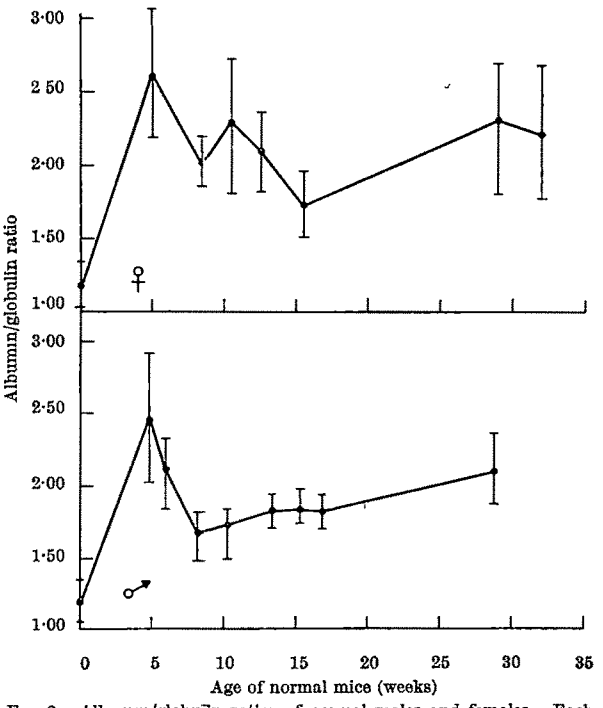

Fig. 2. Albumin/globulin ratios of normal males and females. Each point represents the mean value for at least ten mice. The line bisecting any given point represents the standard deviation for that age group.

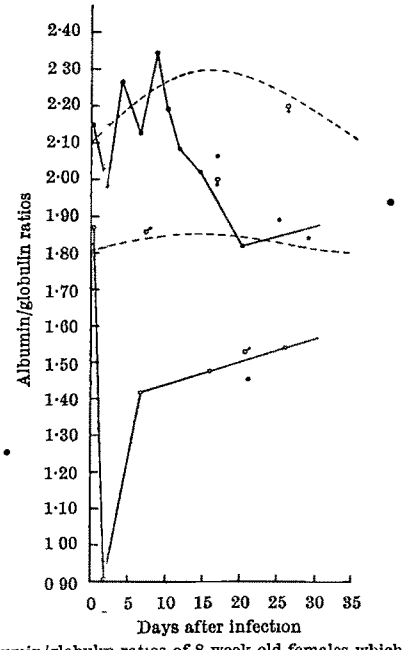

Fig. 3. Albumin/globulin ratios of 8-week-old females which were each injected intraperitoneally with 1×10^7 *S. aureus* compared with those of 13-week-old males which were similarly infected. The dotted lines represent the A/G ratios of uninfected animals.

stable and reproducible for at least 4 weeks than do those of other mouse groups. Serum protein patterns change dramatically with the age of the mice. The low A/G ratios found in newborn mice is attributable to colostrum-transferred maternal antibodies, and the very high A/G ratio found in 8-week-old mice denotes the immature state of their reticulo-endothelial systems. As the mice reach immunological maturity (at about 8 weeks of age) the A/G ratio reached a new, relatively stationary level. The fluctuation shown by the A/G ratios of normal females is believed to be related to oestrous cycle or other hormonal changes, or both. No attempt was made to

determine which group of animals elicits the highest antibody titre to any given antigen. It might well be that some group other than 13-week-old males should be used if the quantity of antibody produced is important. It is possible that the undulations in the A/G ratios exhibited by *S. aureus* infected females during the first 6–8 days after infection are caused by the focalization and subsequent breakdown of foci resulting in reinfection of the mice.

We thank Dr. Eli Sercarz for providing us with the hyperimmune mice used in these experiments. This investigation was supported by the National Science Foundation.

Response to Insulin by Guinea-pig Taenia Coli

THE stimulating action of insulin on the metabolism of heart and striated muscle is well known, but the extent of its influence on smooth muscle is less clear and is variously assessed[1–6]. Preparations so far studied—such as aortic muscle[5–7] and intestinal segments[4]—suffer from the disadvantage that they are damaged during preparation or, like uterine muscle[1–3], have a highly individual endocrine response. Because of its ease of dissection and less specialized function, guinea-pig taenia coli muscle seemed an obvious tissue preparation with which to investigate the possible *in vitro* effects of insulin.

Insulin can without doubt enhance uptake of glucose by strips of this tissue *in vitro*, its retention of glucogen, the accumulation of the unutilized amino-acid, aminoisobutyrate, and the incorporation of carbon-14 labelled glycine into protein (Table 1). The figures given in Table 1, however, showing clear stimulating effects of insulin, are selected observations, and a large number of experiments were recorded in which a consistent stimulus by the hormone was not observed. The explanation for this is uncertain. For undeterminable reasons there seemed to be a much larger variation between strips from different animals than would be found with, for example, rat diaphragm muscle, and in different experiments the absolute values of glucose utilization and glycogen deposition moved between wider than usual limits. Axelsson, Bueding and Bülbring[9] have previously noted such fluctuations in the glycogen content, and they did not find an effect of insulin on glycogen retention. In most of the experiments in Table 1 the taenia preparations rested freely in a small quantity of incubation medium and consequently remained contracted. In other experiments the muscle strips have been tied to weights and placed under a tension of about 2 g. Under these conditions, the stimulating effect of insulin on the incorporation of ^{14}C-glycine was still observed (Table 1).

Table 1. EFFECT OF INSULIN ON THE METABOLIC ACTIVITY OF TAENIA COLI *in vitro*

	Effect of insulin: No insulin added	Insulin added (0·1 unit/ml.)	*P*
Unstretched tissue			
Uptake of glucose (mg/g tissue/h)	(6) 0·53 ± 0·08	0·95 ± 0·13	< 0·05
Glycogen content after incubation (mg glucose/g tissue)	(10) 0·78 ± 0·03	0·95 ± 0·06	< 0·05
Accumulation of carbon-14 labelled-aminoisobutyrate $\left(\frac{\text{(c.p.m./g tissue)}}{\text{(c p m./ml. medium)}}\right)$	(6) 5·3 ± 0·60	7·4 ± 0·69	< 0·05
Incorporation of carbon-14 labelled-glycine into protein (c p m / mg protein)	(9) 403 ± 28	632 ± 58	< 0·01
Tissue under tension			
Incorporation of carbon-14 labelled-glycine into protein (c p.m./ mg protein)	(6) 587 ± 51	657 ± 43 Difference 70 ± 19	< 0·02

Each figure is the mean ± *S.E.* of the mean of the number of observations in parentheses. For methods see refs. 23 and 24. For the experiments with unstretched tissue, two strips of taenia coli were removed from each guinea-pig (of either sex and of weight 200–400 g) and each strip cut into two approximately equal pieces. Medium consisted of Krebs-Ringer bicarbonate, gassed with 95 per cent O_2/5 per cent CO_2 and contained glucose (1 mg/ml.). Incubation was in 1 ml for 2 h at 37° C with shaking. Carbon-14 labelled-glycine was added at a concentration of about 25 μM and 0·15 μc./ml. Carbon-14 labelled-aminoisobutyrate was added at a concentration of about 67 μM and 0·15 μc./ml. When the tissue was incubated under tension, the two ends of a single strip were tied together to a 5 g weight and the loop hooked around a stainless steel frame in 10 ml. of medium containing no glucose.

In a study of glucose metabolism by aortic muscle, Urratia, Beavan and Cahill[5] have also commented on the wide variability in behaviour between pieces of this tissue. They concluded that most of the apparent response to insulin of pieces of aortic muscle was due to the presence of adventitious tissue, and when the muscle was meticulously stripped, response to the hormone disappeared. Thus it is possible that with taenia some of the inter-animal variation results from varying degrees of contamination of the strips with adipose tissue, though it is debatable whether the amount adhering would be sufficient to account for all the insulin effects observed. On the other hand, guinea-pig adipose tissue is not very sensitive to insulin[10,11] and it is possible that the guinea-pig is just less sensitive to ox insulin than are some other species. Because the amino-acid sequence of guinea-pig insulin shows so many variations from other mammalian insulins[12], its use might be advantageous, although the available evidence[10] does not indicate differential sensitivity.

A point of contrast with heart or diaphragm muscle is the greater degree of concentration of aminoisobutyrate by taenia muscle than by these other tissues[13,14]. This may be related to the greater turnover of cellular sodium and potassium ions in smooth muscle as compared with striated muscle[15] and to the probable linkage of amino-acid uptake with the movements of ions[16]. Others have commented on the low oxidative metabolism of smooth muscle[5,6] and its high production of lactate. In our experiments, taenia produced an average of about 10 μmoles of lactate for each gram in a period of 2 h, which indicates the anaerobic glycolysis of most of the glucose taken up. The amount of lactate produced was not affected by insulin.

Various workers have questioned whether with smooth muscle there is as clear a distinction between intracellular and extracellular fluid as with striated muscle[15,17], and Goodford[18] has commented on variations in estimates of extracellular fluid in taenia according to the agents used for its determination. However, figures obtainable with sucrose and sorbitol (Table 2) agree well with Goodford's estimates with lithium and ethylsulphate, although they are higher than those found with inulin or polyglucose[19]. Differences between values found with inulin and other agents in various tissues are not unusual (Table 2). Yalcin and Winegrad[7] found a glucose space in aortic segments greater than the inulin and raffinose spaces and concluded that transport of glucose into the cell may not be the step limiting the rate of glucose utilization in that tissue. Any response to insulin under such circumstances would be of great interest. Our estimates, however, of the glucose space in taenia—24·9 ± 1·4 in the absence of insulin, and 27·5 ± 3·1 in its presence—do not suggest much intracellular accumulation. A preliminary report by Timms, Salama and Engstrom[20] suggests that the glucose space is increased by insulin.

Table 2. COMPARISON OF INULIN, SUCROSE AND SORBITOL SPACES IN VARIOUS MUSCLE PREPARATIONS

	Space (ml /100 g) measured with: Sorbitol	Sucrose	Inulin
Guinea-pig taenia coli	40·2	42·3	22·5
Rat intact diaphragm	24·5	23·8	23·5
Rat isolated hemidiaphragm	47·6	53·3	34·3
Rat extensor digitorum longus	35·8	34·4	19·2

Carbon-14 labelled sorbitol was added at a concentration of about 180 μM and 0·15 μc /ml. Inulin was added at a concentration of 0·6 per cent and sucrose at 1·25 per cent. All were extracted from the tissue after incubation by boiling and the sucrose and inulin estimated after hydrolysis to fructose (ref. 25).

There is thus some evidence that the taenia smooth muscle of the guinea-pig responds to insulin, though the quantitative significance seems to be variable. We may have to contend with the possibility that we cannot categorize all tissues as simply responsive or unresponsive to insulin, however, but that their response varies according to (as yet undetermined) conditions—a situation possibly akin to the limited response of brain slices[21,22].

We thank Dr. D. H. Jenkinson for much advice and discussion on the use and preparation of taenia coli.

Epidermal Keratin and Epidermal Prekeratin

PROGRESS in understanding keratinization of the epidermis has been hampered by the difficulty of preparing a reproducible keratinous protein from the epidermal tissue[1,2]. Several laboratories[1–5] have obtained an alkali- or urea-extractable protein from human, mouse, and cow's snout epidermis which precipitates from solutions at *p*H 5·5. This protein is present in large amounts in fully keratinized human epidermal tissue (callus or stratum corneum)[1,2] and is believed to represent epidermal "keratin". Matoltsy[6–8] has isolated and characterized a similar protein from cow's snout epidermis which is soluble in acetic acid. This protein is termed "prekeratin" by virtue of its ready solubility from whole epidermis which includes incompletely keratinized cells (full-thickness cow's snout epidermis). This report compares human callus keratin (protein precipitating at *p*H 5·5) with the prekeratin of Matoltsy. Their similarities heighten optimism concerning the definition of an epidermal keratin sub-unit.

Human plantar callus keratin was obtained by alkaline solubilization[1,2] (100 ml. of 0·02 M sodium hydroxide (solvent) per gram of dried neutral-buffer washed ground callus, 22° C, 24 h) and by precipitation at *p*H 5·5 by the dropwise addition of dilute hydrochloric acid with *p*H monitoring. The protein was redissolved and precipitated four times.

The approximate molecular weight of protein dissolved out at *p*H 5·5 by 0·02 N sodium hydroxide was determined by comparing its mobility with that of proteins of known molecular weight utilizing 'Sephadex' thin-layer gel filtration, modified by Andrews[9]. 'Sephadex' (*G*-100 superfine, Pharmacia) was equilibrated for 72 h with 0·02 M sodium hydroxide, and plates of 0·5 mm thickness were prepared with a spreader (Shandon Unoplan). Cytochrome *C* (horse heart, type II, Sigma Chemicals), chymotrypsinogen (thrice crystallized, Worthington Biochemical Corporation), γ-globulin (human, fraction II, Sigma Chemical Company), and callus protein which had been precipitated four times and lyophilized at *p*H 5·5 was dissolved in 0·02 M sodium hydroxide and applied to the thin-layer plate (5 μl. aliquots representing 20 μg of protein). The solvent (0·02 M sodium hydroxide) was allowed to flow horizontally for appropriate periods of time and the proteins were located by exposure to iodine vapour. The reference proteins migrated as single compounds for a distance proportional to the log of their molecular weight (Fig. 1). The approximate molecular weight of the protein dissolved out at *p*H 5·5 was estimated at about 50,000 from its comparative migration.

Peptide fingerprints were prepared from tryptic digests of *p*H 5·5 protein (5 mg dissolved in 1·0 ml. of 0·1 M ammonium carbonate and incubated at 37° C for 24 h with 0·1 ml. of 1 : 100 trypsin crystallized three times, Worthington Biochemical Corporation). Two-dimensional peptide maps (descending chromatography of aliquots representing 1 mg of the original protein in a butanol–acetic acid–water medium (4 : 1 : 5); electrophoresis at 3,000 V for 1 h in a formic acid–acetic acid–water medium (6 : 24 : 170) *p*H 2·0) revealed forty-five or forty-six peptides with a light ninhydrin stain. This is comparable to the number of peptides identified by Rothberg[5] in tryptic digests of *p*H 5·5 protein obtained from human callus and psoriatic and ichthyotic scales. With the usual assumptions that complete digestion occurs and that the action of trypsin is specific to peptide bonds formed from arginine and lysine, the *p*H 5·5 protein used in this study should contain forty-four or forty-five arginine and lysine residues.

Amino-acid composition (duplicate hydrolysates, 6 N hydrochloric acid, 24 and 72 h at 110° C in tubes sealed under vacuum) of the four times precipitated *p*H 5·5 protein was determined by automated column chromatography ('Spinco' model 120 amino-acid analyser) and corrected for destruction or delayed release of specific residues[1,2]. Based on the amounts of arginine and lysine present in these samples, a molecular weight which would contain forty-four or forty-five arginine and lysine

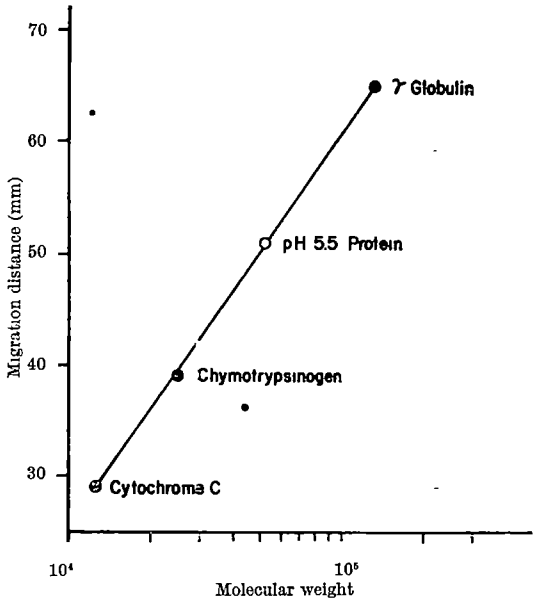

Fig. 1. Thin-layer gel filtration ('Sephadex *G*-100 Superfine' in 0·02 N sodium hydroxide at room temperature). Migration is plotted against (log) molecular weight (cytochrome *C*, 12,400; chymotrypsinogen, 25,000; γ-globulin, 160,000).

residues (and therefore agree with the results of tryptic peptide maps) was calculated. This estimate would require a molecular weight of approximately 50,000, which agrees with the estimate derived from thin-layer gel filtration.

Matoltsy[6–8] has estimated the molecular weight of epidermal prekeratin of the cow's snout to be 640,000 by the method of sedimentation equilibrium. Methionine was the amino-acid present in the least amounts (thirteen residues per molecular weight of 640,000). Because a protein must contain at least one whole residue of the least common amino-acid, the smallest possible molecular weight of prekeratin would be 1/13 of 640,000, or approximately 49,000 (the so-called minimal molecular weight). The number of arginine and lysine residues reported per molecular weight of 640,000 totalled 598. Thus the minimal molecular weight of 49,000 would contain 1/13 of this number, or 46. These two values are essentially identical to those determined for the *p*H 5·5 callus protein in alkaline solution.

Tryptic digests of prekeratin[8] were reported in a one-dimensional system and revealed only about fourteen peptides. Even if one assumes that a second-dimensional separation would reveal two or three times this number of peptides, the total number would be under fifty and therefore would be more compatible with the smaller (minimal) molecular weight. It would be reasonable to assume that a repeating sub-unit of molecular weight of about 50,000 might aggregate during sedimentation equilibrium, resulting in an apparent molecular weight of 640,000.

Thus, the suggested sub-unit molecular weight of 50,000 for prekeratin agrees well with the approximate estimate for *p*H 5·5 keratin (in alkaline solution) derived from gel filtration, amino-acid composition, and peptide maps. The amino-acid composition reported as residues per molecular weight of 50,000 for both *p*H 5·5 keratin and prekeratin is detailed in Table 1. Remarkable similarities are evident. The largest differences occur in those amino-acids (tyrosine, methionine, 1/2 cystine) which are technically most difficult. Both these and several smaller differences are as likely due to species differences as to preparative discrepancies. The presence of small amounts of lipids and less than 0·1 per cent of hexosamine in both preparations[8,10,11] are further points of similarity. Unfortunately, acetic acid does not dissolve protein from human callus or stratum corneum; for this reason, a direct comparison of the two proteins from these tissues is not feasible.

Table 1. AMINO-ACID RESIDUES PER MOLECULAR WEIGHT OF 50,000

	C5·5*	M†

* C5·5, Crounse *p*H 5·5 human epidermal protein (keratin).
† M, Matoltsy cow's snout epidermal protein (prekeratin).

It is likely, therefore, that the more soluble prekeratin, obtained from whole epidermis including incompletely keratinized Malphigian and basal cells, and the less soluble keratin, obtained from fully keratinized callus tissue, differ primarily in their extractability. This interpretation is compatible with the proposed two-component theory of keratinization[12], which states that a low-sulphur fibrous keratin present in the early stages of ectodermal differentiation is stabilized (hence less extractable) by an amorphous protein synthesized at a later stage of keratinization. In the case of wool, the second "cementing" component is believed to be heavily cross-linked with disulphide bonds of cystine. In epidermis, no specific high-sulphur protein has yet been isolated and characterized. Inverse proportionality of cystine and glycine in hair and epidermal proteins has been suggested[13]. Reports of a polypeptide rich in glycine and histidine synthesized high in the epidermis[14,15] might relate to such a second component of epidermal keratinization. In any case, the remarkable similarities in composition of human callus *p*H 5·5 "keratin" and cow's snout epidermal "prekeratin" indicate hopeful progress in the definition of an epidermal keratin sub-unit.

I thank Miss Joyce L. Heline and Mr. Thomas E. [illegible] for technical assistance. This work was supported by the National Institute of Arthritis and Metabolic Diseases, U.S. Public Health Service.

Monovalent Cation Requirement for the Aminoacyl Transfer Reaction in Protein Synthesis

IN this laboratory, previous investigations of the transfer of amino-acids from aminoacyl *s*RNA to polypeptides on ribosomes (the aminoacyl transfer reaction) were carried out with cell fractions prepared from rat liver with buffered solutions containing potassium[1–3]. The aminoacyl transfer reaction was dependent on the concentration of potassium ion in the incubation, and optimal incorporation was obtained when the concentration of potassium in the reaction mixture was between 0·075 and 0·1 M. Recent studies with preparations of *Escherichia coli* have shown that ammonium ions are more effective than potassium ions and that rubidium, caesium, sodium and lithium ions are much less active in promoting aminoacyl transfer[4,5]. Because similar results have been obtained with the rat liver system, solutions containing ammonium are at present being routinely used in this laboratory[6]. This communication presents a detailed investigation of the effective concentrations of various monovalent cations on polypeptide biosynthesis. The results reveal an interesting relationship between the relative biological activity of these ions and some of their physical and chemical thermodynamic properties.

The aminoacyl transfer reaction was carried out in the presence of varying concentrations of the chloride or nitrate salts of several monovalent cations, as shown in Fig. 1. Examination of the concentration optima for various cations indicates that ammonium ions are indeed superior in promoting the transfer of amino-acids from aminoacyl *s*RNA to polypeptides. Potassium is 60 per cent as effective as ammonium, and sodium, rubidium and thallium are only 20–25 per cent as active. Lithium

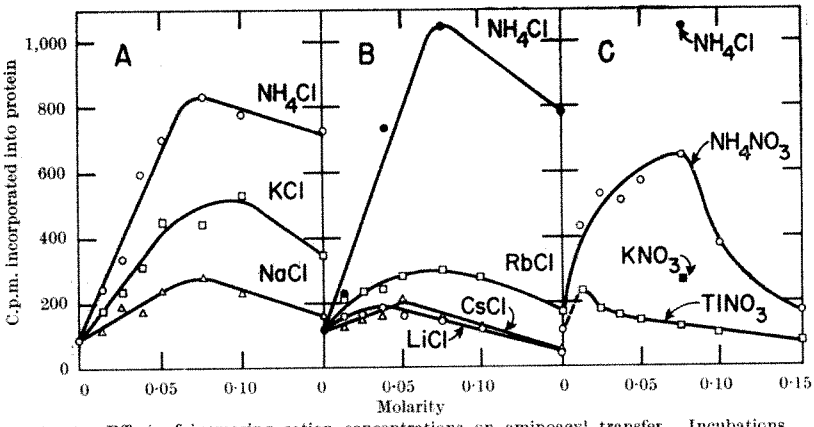

Fig. 1. Effect of increasing cation concentrations on aminoacyl transfer. Incubations, carried out at 37° C in a total volume of 2 ml., contained the following components: 0·6 mg of purified ribosomes, 0·4 μmoles of guanosine triphosphate, 12 μmoles of magnesium chloride, 40 μmoles of glutathione, 120 μmoles of *tris*-Cl or *tris*-NO_3 buffer, *p*H 7·4, 0·1 mg each of aminoacyl transferases I and II, 10,000 c.p.m. of ^{14}C-leucyl *s*RNA, and varying concentrations of the Cl^-- or NO_3^--salts of a monovalent cation as noted. The preparation of the reaction components, from rat liver, has already been described[6]. At the end of the incubation period, the hot 5 per cent trichloroacetic acid-insoluble fraction was prepared and collected on 'Millipore' filters for radioactivity determinations (ref. 6). The Cl^- salts of K^+ and Na^+ (*A*) were assayed in a separate series from those of Rb^+, Cs^+ and Li^+ (*B*). Ammonium chloride was run each time for comparison. Because thallium chloride was too insoluble to test, thallium nitrate (and ammonium nitrate for comparison) was tested in the system (*C*); also for comparison, values obtained with 0·075 M ammonium chloride (solid circle) and potassium nitrate (solid square) are included.

and caesium are the least active of those tested. Relatively high concentrations of all the compounds used, particularly the nitrate salts, led to decreased aminoacyl transfer. Salts of silver and copper could not be assayed because of their low solubility or tendency to precipitate other components of the incubation mixture.

A correlation between the relative activity of the monovalent cation in polypeptide biosynthesis and its crystal ionic radius, in Ångströms, or entropy of formation, at the reference temperature of 25° C, is presented in Fig. 2. The highest activity in the system in which amino-acids are incorporated is exhibited when the ionic radius is about 1·4 Å, or when the entropy value is near 27 calories; the biological activity falls off as the corresponding values deviate from these optima, particularly at the higher values. A similar pattern to that described here is also obtained when relative activities are plotted against the reciprocal of the radii of the hydrated ions. No obvious correlations were, however, found with respect to the standard heats of formation (ΔH_f^0), standard free energies of formation (ΔF_f^0) or oxidation potentials (E^0_{ox}). It is interesting to note that correlations have been suggested between the hydrated radii of various cations and their activity in the ATP : pyruvate phosphotransferase reaction[7] and in the binding of ^{14}C-chloramphenicol to ribosomes[8]. In these reactions, NH_4^+, K^+ and Rb^+ ions are active; their radii are similar but differ from those of Na^+, Cs^+ and Li^+ ions which are inactive.

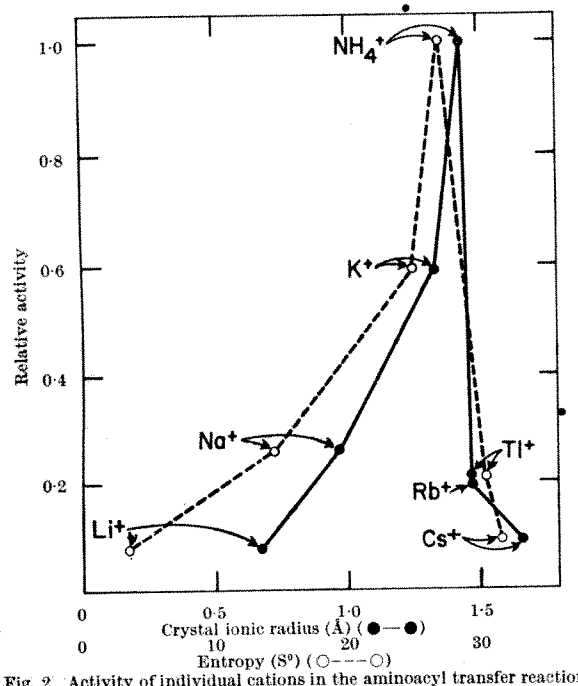

Fig. 2. Activity of individual cations in the aminoacyl transfer reaction as a function of ionic radius or of entropy. The most active cation, NH_4^+, is assigned a value of 1·0; all others are calculated from the percentage of activity at the optimal ion concentration, compared with NH_4^+. Values for Å and S° are taken from *Handbook of Chemistry and Physics* (forty-fifth ed., edit. by West, R. C., Selby, S. M., and Hodgmans, C. D.; The Chemical Rubber Co., Cleveland, Ohio, 1964–1965).

The significance of these physico-chemical characteristics in terms of the role of monovalent cations in protein synthesis remains to be determined. The role(s) of the monovalent cation in protein synthesis have not been firmly established. Studies on aminoacyl transfer in *E. coli* indicate that K^+ or NH_4^+ is involved in the binding of aminoacyl *s*RNA to polyribosomes, before peptide-bond synthesis[5,9]. Preliminary experiments in this laboratory with rat liver preparations, however, suggest that a monovalent cation is involved in an interaction between one of the aminoacyl-transferring enzymes, polyribosomes and guanosine triphosphate, before the participation of aminoacyl *s*RNA.

This work was supported in part by research grants from the American Cancer Society and the U.S. Public Health Service. One of us (K. M.) is the recipient of a career award of the U.S. Public Health Service.

Effect of Oestrogen on the Small Pigmented Spots in Hamsters

IN Syrian golden hamsters pigmented melanocytes of the skin are mainly restricted to the hair bulbs and occasional networks surrounding pilosebaceous units[1]. These melanocytic networks are seen as small pigmented spots in whole mounts of hamster skin. Because these spots bear some resemblance to melanotic naevi in man[2], and develop into melanomas when painted with chemical carcinogens[1,3] they have been the subject of extensive investigations in recent years.

It is well known that diverse endocrinological factors affect pigmentation in man and other animals. This, combined with the fact that small pigmented spots occur more frequently in the female than the male, led us to try the effect of oestrogen on these pigmented spots.

Eighteen male hamsters between twelve and fifteen months old were used in the experiment. The animals

were divided into nine pairs such that the difference in the age of the animals in each pair was less than 3 days. Two 15 mg implants of hexosterol were introduced subcutaneously in the scapular region of the experimental member of each pair. Three months later five pairs of animals in which the hair follicles were in telogen were killed and the skins collected.

On examination of whole mounts made from the skins of these animals it was obvious that the experimental procedure had produced an indubitable increase in both the number and size of the small pigmented spots. Figs. 1 and 2 illustrate this point. The mechanism by which oestrogenic stimulation produces an increase in the number of small pigmented spots is, however, obscure. Here also, as in the case of the increase seen with age[1], the question remains whether this results from the production and migration of new melanocytes or the accumulation of pigment in pre-existing ones.

Another interesting change observed in all experimental animals was that the costovertebral spot was much reduced in size (Figs. 1 and 2). This was found to result from atrophy of the large sebaceous glands normally found in this situation. The status of the melanocytes in this region could not be accurately determined by the methods used, but it is our impression that neither overt regression nor stimulation occurs.

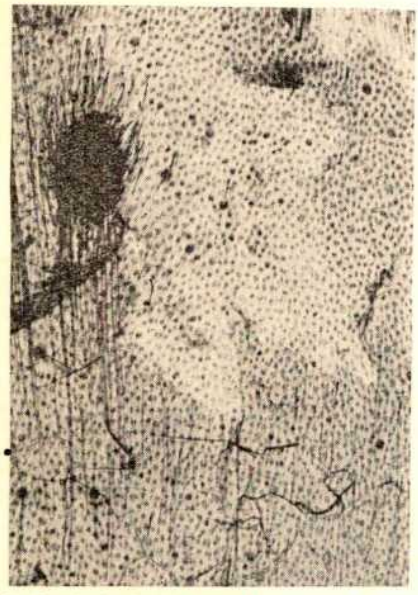

Fig. 1. Skin of control animal showing the left costovertebral spot and a few small pigmented spots.

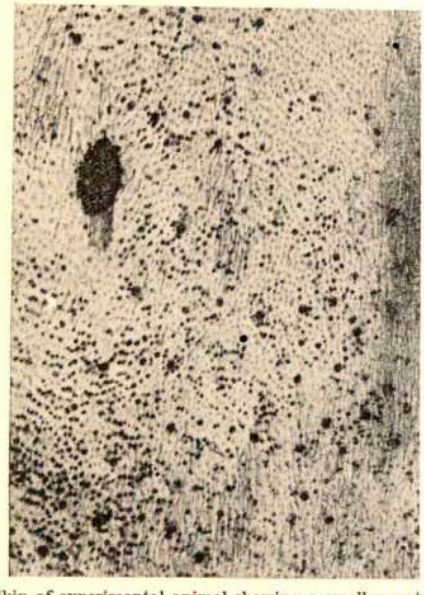

Fig. 2. Skin of experimental animal showing a smaller costovertebral spot but numerous small pigmented spots.

Nuclear Magnetic Resonance Spectroscopic Studies of the Interaction of Phospholipids with Cholesterol

PHOSPHOLIPIDS are important constituents of cell membranes and constitute up to 40 per cent of the dry weight of the brain. We are at present studying the properties of these molecules, using a variety of physical techniques[1] including nuclear magnetic resonance spectroscopy. This is a particularly useful technique since broad line nuclear magnetic resonance spectroscopy can be used for studying molecular motion in the solid and liquid crystalline condition[2], and high resolution techniques[3] can be used to study the detailed interactions of these molecules.

An interaction of considerable biological importance is that of cholesterol with phospholipids. Cholesterol occurs in many membranes, particularly in the myelin sheath and red blood cell membranes, but its precise function and arrangement are not understood. The biochemical importance of the solubilization of cholesterol by phospholipid and its vehicular possibilities have been discussed[4]. Monolayer studies[5,6] have shown that cholesterol, when present in molar equivalents, has a marked effect on the expanded film obtained with unsaturated lecithins (phosphatidylcholines), producing a more condensed film and showing a decrease in the molar area per lecithin molecule.

We have now examined, with high resolution nuclear magnetic resonance spectroscopy, some aqueous systems containing 5 per cent by weight of egg yolk lecithin (EYL) and also a mixture containing 5 per cent by weight of EYL + 2·5 per cent by weight of cholesterol, both of which have been dispersed by ultrasonic radiation[7].

Egg yolk lecithin contains a mixture of saturated and unsaturated hydrocarbon chains. We have shown, by broad line nuclear magnetic resonance studies, that at the temperature at which the high resolution spectra were taken (33·5° C), the material is in a liquid crystalline phase and that the hydrocarbon chains are highly mobile. When the material is placed in water it swells to give myelin forms and tubes. It emulsifies by a simple fragmentation of the myelin forms[8]. These myelin forms can be broken down by the process of ultrasonification into smaller particles or aggregates of molecular weight about 5×10^6 which give optically clear solutions which remain stable for periods as long as a week. The high resolution nuclear magnetic resonance spectra of these aqueous systems (deuterium oxide) have been obtained with a Perkin–Elmer *R*.10 spectrometer at 33·5° C, using 3-(trimethylsilyl)-1-propane sulphonic acid sodium salt (TSS) as a reference material. The two spectra are shown in Fig. 1. The spectrum of EYL dispersed in water (Fig. 1*A*) shows peaks which can be assigned to the various proton groupings present in the molecule. The spectrum is quite similar to that which is observed when the material is dissolved in a solvent such as chloroform; for example, the CH_2 and CH_3 chain protons, the $\overset{+}{N}Me_3$, CHO, CH_2O and $CH_2-\overset{O}{\overset{\|}{C}}$ protons all show distinct peaks, the major difference in the spectrum being in the greater

width of the peak associated with the protons present in the hydrocarbon chain at τ 8·75 p.p.m. Also the peak corresponding to the $\overset{+}{N}(CH_3)_3$ protons is shifted by 0·17 p.p.m. to τ 6·77 p.p.m. from its observed position for EYL dissolved in chloroform[3].

The nuclear magnetic resonance spectra indicate that the nuclear magnetic interactions are being averaged out and that the lecithin molecules in this aqueous phase must have a high degree of mobility comparable with molecules in a liquid state. They further indicate that, while the CH_2 groups of the chains are highly mobile, the values of the spin–spin relaxation times T_2 in water and chloroform (which are related to the line widths) are significantly different, indicating that the water is inhibiting the chain motion in some way.

In the spectrum (Fig. 1*B*) of the 1 : 1 mixture of the lecithin with cholesterol, the major peak arising from the protons associated with the hydrocarbon chains of the lecithin has now disappeared. Only a broad peak is observed in this region, τ 9 p.p.m., which, because of its small area, could arise solely from the protons present in cholesterol. It is not possible to compare the spectrum directly with that of cholesterol in water because cholesterol cannot be dispersed alone. Cholesterol in chloroform, however, shows peaks in the same region as the broad peak referred to already. Further studies with a time averaging computer should provide information about this and the extent of fine structure from these protons. The peak associated with $\overset{+}{N}(CH_3)_3$ protons of the lecithin remains in the spectrum, it has the same chemical shift value and is only slightly broadened from its appearance in the spectrum of lecithin dispersed alone in water.

This demonstration of a selective change in the T_2 relaxation times of protons in different parts of the molecule, and hence a selective change in their correlation times[9], appears to be evidence for the direct interaction of a portion of the phospholipid, and particularly the hydrocarbon chains, with the cholesterol molecule and for the formation of a molecular complex between phospholipid and cholesterol. This is consistent with our recent comment[10] that, if the expanded nature of the phospholipid monomolecular films arises mainly as a consequence of the molecular motion of the hydrocarbon chains, a feature of the cholesterol interaction with phospholipids is to inhibit some of this chain motion. There are other alternative possibilities, however, which might also explain this phenomenon, such as an increase in solution viscosity or an increase in hydrocarbon chain interactions produced by the presence of the cholesterol which we are examining.

Although there have been various speculations[11,12], the exact nature of the interaction between phospholipids and cholesterol is still not known and the various models proposed differ considerably. We are carrying out further nuclear magnetic resonance studies on this phospholipid cholesterol system, including the measurement of relaxation times at differing temperatures and phosphorus-31 resonance spectra, which should help to clarify the nature of the interaction.

HAEMATOLOGY

Chemical Characterization of Haemoglobin G_{St-I}

AMONG the genetic variants of adult human haemoglobin, some thirteen amino-acid substitutions have been described which occur along the primary sequence of the α-polypeptide chain. The most widespread and frequently encountered α-chain variant is the substitution of lysine for asparagine in the 68th residue of haemoglobin A (ref. 1). A structural mutation leading to the substitution of asparagine by lysine in a protein can be the direct result of a single nucleotide base alteration within the triplet code. Here an alteration in triplet AAU or AAC specifying asparagine could result in AAA or AAG which code for lysine[2]. Haemoglobin variants carrying a substitution of lysine for asparagine in the 68th residue of the polypeptide chain have been described in Negro families living in Philadelphia[1], Bristol[3], Azuokoli, St. Louis, Washington and Baltimore[4], and Knoxville[5].

The haemoglobin described in the present work was found in a member (J. D.) of a Negro family living in Marlin, Texas, and was first characterized electrophoretically and chromatographically by Schneider and Haggard[6]. These properties of the Texas variant were found to be identical with those of a variant found simultaneously by Lehmann *et al.* in a woman and her daughter in a West African Negro tribe and designated as Stanleyville I (ref. 7). Accordingly, the Texas variant was designated as G_{St-I}. The object of the present investigation was to identify the amino-acid substitution in Hb G_{St-I}. Fingerprints of haemoglobin G_{St-I} and A

Table 2. N-TERMINAL AMINO-ACIDS IN αTVIII, IX IN HAEMOGLOBINS A AND GSt-I

Haemoglobin A	DNP-derivative	$O.D._{340}$	Haemoglobin GSt-I	DNP-derivative	$O.D._{340}$
αT VIII, IX	Lysine	0·16	αT VIII, IXa, αT I, II, αT IXb	Lysine	0·15
αT I, II	Valine	0·19		Valine	0·17
				Alanine	0·25

revealed an alteration in three positions of the peptide patterns of G_{St-I} (Fig. 1). Peptide αTIX was absent from the neutral peptides on the fingerprint, a finding that was particularly conspicuous after staining with Pauly's reagent. Peptide αTIX of Hb G_{St-I} had split into two fragments, a and b. Close examination of the portion of the fingerprint containing peptide αTI, II revealed the presence of another peptide, αTVIII, IXa, in G_{St-I}. The tryptic peptides αIX and αVIII, IX are composed of residues 62–90 and 61–90, respectively, in the α-polypeptide chain. Because trypsin does not consistently cleave both lysyl residues, 60 and 61, both types of peptides, αVIII, IX (with an additional lysine) and αIX appear in fingerprints of haemoglobin digests. From the tryptic digest of G_{St-I} it was possible to obtain αTIXb free of contaminating peptides; however, αTVIII, IXa migrated on fingerprints in the same position as αTI, II. Thus, although N-terminal analyses and amino-acid analyses were performed on purified preparations of αTIXb, it proved necessary to perform the analyses on mixtures of αTI, II and αTVIII, IXa from G_{St-I}. Peptide αTI, II was analysed so that its amino-acid values could be subtracted from the amino-acid analysis of that area of G_{St-I} fingerprints containing both αTI, II and αTVIII, IXa (Table 1). One residue of asparagine, which was converted to aspartic acid during hydrolysis, has been replaced in G_{St-I} by a residue of lysine.

N-terminal amino-acids were identified by two-dimensional chromatography using toluene and phosphate as the solvents. Standard solutions of dinitrophenyl (DNP) derivatives were included on each chromatogram. N-terminal analyses of peptides αTVIII, IX of haemoglobin A and αTI, II plus αTVIII, IXa and TIXb of haemoglobin G_{St-I} are summarized in Table 2. Both αTVIII, IX of haemoglobin A and αTVIII, IXa of haemoglobin G_{St-I} have N-terminal lysine residues; however, αTIXb from G_{St-I} was shown to have an N-terminal alanine, which occurs as the 69th residue[9] immediately following the site of the amino-acid substitution of lysine in this variant. The cleavage by trypsin at the peptide bond between the 68th and 69th residue was responsible for the new peptide αTIXb the N-terminal of which was alanine.

Haemoglobin G_{St-I} is, therefore, identical with haemoglobin $G_{Philadelphia}$ and can be formulated $\alpha_2{}^{68}\,\text{lys}\,\beta_2\text{A}$.

Importance of the Mechanisms of Blood Coagulation in the Breakdown of Adenosine Triphosphate in Blood

THE data presented in this communication demonstrate that the degradation of adenosine triphosphate (ATP) in whole blood, initiated by the damaged wall of a blood

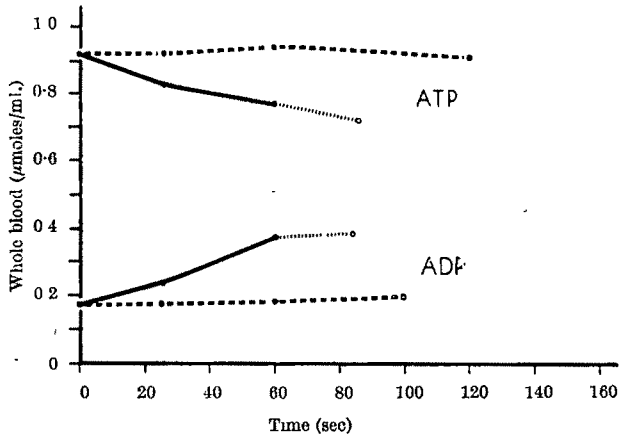

Fig. 1. The top pair of lines represent concentration of ATP obtained by separation of adenosine nucleotides by thin-layer chromatography, while the lower pair of lines represent concentrations of ADP obtained by the same means. The levels from a test-tube containing native whole blood are depicted by the broken line (control) and those from a test-tube containing native whole blood and pieces of guinea-pig aorta are depicted by the solid line. In four of the six experiments the blood in the test-tube containing the vessel wall clotted after 60 sec and no samples of blood could be taken which is indicated by the dotted portion of the solid line. Each point on the graph represents a mean value derived from six guinea-pigs.

vessel, can only take place in conjunction with activation of the coagulation mechanisms.

Ever since it became established that platelets are aggregated by either adenosine diphosphate (ADP) or thrombin there has been much speculation on which of these components takes a more prominent role in the mechanisms of haemostasis and thrombosis. In 1960 Bettex-Galland and Lüscher[1] showed that the addition of thrombin to washed, aged human platelets results in the degradation of ATP to ADP in the platelets, which suggests that thrombin may initiate the process. From this time on, however, the actual details of the mechanism by which platelets are aggregated by ADP received so much attention that the part played by the mechanisms of coagulation in haemostasis was almost disregarded. This point of view was strengthened by Haslam's[2] finding that the aggregation of washed platelets brought about by thrombin could be prevented or arrested when ADP was depleted by altering the equilibrium of several enzyme-substrate systems. Other supporting data were provided by Spaet and Zucker[3], who described the sequence of events leading to aggregation of platelets in contact with collagen fibres, in the omentum of platelets first adhered to the connective tissue and then to each other. As the latter process still occurred in the presence of heparin, these investigators concluded that thrombin does not have a role in the aggregation of platelets, and later they were able to isolate ADP from this system using paper chromatography. Marr, Barboriak and Johnson[4] have since demonstrated the simultaneous occurrence of two major changes appearing during bloodshed following the transection of small arterioles in the mesenteries of guinea-pigs. They found that most of the ATP in whole shed blood was broken down to ADP in 70 sec and in electron micrographs much fibrin could be seen adjacent to the bleeding end of the vessel a mere 30 sec after the haemorrhage had begun. Honour and Mitchell[5] showed that exogenous addition of extracts of red blood cells to vessels undergoing minor injuries resulted in the formation of platelet aggregates which blocked the vessels.

In our experiments 1 in. of aorta, dissected from a 400–450 g guinea-pig, was cut into five pieces and placed in a siliconized test-tube containing 2·0 ml. of iced, native, whole blood drawn by heart puncture from another large guinea-pig. A similar portion of blood served as control. 0·2 ml. samples of blood were drawn into pipettes and delivered into test-tubes containing 0·2 ml. of 10 per cent cold trichloroacetic acid and the adenosine nucleotides were separated by thin-layer chromatography according to Randerath[6], and quantitated by spectrophotometry. A detailed description of our use of these techniques has been published previously[4]. Standards of adenosine nucleotides were included in each experiment.

The results of ATP and ADP assays in native, whole blood at designated intervals after addition of injured vessel wall are shown in Fig. 1. It can be seen that the concentration of ATP fell while that of ADP increased proportionally for 60 sec. Only two values were obtained at 85 sec (indicated by the broken line) as the blood containing the pieces of artery clotted soon after 1 min while the blood in the control tube did not clot for more than 4 min. To obtain these results it was necessary to incubate a large amount of vessel wall with very little blood so the components from the injured vessel wall responsible for these alterations could bring about measurable changes in the concentrations of the adenosine nucleotides.

As can be seen in Fig. 2, 9 mg of ethylenediamine tetracetic acid (EDTA) added to 4 ml. of whole blood inhibit the degradation of ATP brought about by the injured arterial wall. No significant changes in the concentrations of ATP and ADP were observed when the pieces of artery were added to blood anticoagulated with EDTA and no coagulation occurred afterwards in either the blood in the experimental tube containing the blood vessel or the blood in the control tube.

EDTA not only acts as an anticoagulant by chelating sufficient calcium in the plasma to prevent activation of prothrombin but also removes so much calcium that ADP fails to aggregate the platelets—a reaction that requires only very low concentrations of calcium. A compound was therefore sought that would inhibit the activation of prothrombin but not the aggregation of platelets by ADP. Sodium citrate was tried but this compound was found to reduce greatly the total amounts of ATP and ADP in whole blood below those observed in all our previous experiments, perhaps by an inhibitory action on the metabolism of the red blood cell. Sodium oxalate was unsuitable because this compound has an inhibitory action on the activity of enzymes. Heparin was finally chosen, although its anticoagulant action is complicated.

As can be seen in Fig. 3, when heparin was added to whole blood, degradation of ATP brought about by the injured wall of the artery was inhibited and no further

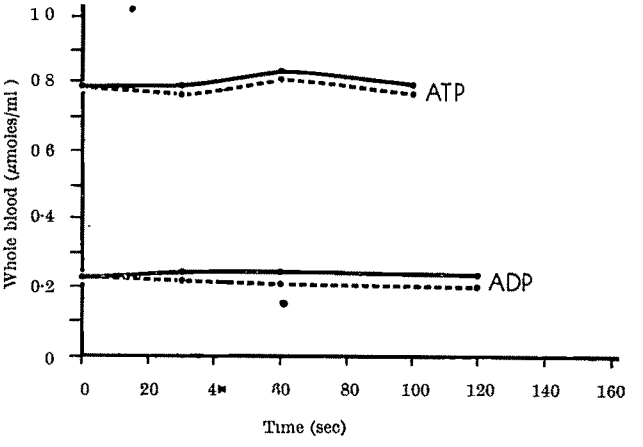

Fig. 2. The top pair of lines represent concentrations of ATP obtained by thin-layer chromatographic separation of adenosine nucleotides while the lower pair of lines represent concentrations of ADP obtained by the same means. The levels from a test-tube containing EDTA plus whole blood are depicted by the broken line (control) and those from a test-tube containing EDTA plus whole blood and pieces of guinea-pig aorta are depicted by the solid line. Each point represents six experiments.

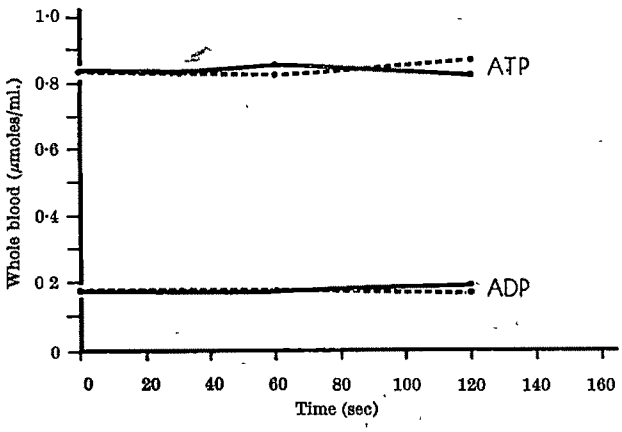

Fig. 3. The top pair of lines represent concentrations of ATP obtained by thin-layer chromatographic separation of adenosine nucleotides while the lower pair of lines represent concentrations of ADP obtained by the same means. The levels from a test-tube containing heparin plus whole blood are depicted by the broken line (control) and those from a test-tube containing heparin plus whole blood and pieces of guinea-pig aorta are depicted by the solid line. Each point represents six experiments.

increase in the concentration of ADP was observed. Similarly, no significant changes in the concentration of either ATP or ADP were observed when pieces of artery were added to blood anticoagulated with heparin. No coagulation was observed in the blood in either the experimental or control tubes.

It is evident that a long sequence of reactions must take place to achieve normal haemostasis. As any experiment can only elucidate a segment of the series it is not surprising that studies of the segment seem to be in conflict. Our findings appear to involve reactions similar to those studied by Bettex-Galland and Lüscher[1]. Spaet and Zucker[3] using a system devoid of red blood cells and containing collagen showed that ADP induced the aggregation of platelets even when the mechanisms of coagulation were depressed by heparin to such a degree that only traces of thrombin could be present. We have shown that the degradation of ATP to ADP in whole red blood cells initiated by the injured arterial wall is completely inhibited when the mechanisms of coagulation are depressed by EDTA or heparin ; this observation is not necessarily at variance with those of Spaet and Zucker as our system involved different components, namely, red blood cells.

Our previous work[4] demonstrated that most of the ADP formed in whole shed blood—in fact, 90 per cent—must come from red blood cells because our electron micrographs prepared 15–25 sec after injury to the vessel wall showed too few platelets, even concentrated in aggregates, to account for the extensive degradation of ATP observed. Thus the degradation of ATP both in platelets in the absence of collagen[1] and in red blood cells seems to require activation of the mechanisms of coagulation.

This investigation was supported in part by the National Heart Institute.

IMMUNOLOGY

Effect of Thalidomide on the Graft versus Host Reaction

LYMPHOID cells from a highly inbred parental strain of rat injected into F_1 hybrids derived from that strain and another inbred strain provoke a reaction, characterized among other manifestations by a hyperplasia of the recipients' spleen and other lymphoid tissues[1]. A striking splenic enlargement can also be produced in the chick embryo by intravenous injection of adult chicken spleen cells, or peripheral white blood cells[2]. The splenomegaly in both instances is due to an attack by the inoculated immunologically competent cells directed against a host incapable of reacting against them[3–5]. The splenomegaly is part of a more generalized graft versus host (GVH) reaction and reduction of the degree of splenomegaly is therefore a measure of the inhibition of the GVH reaction[6,7].

We have investigated the effect of thalidomide on the GVH reaction in the chick embryo and in the rat (Tables 1, 2 and 3).

Chick embryo. Adult hybrids (*NIDR*) and Rhode Island Red (RIR) chickens served as donors. White Leghorn (WL) embryos were used as recipients throughout.

In determining the effect of recipient treatment, blood was obtained by cardiac puncture from untreated *NIDR* birds. The citrated blood was centrifuged, the "buffy coat" removed and resuspended in sufficient plasma to give a 5–10 per cent cell suspension. The recipients were 12 days old embryos, which had grids implanted on their chorio-allantoic membranes (CAM) 4 days previously. These grids localize solutions and facilitate daily treatment[8]. The leucocyte suspension (0·05 ml.) was placed in the meshes of the grid lying on the CAM in one experiment, and injected into a vein of the CAM in another. Whole citrated blood was used with the RIR/WL combination and 0·05 ml. was injected intravenously into 14 days old embryos 6 days after implanting the grids.

L-Thalidomide dissolved in dimethyl sulphoxide (DMSO) was dropped into the central "well" of the grids at the times and doses given in Table 1. Control embryos received similar applications of 0·2 ml. DMSO only. Embryos were killed at 19 days of incubation, their spleens removed and weighed. Table 1 summarizes the results. The greater splenomegaly obtained with RIR than with *NIDR* donors indicates a greater antigenic difference in the RIR/WL combination.

Embryos treated with L-thalidomide before being injected with RIR blood developed the usual splenomegaly (106 mg compared with 91 mg for controls). Splenomegaly was also not inhibited when thalidomide treatment was continued after injection of donor cells, although these embryos received a total of 20 mg of L-thalidomide.

Similar treatment of embryos inoculated with *NIDR* leucocytes, in which splenomegaly was weaker, also failed to influence the course of the reaction.

In a series of experiments to determine the effect of treatment of donor blood, citrated blood incubated with thalidomide was given intravenously to recipients, which were themselves otherwise untreated. About 10 ml. of blood was collected from the wing vein of one RIR donor. Portions 2·5 ml. in volume were centrifuged and 0·25 or 0·375 ml. of the plasma removed. The volume was then restored (to 2·5 ml.) with DMSO (controls) or a solution of D,L-, L- or D-thalidomide in DMSO (treated). The final concentration of thalidomide was 7·5–10 mg/ml. and that of DMSO, 10–15 per cent. The solutions were added dropwise to the cell suspensions which were then incubated at room temperature for approximately 1·5 h. After incubation, the cell suspensions were injected (0·1 ml.) into groups of 14-days-old embryos. Embryos were killed 6 days after injection, their spleens removed and weighed. The results are summarized in Table 2.

Table 1. EFFECT OF L-THALIDOMIDE ON SPLENOMEGALY (GVH REACTION) IN THE CHICK EMBRYO. TREATMENT OF RECIPIENTS ONLY

Donor	Cells	Route	TH treatment	Daily dose (mg)	Survival	Mean spleen wt. ± *S.E.*
NIDR	5 per cent suspension "Buffy coat" cells	CAM-(grid) at 12th day	At 8th, then from 12th to 16th day	0·5	9/11	51 ± 30
				1·0	11/13	37 ± 15
				DMSO	8/10	45 ± 32
NIDR	10 per cent suspension "Buffy coat" cells	CAM-(intravenous) at 12th day	From 12th to 17th day	2 0	12/13	39 ± 22
				DMSO	12/14	39 ± 27
RIR	Whole blood	Intravenous at 14th day	From 9th to 13th day	2·0	11/14	106 ± 89
			From 9th to 19th day	2·0	11/15	119 ± 65
			From 9th to 19th day	DMSO	13/14	91 ± 54

S.E., Standard error. No significant difference between treated and controls in any group.

* Thalidomide 1·25 mg/g daily, suspended in 0 5 per cent carboxy-methyl cellulose (CMC) in physiological saline. Donors and recipients treated for 4 days before spleen cell transfer; recipients for 5 days after.

† Normal range: 450–550 mg.

‡ Significance of difference (*t* test) from the corresponding control value. *N.S*, Not significant ($P > 0·10$).

Incubation of donor blood with D,L-thalidomide at 10 mg/ml. considerably reduced the splenomegaly. The reduction was highly significant ($t = 2·995$; $P \ll 0·01$) despite the wide range of spleen weights in the control and treated embryos. Inhibition of splenomegaly also occurred after incubation with 7·5 mg/ml. D,L-thalidomide, although this was barely significant ($t = 2·2564$; $0·05 > P > 0·02$) as was the inhibition produced with L-thalidomide at 10 mg/ml. ($t = 2·1718$; $0·05 > P > 0·02$). No inhibition of splenomegaly was observed with 7·5 mg/ml. D,L-thalidomide when the DMSO level was reduced to 10 per cent.

By contrast with D,L- and L-thalidomide, incubation of blood with 10 mg/ml. D-thalidomide failed to have any effect on the splenomegaly produced.

Rat. Adult Marshall rats were the donors and (Marshall × August) F_1 hybrids the recipients. Hybrids were treated with D,L-thalidomide (1·25 g/kg body-weight) daily for 4 days before and 5 days after the intraperitoneal injection of paternal (Marshall) strain spleen cells. The thalidomide was administered either orally or intraperitoneally, as a suspension in 0·5 per cent carboxymethylcellulose (CMC) in physiological saline. Control hybrids received either CMC solution alone, or no treatment. Donor rats were given thalidomide, in the same dosage schedule, intraperitoneally for four days before transplantation of their spleens or were untreated. Spleen cell suspensions were prepared by mincing freshly excised spleens with scissors, straining through 150μ copper mesh and suspending the dispersed cells in Ringer's solution. Each hybrid received the equivalent of half a spleen. Nine or ten days after injection of the cell suspension, the hybrids were killed, their spleens excised and weighed. The hybrids weighed 130–170 g and the Marshall rats 160–180 g, but within any one experiment the hybrids (6 per group) were approximately matched for size, as were the Marshall rats. With the strain combination used here the size of the hybrid's spleen on the ninth or tenth day is related linearly to the number of parental strain lymphoid cells injected and is independent of the weight of the animal within the range specified[1]. With this combination of strains there is also no sex difference with respect either to the effectiveness of spleen cells or to response; data for both sexes have therefore been pooled[9].

Table 3 summarizes the results of five experiments. There was a highly significant ($P \ll 0·1$) reduction in splenomegaly in hybrids treated with thalidomide by the oral route, when the lymphoid cell donors had also been pre-treated with the drug (experiments 1 and 2). When donors had not been pre-treated, a less significant ($P = 0·04$) reduction in spleen size was obtained in one experiment and no reduction in another (experiments 2 and 3 respectively). Treatment of the hybrids with the solvent (CMC) alone whether orally or intraperitoneally had no effect on the severity of the GVH reaction (experiment 3).

Less consistent results were obtained when thalidomide was given by the intraperitoneal route. In experiment 4 a very significant ($P < 0·01$) reduction in splenomegaly was produced, but pre-treatment of donors with thalidomide had no effect on the response either of treated or of untreated hybrids. In experiment 5, however, thalidomide apparently failed to diminish the GVH reaction. This variability may be due to non-specific immunological effects of repeated intraperitoneal injections of particulate material.

Interpretation of the results of oral administration of thalidomide would appear to be less ambiguous. Nevertheless, it may be argued that pre-treatment of donor rats intraperitoneally could reduce the potency of their lymphoid cells. In experiment 2, however, a significant reduction in splenomegaly was obtained even when donors had not been pre-treated. Moreover, in experiment 4 pre-treatment of donors was shown to be without effect in untreated hybrids. These results therefore indicate that when thalidomide is given orally to F_1 hybrid rats the GVH reaction evoked by challenge with parental strain lymphoid cells is significantly reduced, and that this effect is enhanced if the lymphoid cell donors are also pre-treated with the drug.

It is evident, therefore, that thalidomide is able to reduce significantly the severity of the GVH reaction in the chick embryo and the rat, though not to suppress it completely. This is in line with findings on the rejection of skin homografts[10] and on the development following a skin homograft of immunoblasts in the draining lymph node[11].

Immunological Unresponsiveness in Adult Rats to the Nematode *Nippostrongylus brasiliensis* induced by Infection in Early Life

ALTHOUGH it is known that mature animals may develop a marked degree of acquired immunity to infection with many species of parasitic nematodes[1,2] the occurrence of immunological unresponsiveness in adult animals, either under field or experimental conditions, has not been definitely established. Observations resulting from experiments with *Mesistocirrus digitatus* in calves[3] and *Haemonchus contortus* in sheep[4] indicated the possible occurrence of tolerance in these infections and formed the basis for a series of experiments with *Nippostrongylus brasiliensis*—a parasite of rats.

Adult rats infected subcutaneously with five hundred or more *N. brasiliensis* larvae acquire a striking immunity to this parasite during the course of the infection[5]. This is manifested towards the end of the second week by a "self-cure" reaction, during which there is a sharp fall in egg production by the parasites, followed over a period of a few days by expulsion of most of the worms from the intestine of the host (see Table 1). The animals are subsequently immune to re-infection.

Table 1. WORMS IN INTESTINE OF BABY AND ADULT RATS INFECTED WITH FIVE HUNDRED *N. brasiliensis* LARVAE

Age at Infection	Days after infection 10 Mean	*S.E.*	26 Mean	*S.E.*
3–4 weeks	177	20	215	28
3–6 weeks	195	23	210	35
Adult	118	31	33	6

In the course of a series of experiments with baby rats, we have found that an infection of *N. brasiliensis* acquired during the first 6 weeks of life is not eliminated in this characteristic fashion and persists well into adult life. In experiment 1, two groups of baby rats were infected subcutaneously with five hundred larvae. These groups were aged 3–4 weeks and 5–6 weeks respectively. The results of worm counts at autopsy on days 10 and 26 are listed in Table 1 and show that the infection had not been eliminated by day 26.

In the second experiment, which was designed to ascertain the duration of the primary infection in baby rats, five litters aged between 2–3 weeks received five hundred larvae per rat. Table 2 shows the results of worm counts of the rats autopsied on days 52, 67 and 87 after infection. Even on these dates it is apparent that the rats had still not undergone the typical self-cure reaction; autopsies of comparably infected adult rats on day 52 yielded a range of 0–5 worms. In view of the fact that a very strong immune response is normally developed within 2 weeks by rats 4–5 weeks younger than those on the date of last autopsy, these results cannot be attributed to immunological immaturity.

Table 2. WORMS IN INTESTINES OF RATS INFECTED AT 2–3 WEEKS OF AGE WITH FIVE HUNDRED *N. brasiliensis* LARVAE

	Days after infection 52	67	87
Mean	143	140	83
S.E.	12	15	18

On day 52 of the infection, a group of these rats was challenged with an infection of 3,000 larvae together with a control group of uninfected rats of the same age. Both groups appeared to be equally susceptible to infection in that the faecal egg counts rose to similar peaks 8 days after infection; on day 10, autopsies of both groups showed similar numbers of worms. Subsequently both groups underwent a typical self-cure reaction. The results of this challenge infection showed that the first infection given when young had not stimulated the high degree of immunity to re-infection characteristic of adult rats. On the other hand, the immunological unresponsiveness which allowed the persistence of the primary infection did not interfere with the immune response to the challenge infection and this occurred in a manner similar to that of rats which are experiencing a primary infection. A superficially similar situation is known to exist in hamsters infected neonatally with the oncogenic *SV* 40 virus[6].

The persistence of the primary infection is unlikely to result from failure of an immunologically mature rat to experience larval antigen since rats of 8–10 weeks which are infected by laparotomy with an adult worm population approximate to that in our unresponsive rats undergo a characteristic self-cure within 2 weeks[7].

Because the ability to self-cure and protect against re-infection can be transmitted with circulating antibody obtained from adult rats which have undergone self-cure, it is necessary, when considering a mechanism for the induction of unresponsiveness, to determine the immunizing ability of sera from infected baby rats. This is being investigated but it would be surprising if these contained protective antibody. We do know, however, that reaginic antibodies as described by Ogilvie[8] appear in the serum of these baby rats 3–4 weeks after infection and that the titre subsequently rises to as high a level as is found in adults following a similar infection. Also intestinal anaphylaxis can be induced in baby rats 3–4 weeks after infection by the intravenous injection of *N. brasiliensis* antigen, this reaction being as marked as that seen in adult rats[9]. Although it is possible that the persistence of this nematode infection during the adult life of the rats is due to acquired immunological tolerance in the classical sense, that is, non-recognition of antigen[10], this seems an improbable explanation in view of the high reaginic titre and the development of a typical immune response after a heavy challenge. Because a number of studies in different species have suggested that the earliest response of the young animal involves macroglobulins[11,12], we have considered it possible that the immune response of the young rat is perhaps initially confined to the production of a limited type of globulin, including reagins. If this is so, one might speculate that these antibodies could subsequently combine with antigen produced by the persisting adult infection in such a way that it is either neutralized or used solely for the stimulation of further synthesis of reagins. This state might cease and immunological competence be established when the rats are heavily challenged because relatively massive amounts of antigen would become available to the host in excess of that capable of reacting with reagin-type antibodies.

The unfixed antigen would then be available for stimulation of a normal immunological response.

PATHOLOGY

Adrenal Necrosis induced by 7-Hydroxymethyl-12-methylbenz(a)anthracene and its Prevention

THIS communication reports our investigation of the action of 7-hydroxymethyl-12-methylbenz(*a*)anthracene (7-OHM-MBA) on the adrenal glands of normal rats and of rats treated by methods that protect the adrenal glands against 7,12-dimethylbenz(*a*)anthracene (9,10-dimethyl-1,2-benzanthracene, or DMBA)[1,2].

After treatment of rats with large doses of DMBA, the zona fasciculata and the zona reticularis are destroyed[3] Recent experiments[2,4] have demonstrated that rats with impaired liver function are protected from the adrenocorticolytic effect of DMBA, and it has been postulated that a metabolite of DMBA, and not DMBA itself, is responsible for adrenal necrosis. The metabolism of DMBA has been investigated and hydroxymethyl compounds identified as metabolites[5]. Synthetic derivatives of DMBA have been tested for their effect on the adrenal glands: while 12-hydroxymethyl-7-methylbenz(*a*)anthracene has no adrenocorticolytic property, 7-OHM-MBA is more potent than DMBA in producing adrenal necrosis[6].

Accredited female Sprague–Dawley rats bred from a specific pathogen-free stock were used; they were obtained from Oxford Laboratory Animal Colonies. Their diet was Thompson rat cake containing 14 per cent skimmed milk supplied by North-Eastern Agricultural Co-operative Society, Ltd., Aberdeen. 7-OHM-MBA was dissolved in arachis oil (10 mg/ml.), and administered by stomach tube. Rats were killed 3 days after treatment; adrenal glands were weighed and fixed in 4 per cent neutral buffered formaldehyde. One gland of each pair was embedded in paraffin wax and 5μ sections were stained with haematoxylin and eosin. Liver sections stained with haematoxylin and eosin were also prepared.

Methods previously shown[1,2] to protect the adrenal glands of rats from DMBA were used: (*a*) Carbon tetrachloride: Rats were treated with 0·3 ml. of a 50 per cent (v/v) solution in olive oil intraperitoneally 24 h before challenge with DMBA or 7-OHM-MBA. (*b*) Partial hepatectomy: Two-thirds of the liver was removed as in previous studies 24 h before challenge with DMBA or 7-OHM-MBA. (*c*) 2-Methyl-1,2-*bis*-(3-pyridyl)-1-propanone ('Metopirone' pure base, Ciba): Rats were given three doses of 10 mg 'Metopirone' in 0·2 ml. olive oil intraperitoneally at 4-h intervals[7] and the challenge of 7-OHM-MBA or DMBA given 4 h after the final dose. Later, rats were given either 15 mg 7-OHM-MBA intragastrically or 3 mg DMBA intravenously (these have been found to produce comparable degrees of adrenal damage) and killed 3 days later.

Action of 7-OHM-MBA on normal intact 50-day Sprague–Dawley rats. Doses of from 5 to 20 mg were given intragastrically to rats of 50 days of age (Table 1). Fifteen milligrams of 7-OHM-MBA intragastrically has the same effect on the adrenal glands as a dose of 35–40 mg DMBA intragastrically or 3·0–3·5 mg DMBA intravenously: thus 7-OHM-MBA is two to three times more potent than DMBA. This is slightly less than previously reported[6] and may result from differences in the stock of rats and/or diet. Damage to the adrenal glands occurs first in the zona reticularis after treatment with DMBA, whereas with 7-OHM-MBA early changes are frequently seen throughout the whole of the zona fasciculata and zona reticularis. The zona glomerulosa may show congestion with both compounds but necrosis has not been seen in this zone with either of them. Rats given 7-OHM-MBA, even up to a dose of 20 mg, appeared healthy, maintained body weight and did not have diarrhoea: this compound is much less toxic than the parent compound, DMBA.

Table 1. INCIDENCE OF ADRENAL NECROSIS IN 50-DAY SPRAGUE–DAWLEY FEMALE RATS TREATED WITH 7-OHM-MBA

Dose (mg)	No. of rats	No. sick	Incidence of severe adrenal necrosis	Weight of adrenal glands (mg) (±S.D.)
5	9	0/9	0/9	21·3±3·4
10	10	0/10	8/10	29·6±9·6
15	10	0/10	9/10	31·1±6·1
20	5	1/5	5/5	33·4±3·4

7-OHM-MBA treatment of "protected" rats. (*a*) *Carbon tetrachloride:* In view of our previous finding[2], which showed the importance of normal liver function for the development of adrenal necrosis after DMBA treatment, we have "protected" rats with carbon tetrachloride and treated them with 7-OHM-MBA or DMBA. The results are shown in Table 2: as would be expected from our previous studies[2], the incidence of severe adrenal necrosis is low in rats treated with DMBA, but the incidence with 7-OHM-MBA is the same as in the control rats given 15 mg derivative (see Table 1). (*b*) *Partial hepatectomy.* This also protects rats from adrenal necrosis induced by DMBA administration[2]. The effects of operation 24 h before treatments with DMBA and 7-OHM-MBA are compared in Table 2. Again, the incidence of severe adrenal necrosis remained high in rats given the derivative while partial protection was achieved in rats given DMBA. (*c*) '*Metopirone*': This compound completely protects adrenal glands against 7-OHM-MBA (Table 3), and is also effective against DMBA given intravenously (Table 3).

7-OHM-MBA is two to three times more potent than DMBA in its adrenocorticolytic action when given in oil intragastrically. Although rats with impaired liver function are protected from the adrenocorticolytic effect of DMBA, they remain susceptible to adrenal necrosis induced by 7-OHM-MBA: the action of 7-OHM-MBA seems to be independent of liver function. This is additional evidence in support of the hypothesis that DMBA must be metabolized by the liver to an active adrenocorticolytic derivative—which may well be 7-OHM-MBA.

'Metopirone' gives complete protection of adrenal glands against 7-OHM-MBA and almost complete protection against DMBA given either intravenously, as here re-

Table 2. EFFECT OF IMPAIRED LIVER FUNCTION ON ADRENAL NECROSIS INDUCED BY 7-OHM-MBA OR BY DMBA

Pretreatment (24 h pre-)	Treatment	No. of rats	No. rats surviving to day +3	No. rats with massive adrenal necrosis
None	15 mg 7-OHM-MBA intragastric	10	10	9/10

ported, or intragastrically[1]. This incomplete protection against DMBA may result from the production of adrenocorticolytic metabolite after 'Metopirone' has ceased to exert its maximal inhibitory action on steroid synthesis. 'Metopirone' inhibits 11β hydroxylation and therefore interferes with the synthesis of corticosterone and cortisol[8]. It has been suggested[3] that the adrenocorticolytic action of DMBA is the result of similarity between its structure and that of corticosterone or cortisol. We have clearly established, however, that DMBA itself is not adrenocorticolytic, but it seems likely from our experiments that 7-OHM-MBA will induce adrenocortical necrosis only if there is active synthesis of corticosterone or related steroid hormones that are hydroxylated at C11.

Wong and Warner[9] have reported protection against DMBA-induced adrenal necrosis by a C17 α-hydroxylase inhibitor *SU* 9055. It will be of interest to investigate the action of this inhibitor in 7-OHM-MBA-induced necrosis.

This work was supported by a grant to one of us (A. R. C.) from the Scottish Hospital Endowments Research Trust and by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign for Research, and by a U.S. Public Health Service research grant from the National Cancer Institute. DMBA in lipid emulsion, prepared by Dr. Paul Schurr (The Upjohn Company, Kalamazoo, Mich., U.S.A.), was the generous gift of Prof. C. Huggins. Dr. T. B. Binns, of CIBA Laboratories, Ltd. (Horsham), kindly supplied us with 'Metopirone'. We thank Mrs. M. Inglis and Mr. G. Milne for their technical assistance.

PHARMACOLOGY

Combined Effects of Chlordiazepoxide and Dexamphetamine on Activity of Rats in an Unfamiliar Environment

IN previous experiments we found that, over a wide range of doses, amphetamine and amylobarbitone affected relatively little the spontaneous activity of rats in an unfamiliar environment, but that some mixtures of these two drugs greatly increased it. This somewhat surprising effect could be regarded as a result of true mutual potentiation[1,2].

Chlordiazepoxide ('Librium', Roche) is a comparatively new drug[3] which, like amylobarbitone, is widely used in the treatment of anxiety. Its effects on the activities of animals seem, in general, to be in the direction of depression; but with relatively small doses stimulation has been reported (refs. 4 and 5), and Maxwell, D. R., and Christmas, A. J., (personal communication), and this again is similar to amylobarbitone. In order to pursue the comparison, dexamphetamine was added to chlordiazepoxide in the present experiments and the effects were analysed of various mixtures on the behaviour of rats in an unfamiliar environment similar to that previously used.

Naive hooded female rats, about 120–130 days old and reared under standard conditions, were injected subcutaneously in the flank with either various doses of chlordiazepoxide alone, or with these same doses mixed with 1·18 mg/kg dexamphetamine, or with this dose of dexamphetamine alone, or with saline as control. The dose of dexamphetamine had previously been found particularly effective in combination with amylobarbitone[2]. Thirty-five minutes later each rat was tested singly for 5 min in a symmetrical Y-shaped runway[1]. Rats were used once only.

The results given here are the mean number of times the rats entered the arms of the Y with all four feet during the 5 min trial; this is a measure of locomotion, and is typically greatest when an animal is first exposed to an unfamiliar environment. Over the middle range of doses (3·3–100 mg/kg chlordiazepoxide) the mixture consistently induced more activity than the constituents alone. Maximal activity occurred with 25 mg/kg chlordiazepoxide + 1·18 mg/kg dexamphetamine (mean entries 30·7, *S.D.* 5·7), and this was significantly more than with the ingredient dose of chlordiazepoxide alone (mean 17·5, *S.D.* 7·4; $P < 0{\cdot}01$), and also more than with dexamphetamine alone (mean 18·1, *S.D.* 6·6; $P < 0{\cdot}01$), and with saline (mean 15·6, *S.D.* 6·5; $P < 0{\cdot}001$). The last three means did not differ significantly from each other.

Fig. 1 shows these results broken down into successive minutes. The most striking contrast is between chlordiazepoxide alone and the mixture. Rats treated with chlordiazepoxide were highly active during the first 2 or 3 min, but then they became immobile in a characteristic crouching position and without even moving their whiskers, though their bodies did not seem flaccid and their eyes were open. This "trance"-like state[6], interrupted by only occasional movements, usually lasted to the end of the trial and beyond, but if the runway was gently

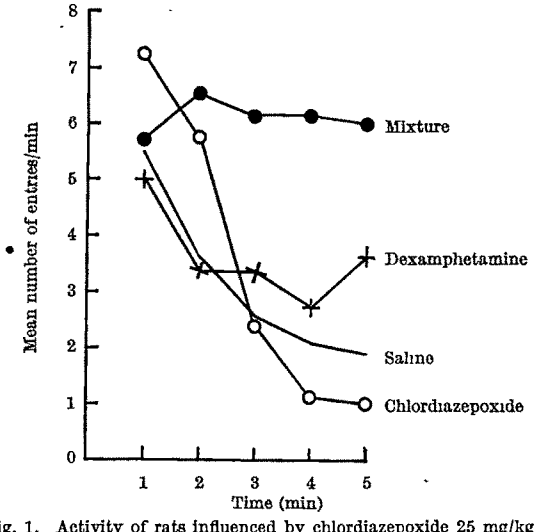

Fig. 1. Activity of rats influenced by chlordiazepoxide 25 mg/kg and dexamphetamine 1·18 mg/kg separately and in combination. The ordinate represents the mean number of entries into the arms of an unfamiliar Y-shaped runway during successive minutes of a 5 min trial by four different groups of rats: ○, chlordiazepoxide ($n = 8$); +, dexamphetamine ($n = 8$); ●, mixture ($n = 7$); —, saline ($n = 19$).

lifted away the rat would, after a few moments, "come to" and spontaneously run around the floor of the laboratory. If the rat was put back into the Y the cycle was repeated. The effect was not dependent on any sudden change in the time course of the action of the drug, because it occurred equally if rats were tested at various times other than 35 min after injection. The activity of the mixture rats, on the other hand, was high throughout the trial, and no "trances" were observed. As a measure of change in the amount of activity, the mean number of entries in the fifth minute was subtracted from the mean in the first minute. The mean change with chlordiazepoxide alone was 6·3 entries, compared with −0·3 with the mixture ($P < 0.001$), 1·4 with dexamphetamine ($P < 0.01$) and 3·6 with saline ($P < 0.01$). Similar trends were found over the whole range of doses studied except at the extremes.

Amphetamine is increasingly being found able to interact in a variety of ways with different centrally acting drugs depending on the doses and the kind of behaviour studied[1,2,7–12]. In the present case dexamphetamine prevented the sharp decline in activity which normally occurred with chlordiazepoxide and so activity was maintained evenly throughout the trial. It is unlikely that a new compound was formed by giving the two drugs as a mixture because both are strong bases. With dexamphetamine-barbiturate mixtures activity was also evenly maintained[2], and in this respect the two kinds of mixture are similar. But the decline in activity with amylobarbitone alone was much more gradual than with chlordiazepoxide, and the rats appeared sedated and sluggish and not in a "trance". The abrupt change from high activity to immobility which occurred with chlordiazepoxide and which seemed to depend mainly on length of exposure to an unfamiliar environment was unlike anything observed with amylobarbitone and is altogether behaviourally striking.

We thank Prof. A. S. V. Burgen, Prof. W. S. Feldberg and Dr. D. H. Jenkinson for discussion, Mr. J. K. Hall for statistical help and Mr. George Clarke for help in carrying out the experiments. The work was supported by a research grant from the National Institute of Mental Health, U.S. Public Health Service.

PHYSIOLOGY

Effects of Temperature on Photo-sensitivity of Spermatozoa

ADVERSE effects of light on the movement and life-span of spermatozoa have repeatedly been demonstrated[1–7]. Norman, Goldberg and Porterfield[7] were unable to detect any relationship between light effects and temperature in a few experiments by means of simple visual observational methods. A definite dependence of photo-sensitivity on temperature has now been demonstrated in specific investigations using Rikmenspoel's photo-electric method[3–6,8–11].

In nineteen series of experiments, using sixty-seven ejaculates from ten different bulls of the Dutch–Friesian and Meuse–Rhine–Yssel breeds, sub-samples of each diluted ejaculate were incubated in glass tubes placed in water baths kept at different temperatures, ranging from 5°–40° C, with 5° C intervals. Dilutions (1 : 70) were made with Rikmenspoel's ultramicroscopically clear egg-yolk–citrate medium[12], *p*H 6·75 ± 0·05 (measured at 22°–23° C, *p*H change 0·03 per cent/°C[13]).

A constant illumination of 983 ± 3 lux was maintained, using a battery of incandescent bulbs (220 V, 150 W) with internal mirrors as the light sources. The dark controls were kept in small tubes of the size of the experimental specimens, but made of brown glass, painted black, wrapped in aluminium foil and pressed into a white tube of soft plastic to avoid rise of temperature due to the heating effect of the light. The control tubes were placed alongside the unprotected glass tubes in the same water baths. All the tubes in the water baths were gently agitated by a single agitator in order to prevent sedimentation of the sperms during the treatment. A cooling tank, operated with running cold water, was placed between the water baths and the battery of lamps. The whole equipment was installed in a thermostatically controlled room kept at 5° C.

Drops were taken at regular intervals from the test-tubes and placed in the photo-electric equipment[3–6]. All recordings were made at a temperature of 37·0° C. The recordings were analysed for rates of velocity decrease with time ($-\partial\bar{v}/\partial t$) and for the rate constants k of the decrease in numbers of normally moving spermatozoa ($k_N = \mathrm{d}(\ln N)/\mathrm{d}t$) and of migration rates, the latter being defined as the product of N with the mean velocity $\bar{v}$. Over periods exceeding those of the present experiments both N and $N\bar{v}$ decrease exponentially with time

$$y(t) = y_0.\exp(-kt) \qquad (1)$$

where $y = N$ or $N.\bar{v}$, respectively[3,12]. The rate constants k_N and $K_{N\bar{v}}$ were obtained from the slopes of the regression lines on a semi-logarithmic plot.

The relationship between these three rate constants and temperature was found to fit the Arrhenius equation for temperature-dependence of the rate constants of chemical reactions

$$k = A.\exp(-E_A/RT) \qquad (2)$$

where A is a constant representing the probability that a reaction occurs, E_A, the apparent energy of activation, R, the gas constant (1·987 cal/mole degree), and T, the absolute temperature. Consequently, a linear relationship is obtained by plotting log ($-\partial\bar{v}/\partial t$), log k_N or log $k_{N\bar{v}}$ as a function of $1/T$(Figs. 1 and 2). The apparent energies of activation can be derived from the slopes of these plots. This comes out to be 18,400 ± 250 cal/mole for the samples kept in darkness and only 9,300 ± 150 cal/mole for the samples under illumination. This result clearly demonstrates the accelerating effect of light on the rate of deterioration of bovine spermatozoa.

Photo-sensitivity can now be defined quantitatively by the factor with which the rate of deterioration is increased by a constant level of illumination, I. This means that it is measured by

$$Y_I = (k_y)_I/(k_y)_{I=0} \qquad (3)$$

where k_y represents either $-\partial\bar{v}/\partial t$, k_N or $k_{N\bar{v}}$ (ref. 13).

The value of Y_I is independent of which of these parameters is chosen, and the individual values can therefore be averaged to combine the total result into a single relationship (Fig. 3). Obviously photo-sensitivity decreases with increasing temperature, vanishing at ~48° C, where $Y_I = 1$. The apparent energy of activation of the photochemical process is −3,532 cal/mole, the negative sign appearing as an indication of the light acting itself as an activator or catalyst. The apparent temperature coefficients (Q_{10}) for different regions of the temperature range are shown in Table 1.

The very low Q_{10} values of photo-sensitivity show clearly that its temperature dependence is mainly due

Table 1

Temperature range °C	Q_{10} of rate constants Darkness	Light	Q_{10} of light sensitivity
0–10	3 27	1 83	0 80
10–20	3 06	1 76	0 81
20–30	2 84	1 69	0 82
30–40	2 66	1·64	0 83

to the photochemical process itself and not to secondary thermal reactions.

Norman *et al.*[7] chose the period of time after the beginning of their observations at which movements stopped

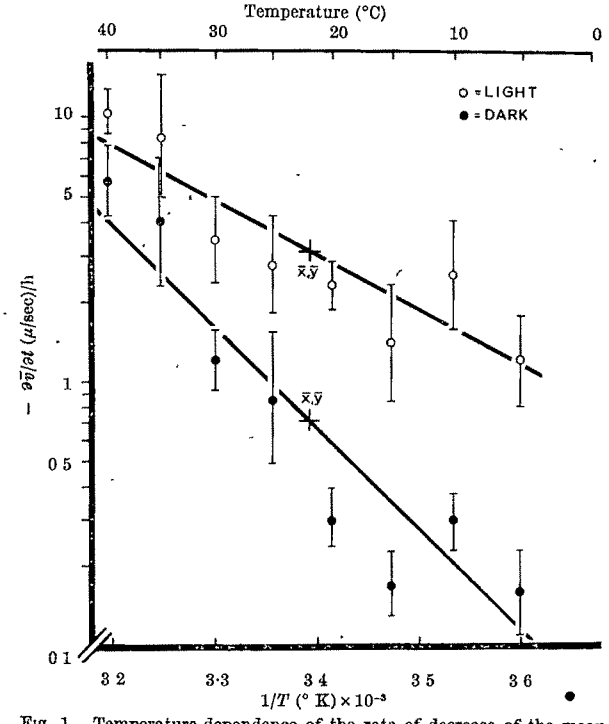

Fig. 1. Temperature-dependence of the rate of decrease of the mean velocity in (μ/sec)/h of storage of bull spermatozoa, illustrating the applicability of the Arrhenius equation (2). Ordinate logarithmic Corr. $1/T \times \log(-\partial\bar{v}/\partial t)$ (in darkness, $r = -0\,94$, under illumination at 983 ± 3 lux, $r = -0\,90$).

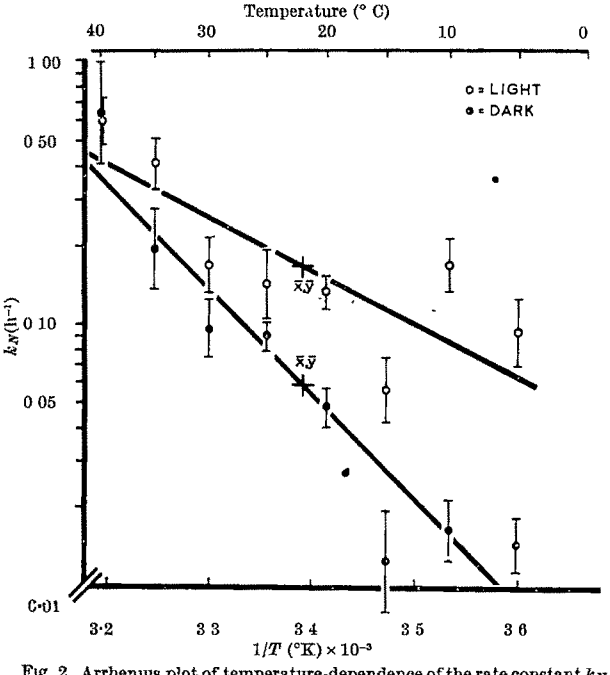

Fig 2 Arrhenius plot of temperature-dependence of the rate constant k_N of decrease of numbers of normally moving bull spermatozoa with time, under illumination at 983 ± 3 lux and in darkness Ordinate logarithmic. Corr. $1/T \times \log k_N$. (In darkness, $r = -0\,95$, under illumination, $r = -0\,78$.)

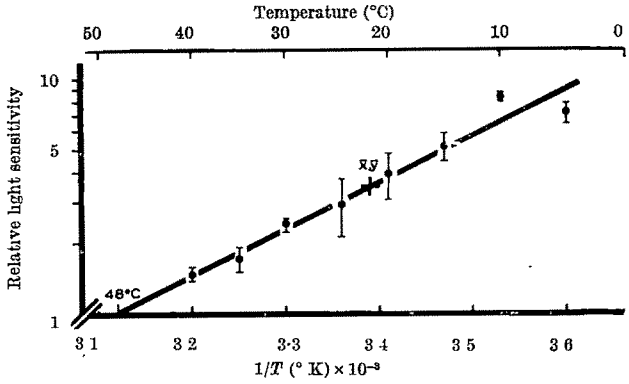

Fig 3. Arrhenius plot of temperature-dependence of photo-sensitivity of bull spermatozoa, defined as the factor by which deterioration is accelerated under a constant level of illumination of 983 ± 3 lux. Ordinate logarithmic. ($r = 0\,98$; $10^{-5} > P > 10^{-6}$.)

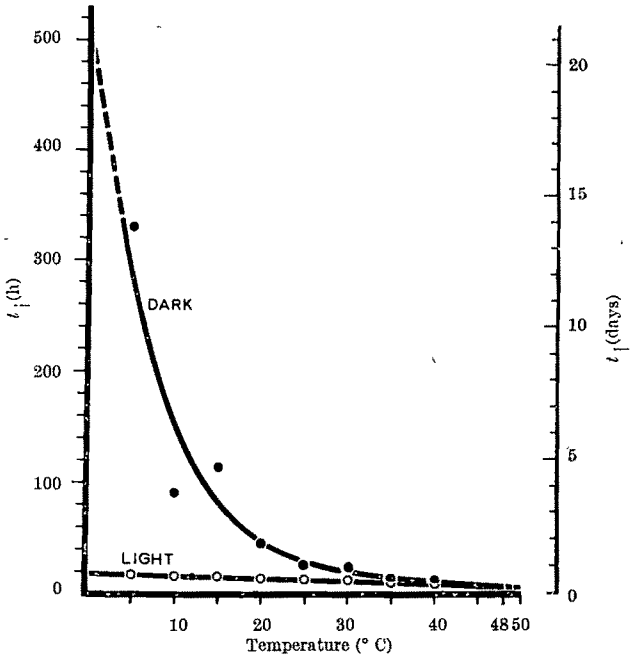

Fig. 4. Temperature-dependence of the time $t_\dagger$, after the beginning of the incubations, at which no more normally moving spermatozoa are encountered. Upper curve, darkness, lower curve, constant illumination at 983 ± 3 lux Relative photo-sensitivity is represented at each temperature by the distance between the two curves. The curves coincide at ~48° C, at this temperature spermatozoa are obviously killed by heat alone without further contribution of light absorption The curves as drawn are the most probable ones calculated by functional analysis of the data.

as a parameter for the process of deterioration. This has the important drawback that this moment $t_\dagger$ can only be determined with reasonable accuracy in cases where life-spans are short enough to allow close and continuous observation of the process of deterioration. Even then, the statistical error is large, since one or two sperms that have a markedly longer life-span, or have not yet received a sufficient number of hits, can influence the result considerably. It can be shown that the relationship between the swimming velocities of spermatozoa and time can be described empirically by the linear equation[13]

$$\log\,[(\bar{v}_0 - \bar{v}(t)]/\bar{v}_0 = k_v\,(\log t - \log t_\dagger) \qquad (4)$$

Hence, from the plot of $\log\,[\bar{v}_0 - \bar{v}(t)]/\bar{v}_0$ against $\log\,t$, the value of $\log\,t_\dagger$ can be read by extrapolating the linear regression line of all data to the point where $\bar{v}(t) = 0$. Although this indirect method is more reliable than direct observation, $t_\dagger$ is still more uncertain than are the rate constants and useful results could only be obtained from the pooled data. Furthermore, the ratio of $t_\dagger$ values obtained under different conditions is not a linear measure

of a biological effect. The total result obtained in the present series of experiments, however, is again a convincing demonstration of the temperature-dependence of photo-sensitivity (Fig. 4).

Because of these effects of temperature on photo-sensitivity of spermatozoa it can be inferred from photochemistry and target theory that this photo-sensitivity depends on either a one-target multiple-hit, or a multiple-target process. Then it follows that at certain levels of illumination deviations from Bunsen and Roscoe's reciprocity law must occur (Schwarzschild effect), and an intermittency effect can also be expected[14].

These investigations are being continued. A detailed account will be presented elsewhere.

Critical Flicker Fusion Perimetry and the Adaptation Level of the Eye

MOST scientists concerned with the physiology of vision agree that the temporal resolution of the cone system is greater than that of the rod system. In only a few of the experimental studies, however, is the evidence convincing that exclusively rods or exclusively cones were indeed functioning over some appropriate range of stimulus environments. Colour visibility, small stimulus fields, and widely discrete levels of adaptation have been tried with only indifferent success. Moreover, the cone system is reported only to be generally faster, not always so. Many of the studies find that the rods sometimes resolve light pulses at higher frequencies than do the cones. Our predictive knowledge of this whole problem is poor. We can probably safely assert only that a small dim stimulus in the retinal periphery will be less adequately resolved than a similar stimulus in or near the fovea, while, on the contrary, a large bright stimulus will be better resolved in the periphery. There is some additional evidence for an annulus of high resolution at about 10° from the fovea

Every supraliminal stimulus presented to the eye affects its adaptation level, as was particularly emphasized by DeLange[1]. While the stimulus level can be used to control the adaptation level[1], so also can the level of the surrounding intensity[2]. Furthermore, it is possible to determine the increase in intensity (ΔI) above a constantly monitored instantaneous threshold (τ) required to resolve a constant flicker[3], and to measure the flicker resolution for a stimulus presented at some constant multiple ($\varkappa$) of the instantaneous threshold[4,5].

The relative integrity of physical units depends on the constancy of the physical zero and the fact that it is possible to specify it. The same is true for physiological units. We would like to suggest that whenever possible physiological intensities should be specified with respect to the physiological zero (threshold) then in force. In the more traditional constant-response method of Shikano[8], though his data could be replotted with respect to the physiological zero, this is difficult to do. It can be done automatically by the methods of DeLange and Hecht[1,2]; however, as usually used, the τ-coefficient ($\varkappa$) is restricted to unity. In essence, these methods consider the response of "fusion" to be their constant-response, as Shikano considered the response of "resolution" to be his.

Although Hecht and his colleagues have applied their methods extensively to the "duplexity" problem (that is, the simultaneous operation of rods and cones), their results show only that the eye functions more slowly in dim light; they have not shown how the rods or the cones function by themselves. Those workers using the DeLange sine-wave methods have not yet systematically studied the duplexity problem. We have used the method of constant $\varkappa$, feeling that functional differences between the rods and the cones might more readily appear with such constant physiological stimuli than with the usual physically constant ones. Unfortunately, large supra-threshold stimuli are necessary because the flicker resolution of the eye is very erratic near τ. Thus contamination of τ cannot be avoided. It is therefore necessary to obtain some measure of the degree of distortion in the threshold curve brought about by the presentation of the flashes of the critical flicker fusion test at some $\varkappa\tau$ well above threshold.

Our experiment consisted of obtaining uncontaminated dark-adaptation curves on the test eye in separate sessions, and taking experimental measurements of critical flicker fusions and of thresholds at alternate minutes in the same eye. Otherwise, identical conditions were used throughout the experiment. After exploration, a $\varkappa = 10$ was chosen because it did not seriously contaminate τ yet still allowed reliable critical flicker fusions to be taken.

The apparatus consisted of a Sylvania *R*1131*C* glow modulator lamp connected to a Grason–Stadler flicker fusion apparatus (model *E*622), interconnected by a system of lenses and filters to a 60 cm diameter perimeter The light was focused on a ground-glass screen at an exit-port at the centre of the perimeter. The flicker source produced a square wave white light pulse (50 per cent on time—thus 127 per cent modulation depth—DeLange[1]) with a continuously variable frequency of from 1 to 125 c/s. The colour of the light was acceptably neutral over 2 log units of intensity by way of current control, and four additional log units by way of neutral density step-filters.

The peak output of the light under steady conditions was 0·024 apparent ft.-candles (0·082 candles/m²). Using a 5 mm pupil and 1 sec bursts (to avoid the Troxler effect), we thus had 2·05 photopic-troland-seconds at the retina. The relative brightness of the lamp was independent of the frequency. A small red fixation light was placed just above the stimulus. The observer's pupil was dilated with 1 per cent mydriacyl. All observations were preceded by light adaptation for 3 min to about 2,642 candles/m² of white light.

As noted, two types of measurements were made: a 30 min run of alternating flicker (at $\varkappa\tau$) and light threshold readings, and a 30 min control run of pure threshold readings. The $\varkappa\tau$ was obtained by sliding a 1 log density filter in and out of the beam during the approximately 40 sec mechanical lag between the flicker and the threshold readings. The results are means of at least five runs, and are reported in Fig. 1 and Fig. 2. The legends describe the specific conditions.

In Fig. 1 the threshold curves do not have alpha flex points and they have high final values. On the basis of accepted principles in vision, we may take them to be pure cone curves. Also, on this basis, we may observe that there is a clear and steady fall in flicker resolution with time in the dark despite the fact that there is no evidence at all for flicker alpha points (thus no rod intrusion). This suggests that a gradual decrease in

lateral inhibition has occurred within the cone system and/or an increase in neural convergence, and that at least part of the drop in τ itself may be neural and not photochemical in nature.

Our crucial finding is shown in Fig. 2: the flex point in the curves for critical flicker fusion. We believe that this is the first time such flex points have been shown conclusively. For both observers this is delayed from the threshold alpha by the approximate time needed for the intensity of the critical flicker fusion stimulus to fall to the level at which the threshold alpha occurred. Because the alternate method necessitated placing the critical flicker fusion stimulus one log unit above the threshold, the flickering stimulus did not reach the rod environment until a few minutes later than the τ alpha. (The early flex point (at 8 min) is an experimental artefact arising from the sudden deceleration in the critical flicker fusion stimulus intensity at the τ-alpha point.)

As an aside, we may note that although the critical flicker fusion stimulus itself was one log above the threshold, the experimental "contaminated" threshold curves were never contaminated to this degree. Possibly this

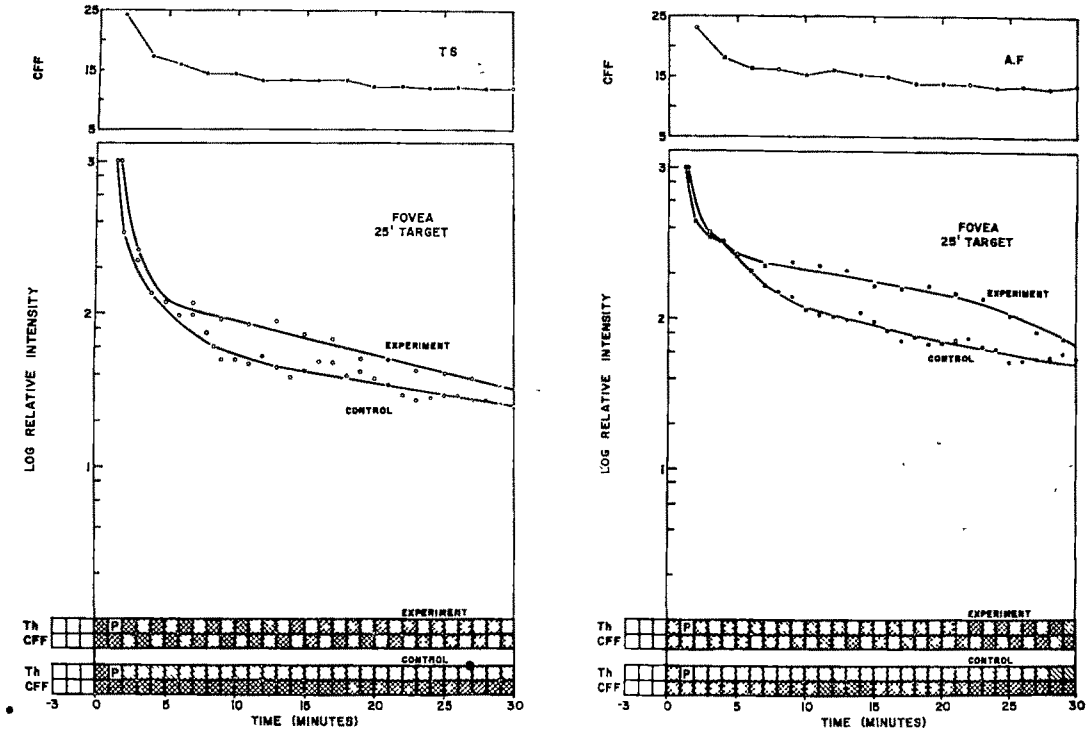

Fig. 1. A pure rod-free curve obtained with a 25′ central field.

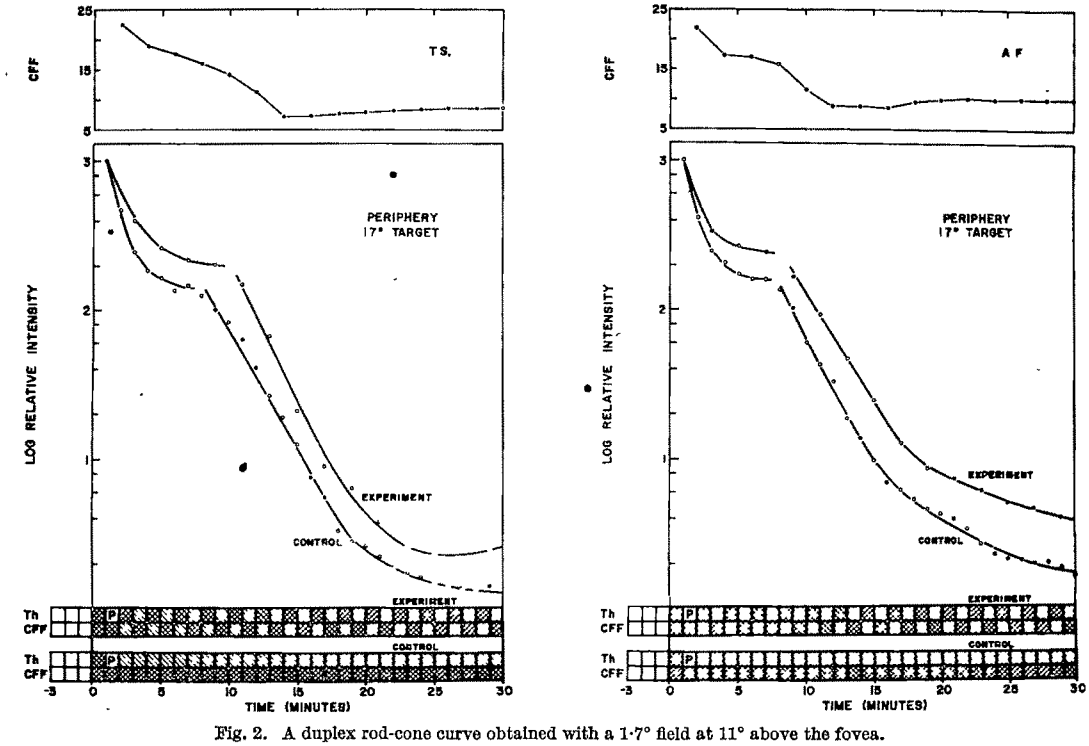

Fig. 2. A duplex rod-cone curve obtained with a 1·7° field at 11° above the fovea.

Table 1

Obs.	25′ at 0°	1·7° at 11°	t-test
A. F.	13 7 c/s	10 0 c/s	2·77
T. S.	11·9 c/s	8 65 c/s	9 56

results from the time delay between the last critical flicker fusion burst presentation and the subsequent alternate threshold measurement. In any event, the two threshold dark-adaptation curves parallel each other rather well—this is true for both observers under both conditions of test—and give a concise picture of the logic of the experiment.

Finally, in comparing the two figures, we may consider the last critical flicker fusion values after dark-adaptation for 30 min, as in Table 1.

The underlined value of the t-test ($N = 5$) is significant (at P less than 0·01), the other is nearly so. This means that the critical flicker fusion of the final pure cone is significantly higher than the final pure rod value, which is another way of saying that the cones have greater temporal resolution.

The results seem conclusive as to the superior temporal resolution of the cone system over that of the rod system. These flicker dark-adaptation curves show this functional duplexity in a clearer fashion than it has been shown heretofore because the alternate threshold monitoring procedure clearly informs us when we are in a pure cone (whole of Fig. 1) or a pure rod (latter part of Fig. 2) environment. We cannot yet say definitely why the curves for critical flicker fusion fall rapidly to alpha (or just fall, as in Fig. 1), or why they then rise slowly. There is an experimental flaw which might account for the fall: the fact is that κ is undoubtedly more than 10 during the fast falling cone portion of the threshold curve—actually, it appeared brighter here than later on—yet we, in default, must take it as 10. There are more attractive physiological speculations, however, as we have mentioned: the horizontal inhibitory interactions between the cones may decrease with time in the dark so that cone resiliency also decreases. This hypothesis would also permit us to explain the slight increase in rod resolution as a result of a slight increase in inhibitory interactions. A final decision on this awaits further investigation.

Activation of "Secondary" Impulse Trigger Sites in Hippocampal Neurones

Intracellularly recorded spike potentials of hippocampal neurones occasionally exhibit fast prepotentials superimposed on spontaneous slow depolarizations and excitatory postsynaptic potentials evoked by stimulation of the subiculum[1]. Although the origin and nature of fast prepotentials have not been determined, available data suggest that they represent electrotonic reflexions of partial spikes evoked in dendrites by pathways arising in the subiculum[1]. Two investigations which are summarized here have permitted further analysis of fast prepotentials as well as the definition of some of the factors conditioning their development in hippocampal neurones. The results are illustrated in contrast with findings in elements which did not exhibit fast prepotentials during a long period of spontaneous activity or in response to low frequency (1/sec) stimulation of the perforant pathway in the subiculum.

Intracellular recordings from hippocampal pyramidal neurones of *encéphale isolé* cats were obtained with micropipettes filled with 2 M potassium citrate inserted as closely as possible to a microelectrode filled with saline and located at the cell body layer and used for registering of extracellular activity. In one study stimulation of the fimbria or fornix was used to evoke inhibitory postsynaptic potentials of short latency period (Fig. 1*A* 3) in a neurone which also exhibited 3–4 msec latency excitatory postsynaptic potentials and spike discharges in response to 1/sec stimulation of the subiculum (*B* 3) (ref. 2). It was noted that many neurones also showed a brief delayed depolarizing potential on the falling phase of the spike evoked by stimulation of the subiculum (*D* 2*b*) as well as a succeeding prolonged inhibitory postsynaptic potential (*B* 3). Spontaneous spikes exhibited prominent depolarizing after-potentials[3].

Inhibitory postsynaptic potentials produced by conditioning stimulation of the fimbria effectively blocked spike discharges associated with the early excitatory postsynaptic potentials evoked by the subiculum (*D* 2*b*). Under these conditions a fast prepotential appeared (at arrow in *D*3) on the crest of the early excitatory postsynaptic potential. Cell discharge was secured by the fast prepotential which was temporally related to the delayed depolarizing potential in the unconditioned response evoked by subiculum stimulation (*D* 2*b*). Variations in timing or magnitude of conditioning inhibitory postsynaptic potentials as well as alterations in early excitatory postsynaptic potentials evoked by the subiculum stimulation or previous spontaneous activity frequently resulted in failure of the fast prepotential to secure cell discharge (*D* 4 and *D* 5).

Marked changes were observed in focal activity recorded from the cell body layer during conditioning by the fimbria of responses evoked by the subiculum stimulation. The unconditioned response consisted of a prominent slow positivity with a superposed negative spike signalling cell body discharges (*B*, *C* 2). Appearance of the fast prepotential during the fimbrial-evoked inhibitory postsynaptic potential was associated with an extracellularly recorded diphasic positive–negative spike (*C* 3) the early positive component of which corresponded to the negative spike of the unconditioned focal response evoked by stimulation of the subiculum (*C* 2). The positive–negative spike recorded at the cell body layer during the appearance of the fast prepotential is consistent with a remote or dendritic origin of the latter and development of a dendrosomatic spike sequence in a relatively large population of cells.

Activation of fast prepotentials was produced in a second type of study illustrated in Fig. 1*E*. In this experiment the frequency of subiculum stimulation was increased to 25/sec for several seconds. During the early phases of repetitive stimulation the excitatory postsynaptic potentials increased in latency and amplitude and cell discharge was obtained on the crest of the excitatory postsynaptic potentials (*E* 2). The brief delayed depolarizing potential and the succeeding inhibitory postsynaptic potential evoked by 1/sec stimulation of the subiculum (*E* 1) were not observed during 25/sec stimulation. The excitatory postsynaptic potentials were depressed during continued repetitive stimulation of the subiculum, and many failed to elicit spike discharges (*E* 3). This depression of evoked excitatory postsynaptic potentials was accompanied by minimal depolarization of the membrane (6–8 mV) (ref. 4). When repetitive stimulation was stopped two varieties of spike prepotentials were observed. Spontaneous discharges arose from slow depolarizing prepotentials (excitatory postsynaptic potentials) (*E* 4*a*), whereas spikes evoked by 1/sec stimulation of the subiculum were triggered by fast prepotentials (*E* 4*b*). A small negative component preceded the fast prepotentials in some instances (*E* 4*b*) in the period immediately following activation, whereas later this component was absent and the fast prepotentials

appeared to arise directly from the baseline or from a small slow depolarizing potential (*E* 5). The relationship between the small negative component preceding the fast prepotentials in *E* 4*b* and field activity of spikes in distal dendritic regions following repetitive stimulation of the perforant pathway has been considered elsewhere[4].

The studies summarized here indicate that hyperpolarization of the membrane produced by inhibitory postsynaptic potentials generated in, or close to, the soma of hippocampal neurones[5] as well as repetitive activation of axodendritic excitatory synaptic pathways may facilitate the appearance of partial spikes of fast prepotentials remote from the cell body, presumably in some part of the dendritic system[1]. Other aspects of this investigation have revealed spikes arising directly from the baseline in hippocampal neurones during seizure activity initiated by repetitive stimulation of the subiculum[4]. Evidently, fast prepotentials represent a potentially explosive response of the hippocampal dendrites which, under appropriate conditions, may lead to all-or-one propagated activity in these elements. Conditions favouring the appearance of fast prepotentials are associated with depression of early excitatory postsynaptic potentials evoked by stimulation of the subiculum, suggesting that this factor is probably also of importance in the development of fast prepotentials. It is of interest to note that depression of axosomatic excitatory postsynaptic potentials by inhibitory postsynaptic potentials and repetitive stimulation of axodendritic synapses may also condition the development of partial and conducted spikes in dendrites of immature neocortical neurones[6,7]. This suggests that many of the properties of immature neocortical neurones which are not encountered in the vast majority of neocortical neurones in adult animals[8,9] are "retained" in mature hippocampal neurones. Probably in both immature neocortical neurones and hippocampal neurones secondary impulse "trigger" sites in dendrites not only increase the synaptic security of axodendritic pathways[10,11] but may also serve to facilitate dendritic input channels during selective inhibition or depression of excitatory axosomatic synaptic pathways as demonstrated here.

Renal Production of Erythropoietin and Renin after Experimental Kidney Infarction

IN previous experiments we have shown that injection of plastic microspheres into a renal artery results in production of erythropoietin and reticulocytosis[1] and development of hypertension[2].

In the present investigations we have attempted to elucidate further these phenomena by asking the following questions. Is the hypertension related to renin secretion? If renin is released by the kidney, is the time course of release the same as that for erythropoietin? Both questions have a bearing on the possible identity of these hormones and the nature of the stimulus regulating their release.

All experiments were carried out on trained, unanaesthetized mongrel dogs. Before training, a silicon-rubber catheter (silastic) was surgically implanted in one carotid artery. The dogs were then trained to stand quietly while their blood pressure was measured directly using a mercury manometer attached to the carotid catheter. Arterial blood samples were obtained on several successive days for determination on haematocrit, reticulocyte percentage renin and erythropoietin activity. In one dog renal venous blood was also sampled from a chronically implanted catheter[1] placed in the renal vein at the time of injecting the microspheres. Following control determinations the dogs were anaesthetized and about 200,000 plastic microspheres of 30–170μ diameter were injected into the left renal artery. Periodically, blood was sampled for analysis. Erythropoietin was assayed using 48 h iron-59 uptake in the polycythaemic mouse[1]. Plasma renin concentrations were determined indirectly by a modification of the method of Bouchor *et al.*[3].

The results for the dog in which renal venous blood was collected are shown in Fig. 1. Table 1 presents the data obtained from three other dogs. In all animals the injection of microspheres resulted in increased arterial concentrations of erythropoietin and renin reticulocyte percentage and mean arterial blood pressure (MABP). Peak

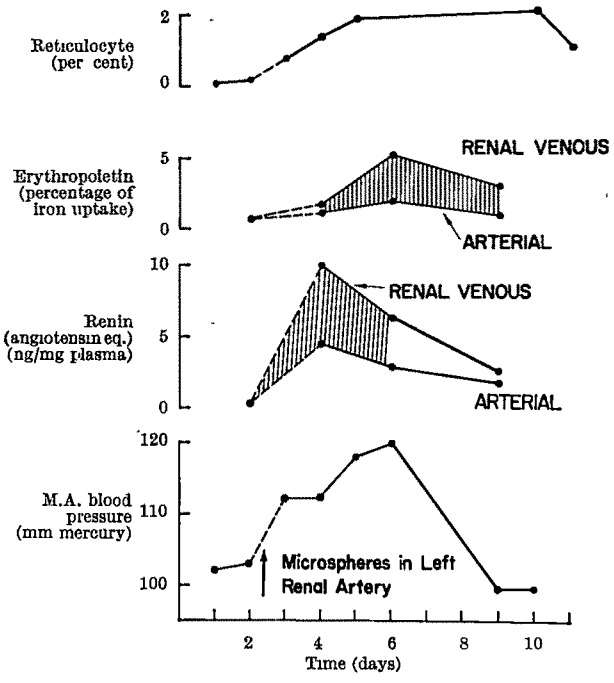

Fig. 1. Alterations in renin, erythropoietin, reticulocyte percentage and blood pressure following renal arterial injection of microspheres in dog Number 1.

reticulocyte percentage always occurred after the maximum in erythropoietin and peak blood pressure after the renin maximum. There was no constant temporal relationship between erythropoietin and renin plasma levels in the dogs. In one dog the renin maximum occurred first, in one dog erythropoietin preceded renin, and in one dog the renin and erythropoietin maximum coincided. In dog 4 the timing of the samples was such that the relation between erythropoietin and renin maxima could not be accurately determined.

These data indicate that the kidney of the unanaesthetized dog produces both an erythropoietic stimulating factor and a hypertensive factor following injection of microspheres into the renal artery, and that the two factors are separate substances. Although the response in terms of the liberation of hormones and changes in the percentage of reticulocyte and in the blood pressure is transient, increased release of hormones persists for several days. Thus it seems probable that the increased hormone levels represent actual production rather than release of stored hormones. These results indicate that the same stimulus can result in the production of both renin and erythropoietin. The present experiments are in agreement with the clinical findings of Luke *et al.*[4], who reported co-existing hypertension and polycythaemia in a patient with unilateral renal arterial stenosis. Red cell volume returned to normal and blood pressure to near normal after unilateral nephrectomy. Unfortunately, no erythropoietin or renin studies were carried out on the patient.

Thyrocalcitonin: Failure to demonstrate a Parathyroid Releasing Factor

Thyrocalcitonin[1] is the plasma calcium lowering hormone secreted by the thyroid in response to a high blood calcium stimulus[2–5]. The hormone is identical to calcitonin which was originally thought to be of parathyroid origin[6]. The possible interrelated roles of the thyroid and parathyroids have been studied by Gittes and Irvin[7]. Their results suggested that a parathyroid factor might be responsible for the release of the hormone from the thyroid: parathyroidectomized rats were found less able to counteract the hypercalcaemia induced by exogenous parathyroid hormone than intact rats. The studies of these workers have been repeated, in part, to investigate the possibility of a parathyroid releasing factor by assessing the ability of parathyroidectomized animals to withstand an intraperitoneal challenge of calcium chloride.

Thirteen intact and sixteen parathyroidectomized male Wistar hooded rats weighing between 120 and 150 g were used. Parathyroidectomy was performed by electrocautery and only animals with plasma calcium of 3 m.equiv./l. or lower 1 week after the operation were included in the investigation. To prevent hypocalcaemia in the parathyroidectomized group, all animals were maintained on a high calcium–low phosphate diet[8] for 3 weeks. Before they were challenged with calcium, blood samples were collected in heparinized tubes by intraorbital puncture from each rat. 5 mg calcium chloride/100 g of rat weight were given by intraperitoneal injection and further blood samples were obtained after 1 and 3 h by the same technique. Plasma from all blood specimens was separated within 1 h and calcium determined by flame spectrophotometry[9].

The results are summarized in Fig. 1. In 1 h plasma calcium rose in the intact rats to 9·97 ± 0·14 m.equiv./l. and to 8·94 ± 0·17 m.equiv./l. in the parathyroidectomized rats. After 3 h plasma calcium fell to near equal levels in both groups (7·21 ± 0·09 m.equiv./l. for intact rats and 7·11 ± 0·14 m.equiv./l. for parathyroidectomized animals.)

The presence of the parathyroids in the intact animals provided no additional protection against exogenously induced hypercalcaemia. The thyroids in parathyroidectomized rats appeared to secrete thyrocalcitonin as efficiently as they did in intact animals. Similar intraperitoneal challenge to thyro-parathyroidectomized animals produced more marked hypercalcaemia[10]. Cumulative evidence unequivocally favours a thyroid origin for the calcium-lowering hormone. The data presented do not support the existence of a parathyroid releasing factor for thyrocalcitonin.

This work was done during the tenure of an Advanced Research Fellowship of the American Heart Association.

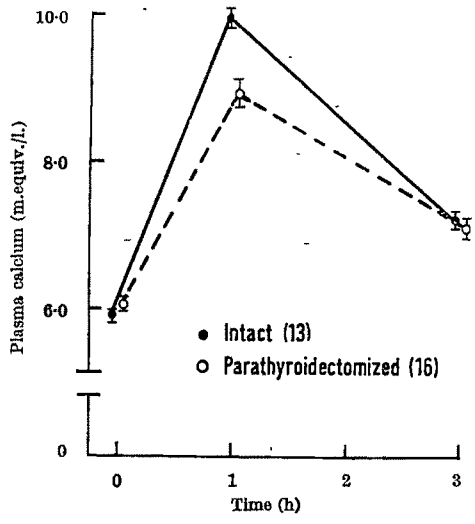

Fig. 1. Effect on plasma calcium of intraperitoneal calcium chloride (5 mg/100 g) given to intact and parathyroidectomized rats. Number of animals in each group is shown in parenthesis. The vertical bars indicate the standard error of the mean for each value.

I thank Miss Lynette Luck for performing the calcium determinations.

BIOLOGY

Responses of some Anomuran and Brachyuran Crustaceans to High-speed Centrifugation

As part of a wider investigation of Crustacea in this laboratory[1], we have been seeking a method for removing hermit crabs from their "host" shells without damaging them. The generally recommended methods—application of heat, immersion in deaerated water, exposure to fresh water, etc.—have not proved particularly satisfactory for our purposes.

It seemed possible that mild centrifuging might disturb the crab sufficiently to cause it to vacate its shell and move toward an area of lesser centrifugal force. Preliminary trials with a hand-operated centrifuge were notably unsuccessful. Experiments were then carried out on an International Model *CS* Electric Centrifuge using head No. 242 with 250 ml. bottles. Initial runs with four *Pagurus floridanus* Benedict spun at 200 r.p.m. (8·5*g*) for 5 min did not appear to discomfit the animals in any way. (All relative gravity values given in this report were obtained from the nomograph supplied with the centrifuge.) They were active when the centrifuge was stopped and immediately showed "normal" responses (fright reactions, attempts to turn shells over when placed upside down). Further tests on these animals with maximum acceleration to and deceleration from speeds as high as 2,000 r.p.m. (800*g*) also apparently did not disturb normal behaviour patterns.

Because an adequate supply of *P. floridanus* was not readily available, tests were run on another hermit crab, *Clibanarius vittatus* (Bosc), which we were able to obtain in large quantities. Several hundred of these, collected along the beach at Ship Island, Mississippi, were sorted into rough size categories based on maximum dimension of the occupied gastropod shell. Shells of two gastropod genera (*Thais* and *Polinices*) were represented in this series.

Nine tests were run, using thirty-five hermit crabs selected from the various size groups. Crabs of several sizes in both types of shell and crabs without shell were exposed for varying periods to centrifugal forces in the range 800–2,700*g*. Table 1 presents test conditions and results. In all cases, acceleration and deceleration were the maximum obtainable with the centrifuge and electric brake. Acceleration times ranged from 15 sec to 26 sec, and deceleration times from 13 sec to 25 sec. Heads Nos. 240 and 242, with 50 ml. and 250 ml. tubes, respectively, were used throughout the investigation.

As Table 1 shows, maximum mortality in any single experiment was 50 per cent at termination of the experiment (22–26 h after centrifugation). Further, overall survival was twenty-nine crabs out of thirty-five, all of which had been exposed to centrifugal forces of at least 800*g*. The death of one animal (Experiment 9) was probably not related to centrifugation; it climbed from its beaker during the night, fell to the floor, and was found desiccated, but alive, 15·5 h after centrifugation.

To test the possibility that the observed resistance to centrifugal force might be a trait peculiar to the Anomura, we performed similar experiments on two genera of brachyuran crustaceans (*Sesarma reticulatum* (Say) and *Uca* sp.) (Table 2). It is apparent that these forms are considerably less resistant than the anomurans to high centrifugal forces. Some individuals of both species,

8	4	2,700	3	All dead at 112 min
9	2	2,700	0*	One alive and active at 80 min
10	2	800	30	One moribund and one active at 90 min

* Zero exposure time represents acceleration to maximum speed followed by immediate deceleration with braking.

however, were able to survive (short-term) after exposure to more than 800*g*.

Waterman[2] makes no reference to forces greater than 2·2*g* in his 1961 work, *The Physiology of Crustacea*. A search of abstracts since 1960 reveals only one pertinent reference. Eberly *et al.*[3] studied the effects of centrifugal force on nymphs of the grasshopper *Melanoplus differentialis* (the size of nymphs was not specified). They reported 50 per cent mortalities in 9 days at 9*g* and in 20 min at 10,000*g*. We were not able to obtain nymphs of *Melanoplus* locally at this season, but were able to capture two half-grown (40–50 mm) nymphs of lubber grasshoppers (*Romalea* sp.). Centrifugation at 800*g* for 10 min eviscerated and killed one nymph; centrifugation at 2,700*g* for 1 min reduced the remaining nymph to mush. Thus, we very much doubt the validity of the 10,000*g* value.

In view of the tolerance of anomuran crustaceans to extremely high centrifugal forces and because of their availability in quantity, hermit crabs could well be used as experimental organisms for extraterrestrial investigations. The use of hermit crabs in instrumented shells or simulated shells seems feasible. Furthermore, detailed physiological and biochemical investigations of the resistance mechanism could well provide valuable guidance in the design of life support systems for higher animals.

We thank J. Christmas, N. Whatley and Miss C. Stone for assistance in collecting and handling the experimental animals. This investigation was supported by the research fund of the Gulf Coast Research Laboratory.

Feeding Habits of the Squid, *Illex illecebrosus*

OBSERVATIONS have occasionally been made on the method of attack on prey by *Illex* in the inshore zone where it feeds mainly on small fishes[1–3]. This communication suggests a way in which the squid is able to capture smaller food organisms—mainly small crustaceans (Euphausiids)[4]—when it is schooling in the offshore zone.

It is generally agreed that fish such as herring, mackerel, etc., when swimming in schools, feed on the small crustaceans (copepods, etc.) which are abundant in the oceans. These they take into their mouths together with the water used to perfuse the gills in respiration and strain them from this water by means of gill rakers. During such feeding the school of fish remains intact. With the squid, *Illex*, this method of feeding is impossible not only because of its anatomy but also because of the way the individuals orientate themselves when schooling. When swimming in a school they generally orientate themselves with their tail forward. In this position the animal is propelled by successive and continuous jets from the siphon which is now at the rear end. Although the head is also at the rear end in this position, vision forwards or backwards is unimpeded because the eyes are appreciably protruded. When moving in well-formed, evenly spaced schools, the squid maintains its arms and tentacles compactly together and the siphon is held straight. When moving through swarms of small crustaceans, however, individual squids are able to trap some of their prey in their own wake by expanding their arms and thus creating a turbulence. The mantle intake and siphon ejection of water which effect propulsion also add to the turbulence in their wake. The prey pulled into this turbulence is easily captured by the suction cups on the arms or tentacles and then transferred to the mouth. This method of feeding is accomplished without breaking up the formation of the school. Fewer squids appear to fall prey to their fellows in the offshore zone where this type of feeding in schools is generally predominant[4].

It is probably not always possible for a squid to swim past a small active fish sufficiently close or fast to capture it in the turbulent wake set up by expanding its arms. Observations of the capture of fish by *Illex* reveal that although the squid swims past the fish or lure, it then turns and darts with arms forward and grabs its prey[1–3]. This invariably causes the schooling pattern to break up. It is quite probable that there is a connexion between break-up of schools and the not uncommon finding of squids in stomachs of inshore squids[4,5]. The change from feeding mainly on small crustaceans to feeding mostly on fish may in part be responsible for this. It would seem that squids have to learn this method of feeding because in the first seasonal occurrence of squid in the inshore zone there is a period in which fish-shaped lures do not attract them (the period during which fishermen consider the squids to be "blind"). Lures with dangling hooks designed in the shape of euphausiids would take into account the feeding method of squids and could well be used in the offshore zone and possibly also during the period in which they learn to feed on fish.

The observations referred to in this communication were made in inshore waters off Newfoundland at Holyrood where the squids are present from July–October, and offshore on the south-west edge of the Grand Banks where they are commonly present early in June.

I thank M. C. Mercer for help in preparing this manuscript.

[5] Mercer, M. C., *Manuscr. Rep. Ser. (Biol.) Fish. Res. Bd. Canada*, No. 834 (1965). Mercer also argues that some squid in the stomachs of inshore squids may be derived from bites taken after capture and when thrown together, and that cannibalism inshore may be rated higher than it actually is.

Corpus Allatum and Sexual Receptivity in Female *Drosophila melanogaster*

IN a number of insects the hormone secreted by the corpus allatum is known to affect reproductive behaviour. In female insects so far studied the hormone operates in one of two ways. It may control pheromone secretion and thus determine whether a female attracts courtship from males, for example, the cockroach *Byrsotria*. Here, Barth[1] showed that there is no effect on behaviour itself because if males are induced to court allatectomized females by adding pheromone artificially, the latter respond normally and mate. Alternatively, the hormone may affect the sexual receptivity of females, as in the grasshopper *Gomphocerus*. In this case pheromones are not important and Loher[2] has shown that allatectomized females, although courted normally, do not respond. Implanting mature corpora allata induced the return of receptivity within 7 days.

Few *Drosophila melanogaster* females kept on a 12 h : 12 h light/dark cycle are receptive to males on the day of eclosion (day 0) or on day 1, but almost all are fully receptive by the morning of day 2. This change in behaviour runs parallel to the growth of the corpus allatum[3] which is small at eclosion. Feedback from the ovaries

which grow under the influence of its hormone is known not to affect receptivity[4]. Accordingly, the effect on injecting mature corpora allata into pupae just before eclosion has been tested.

Corpora allata, together with the associated complex of fused corpus cardiacum and hypocerebral ganglion, were dissected from 6–12 day old virgin females and briefly stored in *Drosophila* Ringer's solution[5]. Single glands, together with a little Ringer's solution, were injected into the abdomens of pupae, 17–19 h before eclosion, through a glass needle using the technique of Ephrussi and Beadle[5]. Control pupae received a small piece of the aorta dissected from the same donor flies. Mortality was about 50 per cent, but with two exceptions all flies which survived day 0 went on to mate and lay fertile eggs.

Injected flies were tested for receptivity on the morning of day 1. Each was placed with a single male in a 'Perspex' observation cell[6] 1 in. in diameter. Males court females of all ages with equal persistence and will continue courting unreceptive virgin females for several hours. In practice, 30 min without acceptance is a suitable criterion because more than 90 per cent of receptive females accept in less than 10 min. Forced matings are not uncommon and the female can be seen struggling to push the male off, but unless she succeeded in doing so within a few minutes she was recorded as receptive.

Table 1. RECEPTIVITY OF *D. melanogaster* FEMALES MEASURED ON DAY 1

	Receptive on day 1	Unreceptive on day 1	Total
Corpus allatum injected	20	0*	20
Control, aorta injected	7	16†	23
Control, not injected	7	18	25

The difference between the two injected groups is highly significant (χ^2 with Yates's correction = 19·23, $P < 0{\cdot}001$).

* Two flies injected with allata were unreceptive on day 1 but died on day 2.

† These flies were tested for the normal appearance of receptivity on days 2 or 3, and all were receptive.

The results are given in Table 1 and strongly suggest that the presence of a mature corpus allatum in young flies induces the precocious onset of receptivity. This could result from the direct action of its hormone on some receptivity mechanism in the central nervous system. Alternatively, as Highnam[7] points out, the hormone may facilitate the release of stored neurosecretory products and these may affect behaviour. Preliminary experiments indicate that, given at this stage, the hormone requires some time to take effect and that females with implanted glands are not receptive on day 0.

The assistance of Miss M. C. Hill is gratefully acknowledged. This work was supported by a grant from the Science Research Council.

Impairment of Oxidative Phosphorylation by D-threo- and L-threo-Chloramphenicol

WE reported earlier that high concentrations of chloramphenicol impair certain energy-linked functions of mitochondria[1,2]. The experiments were carried out with the D-threo isomer (the antibiotic) which effectively blocks protein synthesis in bacteria[3]. Of principal interest is the suppression of respiration and oxidative phosphorylation. If these effects are produced *in vivo*, it cannot be assumed that responses produced in tissue by D-threo-chloramphenicol are necessarily related to inhibition of protein synthesis. This is not to deny that protein synthesis can be blocked; but it becomes essential that the investigator establishes that impairment of phosphorylation is not also, or even primarily, involved whenever concentrations of the order of 0·5 mg/ml. or greater are used.

One way of avoiding this difficulty is to use L-threo-chloramphenicol as a control treatment. The L-threo isomer is relatively ineffective in inhibiting protein synthesis[3]. Ellis[4] has reported that both the D-threo and L-threo isomers are effective in inhibition of ion accumulation, and he suggests that there is not necessarily any connexion between the uptake of ions and the synthesis of protein. Recently, Billet *et al.*[5] have used the L-threo isomer as a control to establish that the effects of the D-threo isomer on the development of the chick embryo result from inhibition of protein synthesis. The D-isomer was effective in arresting development while the L-isomer was not. There is thus support for the postulate that the antibiotic impairs development through inhibition of protein synthesis.

Table 1. IMPAIRMENT OF OXIDATION AND PHOSPHORYLATION BY D-THREO AND L-THREO-CHLORAMPHENICOL

Chloramphenicol	$Qo_2(N)$	P/O
none (0·1 ml. ethanol/vessel)	2443	1·70
D-threo (1 mg/ml.)	1102	0·98
L-threo (1 mg/ml.)	717	0·46

R. J. Ellis and W. Landauer have questioned (personal communications) whether L-threo-chloramphenicol will also suppress oxidative phosphorylation. In order to answer this point we carried out experiments with mitochondria from 3 day etiolated corn shoots as previously described except that 40 μmoles each of pyruvate and malate were used as substrate instead of pyruvate and succinate. The compounds were dissolved in absolute ethanol, with equivalent ethanol added to the control. The ethanol tends to have an inhibitory effect on oxidative phosphorylation. A typical result is given in Table 1. This shows that the L-threo isomer effectively suppresses oxidation and phosphorylation; indeed, it is consistently more effective than the D-threo isomer. This result can be correlated with the slightly greater inhibitory effect of root growth with the L-threo isomer[6].

Thus when only the D-threo isomer is effective on tissue (for example, Billet *et al.*[5]) there is reason to believe that protein synthesis is the process being inhibited. Where both the D and L compounds are effective (for example, Ellis[4] and Ronnicke[6]), the impairment of phosphorylation is probably involved. The mechanism responsible for the impairment of phosphorylation is still unknown. As reported previously[2], the antibiotic does not act like a true uncoupler; however, it does exhibit certain similarities to the respiration-suppressing phase of uncoupler action. More recent work has shown that chloramphenicol increases the rate and extent of mitochondrial swelling[7], which suggests that the compound acts by damaging the mitochondrial membrane rather than by specifically interfering with a phosphorylated intermediate.

We thank Dr. R. J. Ellis and Parke Davis and Co. for supplies of D-threo- and L-threo-chloramphenicol. This work was supported by the U.S. Atomic Energy Commission.

Specific Inhibition by Uracil Derivatives of the Mechanism of Dormancy Release in Light-sensitive Lettuce Seeds

RECENT studies have shown that pyrimidine analogues are effective in preventing the inhibition of *Lepidium*[1], *Eragrostis*[2], *Brassica*[3], and *Lactuca*[4] seeds. Investigations made in this laboratory of the effects on germination of a wide range of inhibitors of the synthesis of nucleic acids and proteins, including purine, pyrimidine and amino-acid analogues, have indicated that inhibition by uracil derivatives is intimately connected with the processes responsible for the release from seed dormancy.

The experiments reported here concern the effects of 2-thiouracil, 5-fluorouracil, and 5-bromouracil on the germination of intact seeds and "half seeds" of lettuce (*Lactuca sativa* L.), var. 'Attractie'. The failure of light sensitive lettuce seeds to germinate in the dark is dependent on the presence of intact seed covers (endosperm plus pericarp); removing the seed covers or simply cutting the seed in half allows 100 per cent germination in the dark[5]. Similarly, irradiation of the intact seed with red light of low energy (660 mμ), treatment with gibberellic acid or thiourea, or incubation at a relatively low temperature, enables the embryo to overcome the resistance of the seed covers and to germinate. It is significant that with each of the three uracil derivatives, a higher concentration is required for the inhibition of half seeds than for the inhibition of intact seeds.

Lettuce seeds (var. 'Attractie') obtained from Thompson and Morgan (Ipswich), Ltd., were incubated on Whatman seed test papers in 4 ml. of solution in 9 cm Petri dishes at 25 ± 0·5° C. Intact seeds were either incubated completely in the dark or irradiated with red light at an intensity of 5,800 ergs $cm^{-2}.sec^{-1}$ for 10 min, 2 h after inhibition, percentage germination being recorded 20 h later. Half seeds were prepared by cutting whole seeds transversely into two equal pieces; the halves containing the embryos were incubated in the dark as above. Observable geotropic curvature of the radicle was taken to indicate germination of half seeds. The 5-fluorouracil was a gift from Dr. M. Black, of Queen Elizabeth College, London.

2-Thiouracil, 5-fluorouracil and 5-bromouracil all inhibit the germination of the intact seeds, but at widely different concentrations, 5-fluorouracil being the most inhibitory and 5-bromouracil the least so (Figs. 1, 2 and 3). In the case of 2-thiouracil and 5-fluorouracil, intact seeds which had been maintained in the dark or irradiated with red light were inhibited at concentrations seven to twenty times smaller than those required to inhibit the germination of half seeds. Inhibition of half seed germination was not detected at any of the concentrations of 5-bromouracil used.

Although other analogues of nucleic acid precursors—for example, azaadenine and azaguanine—inhibited

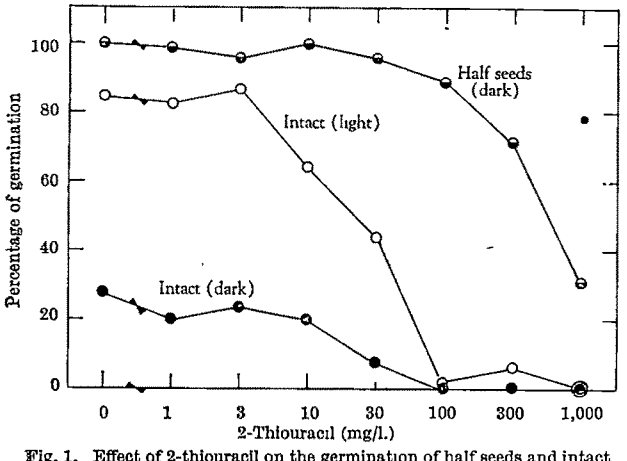

Fig. 1. Effect of 2-thiouracil on the germination of half seeds and intact seeds.

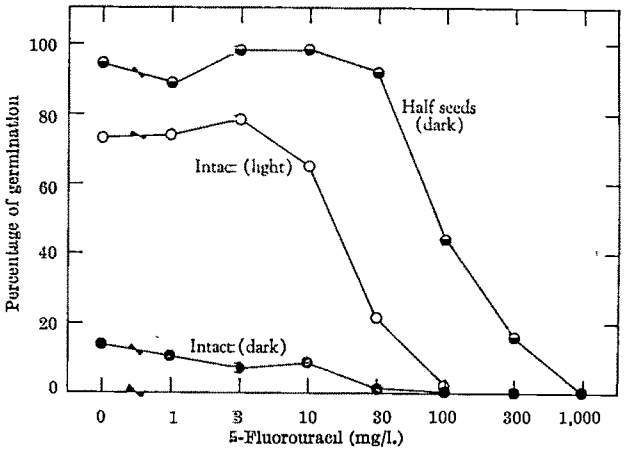

Fig 2. Effect of 5-fluorouracil on the germination of half seeds and intact seeds.

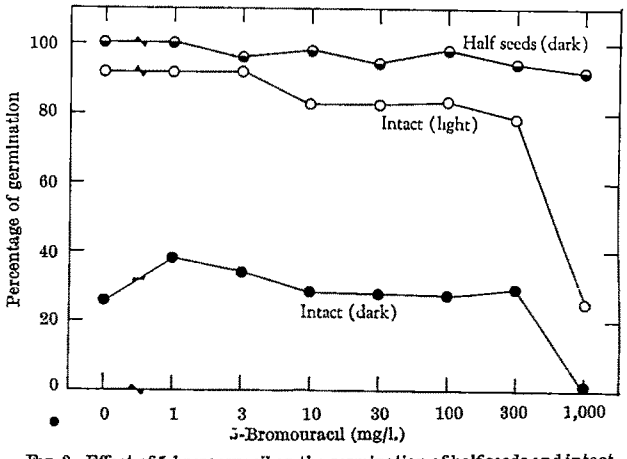

Fig. 3. Effect of 5-bromouracil on the germination of half seeds and intact seeds.

germination, there was no significant difference between the concentrations required for 50 per cent inhibition of intact seeds and of half seeds. Similarly, other experiments with inhibitors of protein synthesis (chloramphenicol, puromycin and *cyclo*heximide) and analogues of amino-acids (4-fluorophenylalanine) have shown that intact seeds and half seeds do not respond differently[6].

On the basis of these preliminary observations, it would seem reasonable to suggest that the uracil derivatives specifically inhibit the mechanism responsible for the ability of the embryo to overcome the restriction of the seed covers. Since 5-fluorouracil, 5-bromouracil, and 2-thiouracil are commonly held to be inhibitors of nucleic acid synthesis, it is tempting to suggest that they are acting in such a manner here. As yet, however, there is no evidence for such a conclusion because other inhibitors of nucleic acid synthesis do not have a similar differential effect on the germination of intact seeds and half seeds. If the inhibitors act on nucleic acid synthesis, it would seem that the uracil derivatives inhibit a facet of nucleic acid metabolism specifically related to the ability of the embryo to overcome the restriction of the seed coat. Experiments are at present being conducted to test for reversal of the inhibition with nucleic acid precursors, and to determine the effect of the inhibitors on the rate of incorporation of isotopic uridine into ribonucleic acid.

It is tempting to conclude that the uracil derivatives specifically inhibit the mechanism catalysed by phytochrome which results in the release from dormancy. It remains, however, to be seen whether this inhibition is directly related to the photo-morphogenetic process. Nevertheless, further investigation of pyrimidine and

nucleic acid metabolism should assist in elucidating the mechanism of dormancy release in light-sensitive seeds.

Presence of Adenosine Triphosphate in the Skin Venom of Amphibia

PRUSOFF'S discovery of adenosine triphosphate (ATP) and 5-hydroxytryptamine (5-HT) in enterochromaffin cell granula[1] stimulated us to an attempt to extend this observation to other sections of Erspamer's enterochromaffin cell system[2,3]. In a preliminary investigation[4,5] we demonstrated the existence of ATP in "venom" squeezed manually from the parotoid glands of *Bufo vulgaris* and *viridis*, while we were unable to observe ATP in venom from *Salamandra maculosa* and *Salamandra atra* with the procedure used at that time.

This communication reports the results of investigations carried out on twenty-two species of Amphibia. The venom if possible was squeezed manually from the parotoids, otherwise ether stimulation was used[6].

The presence of ATP was usually demonstrated by the method of Strehler and Totter[7] using diluted Sigma 'Buffered Firefly Extract'. Light emission was evaluated subjectively, or objectively by photographic and photometric means as well as by direct reaction with paper chromatograms. The photo-emission reaction was detected with a Photovolt photometer 520 coupled with a photomultiplier "1*P*21" and recorded with a Microcord 44 Record (Photovolt). The sample was placed in a 'Plexiglas' cylinder sealed at one end to a glass plate with chloroform and adapted to a lightproof apparatus connected by means of 'Teflon' micro tubes with two syringes which allowed the introduction of reagents. The apparatus was tightly screwed to the photomultiplier assembly. Although the instruments and the procedures used fulfil the requirements for a quantitative evaluation, we nevertheless intend to attribute only qualitative or roughly semi-quantitative values to our data because the material we were dealing with was not homogeneous. This limitation must be taken into consideration particularly when considering the "venom" collected by ether stimulation, as such "venom" contains the secretions of both granulous and mucous glands in proportions which cannot be evaluated. We also carried out investigations using paper chromatography and electrophoresis in order to demonstrate the possible linkage between oxyindolic derivatives and ATP[8]. As a result of our findings we were able to confirm and substantiate the lucipherin–lucipherase reaction.

ATP was demonstrated in the skin venom in all the species examined except for *Bombinator pachypus*. Notably, we succeeded in finding ATP in the venom from *Salamandra maculosa* and *S. atra*; techniques used on previous occasions had given negative results for these two species. From our data we therefore conclude that ATP is of usual occurrence in the "venoms" of Amphibia. Of especial interest is the observation that ATP is present in species where the "venom" does not contain 5-HT, but where other oxyindolic derivatives are present or where indolic substances have not previously been found[9,10]. The absence of ATP in *Bombinator pachypus*—a species with a high concentration of 5-HT in the venom[9,11]—may be explained because the 5-HT exists in a free form, or is bound to an unknown compound which may resemble ATP in being a nucleotide. The hypothesis that there are substances in this "venom" which inhibit the common reaction may be discarded in view of the finding that the addition of small amounts (20γ) of ATP to the reaction mixture will rapidly produce photoemission by the "venom" of *Bombinator*.

In the species we examined variable quantities of ATP were estimated. In summary we may conclude that: (1) there is no constant relationship between ATP and 5-HT. A high concentration of ATP does not always correspond to high concentration of 5-HT and vice-versa; (2) apart from the possible relationship between ATP and 5-HT, ATP may be present in very high concentration in some species, while in others it is scarcely detectable.

The finding of ATP in yet another section of Erspamer's enterochromaffin cell system raises the possibility of being able to demonstrate the presence of ATP in other sections. Our observations are, in our opinion, particularly interesting, in view of the large variation in the composition of the granulous venom of Amphibia[9]. Such variability is not comparable with other sections of the system. Any interpretation of the functional significance of the ATP–5-HT linkage in the structures of the enterochromaffin cell system, however, must take into account the differences in the function of 5-HT which occur in different sections of the system.

GENETICS

Age and Chromosomes

RECENTLY, I carried out chromosome analyses and sex chromatin determinations on ten patients—five females and five males—between 63 and 91 years old. The organic status of these individuals was variable, and all were ill in some way. Nevertheless, the results obtained in this investigation were reasonably uniform; their chromosomes and Barr bodies appeared normal and manifested the characteristics of the corresponding sex (Table 1).

These observations do not agree with those of Jacobs *et al.*[1], who stated that the number of aneuploid cells in blood culture increases with the age of the donor, particularly above the age of 60 years. It was further claimed that these aneuploid cells lacked the sex chromosome corresponding to their sex: *X* in females and *Y* in males.

As shown in Table 2, the chromosome counts were established for 564 cells and the percentage of each was calculated. The distribution around the modal diploid number, forty-six, is similar to that found in normal cultured cells[2–4]. Of the 564 cells, thirty-five were karyo-

typed and eight cells had only forty-five chromosomes and there was no consistency in the identity of the missing chromosome (Table 3). In five out of these eight instances, a chromosome of the 6–12–*X* series was missing. The missing chromosomes were particularized as follows: in two instances, either number 7 or number 8 was absent; in another two instances, number 6 or *X* was missing, and in another case, number 9. It is worth emphasizing that two of these karoytypes were obtained from male patients. In the remaining three instances where only forty-five chromosomes were present, the chromosomes that were lost were two from the 13–15 and one from the 19–20 groups. It is possible, as suggested by Miller *et al.*[5] and Morishima *et al.*[6], that during metaphase, chromosome distribution does not occur randomly and that sex chromosomes may have a particular tendency to move towards the periphery. If this is so, when the cell membrane is disrupted, there is a possibility that one of these peripheral chromosomes may be lost from the cell rather than one in the centre.

Bearing in mind the possibility of a greater chance of a chromosome loss from the 6–12–*X* group than in the others, Therkelsen[7] analysed a total of 177 metaphases from cultures of peripheral blood from seven females

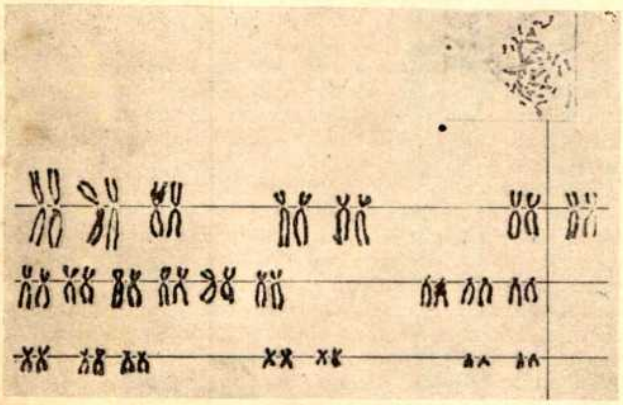

Fig. 1. Normal male karyotype (case No. 5).

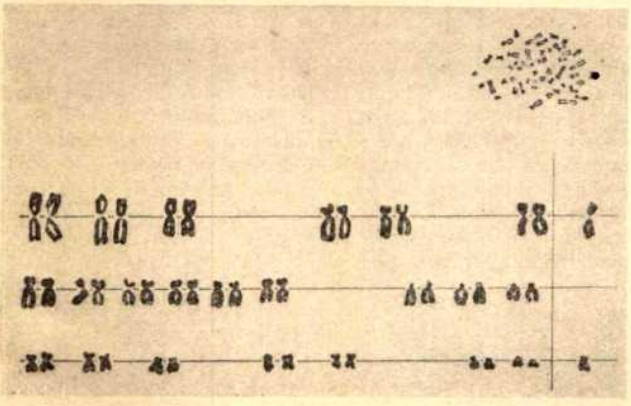

Fig. 2. Normal female karyotype (case No. 7).

Table 3. ANALYSES OF EIGHT CELLS WITH FORTY-FIVE CHROMOSOMES

Corresponding to case No.	Sex	Presumed missing chromosome
1	♂	7–8
1	♂	13–15

4	♂	6–X
4	♀	7–8
6	♀	2
8	♀	9
9	♂	6–X

aged between 18 and 24 years. He found that of thirty-one chromosomes which were missing, eighteen belonged to the 6–12–*X* group.

It is quite possible that in my present investigations selective forces were operating in the cell culture to eliminate most of the cells with less than forty-six chromosomes and any with more than this number. No true increase in forty-five chromosomes was found, however, in any of the elderly patients investigated. Only autoradiography will show whether the lost chromosome (in cells with forty-five chromosomes) is an *X* or *Y*. The possible absence of the *X* is open to question in my investigations, but it is certain that it was never the *Y* chromosome that was missing. Furthermore, if there was any fault in cell division in aged people resulting in cells with forty-five chromosomes, about the same proportion of cells with forty-seven chromosomes could also be expected.

This investigation was carried out at the Institute for Medical Genetics, Uppsala, Sweden, during the tenure of a fellowship from the Consejo Nacional de Investigaciones Científicas y Técnicas Buenos Aires, Argentina.

SOIL SCIENCE

A Circuit for Integration of Temperature Duration greater than Preset Values

A SIMPLE instrument for measuring soil temperatures greater than pre-selected values has been developed for studies of biological processes in the soil[1]. Mean temperatures can be measured by using a thermistor in a circuit with a voltameter[2]. The basic form has been extended to measure the integral of temperature × time above the pre-selected value by building the thermistor, the voltameter and a diode into a wheatstone bridge circuit.

In the circuit shown in Fig. 1, the diode controls the direction of current flow through the central arm, allowing current to pass only when temperatures rise above the set value. By reversing the diode, temperatures below the pre-selected point could be measured. The resistor values depend on the power requirements and the resistance of the thermistor and in our work included a fixed resistor of 500 ohm and two variable resistors of 1 kΩ and 5 kΩ. The resistance of the thermistor was about 1·4 kΩ at 100° F. Copper wire of high purity was found necessary for the electrodes and the voltameter was made up with 8 s.w.g. electrolytic grade copper wire in a 10 per cent solution of copper sulphate. In measuring the copper transferred, the average of the weight changes of both electrodes was determined because, as a result of the low current density, the weight lost by one did not always equal the weight gained by the other.

Table 1. COMPARISON OF TEMPERATURE INTEGRALS OBSERVED FROM VOLTAMETER WEIGHT CHANGES AND CALCULATED FROM TEMPERATURE–TIME CURVES

	Circuit No.	Calculated (° F h)	Observed (° F h)	Difference (per cent)
1st week	1	226	229	+1·3
	2	143	153	+7·0
	3	190	184	−3·2
2nd week	1	24	26	+7·7
	2	65	70	+7·7
	3	112	122	+8·9
3rd week	1	290	296	+2·1
	2	369	340	−7·8
	3	433	407	−6·0
4th week	1	533	554	+3·9
	2	460	454	−1·3
	3	466	460	−1·3

By calibration, the relationship between the temperature of the thermistor and the current that passed through the central arm was shown to be linear (see Fig. 2). Small variations in voltage supply from the battery and large variations in the ambient air temperature around the circuits made little difference to their performance (Fig. 2).

The chief difference between the calibration curves of the circuits results from differences in the temperature-resistance characteristics of the thermistors. The calibration curves are related to each other by the formula xy = constant, where x is the slope and y the factor for that circuit. The differences are not important because either the resistor R_2 can be set initially (to adjust the current in the central arm to a standard value) so that one calibration curve fits many circuits, or the individual factors can be used when converting from weight change of the electrodes to degree-hours. (Here "degree-hours" means the integral of time × temperature above a particular value; for example, 103° F for 9 h with a base temperature of 95° F is 72° F-hours.)

The circuits were initially tested with the thermistor at constant temperature for fixed periods of time. Agreement between observed and calculated values of degree-hours was good; in 80 per cent of the figures the variation

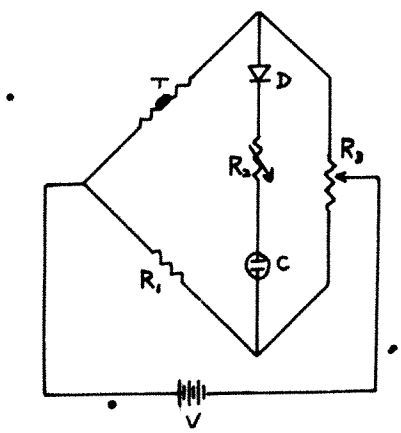

Fig. 1. Integrating circuit. R_1, 500 Ω; R_2, 1 k Ω variable; R_3, 5 k Ω variable; D, Philips diode $OA9$; T, Philips thermistor $928/3K$; C, copper voltameter; V, 12 V car battery.

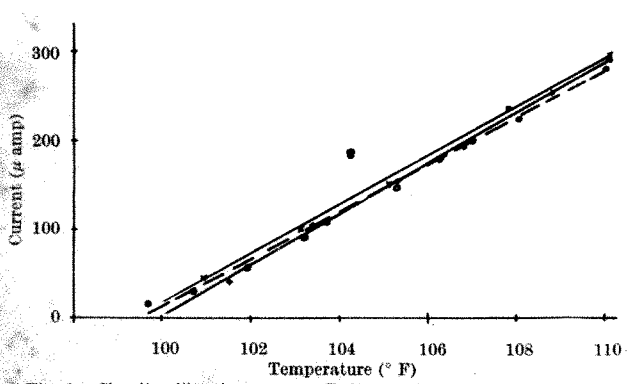

Fig. 2. Circuit calibration curves. Battery voltage and ambient temperature: ×——×, 12 V and 85°–90° F; +——+, 12·1 V and 60°–65° F; ○— —○, 11·8 V, 65° and 85° F.

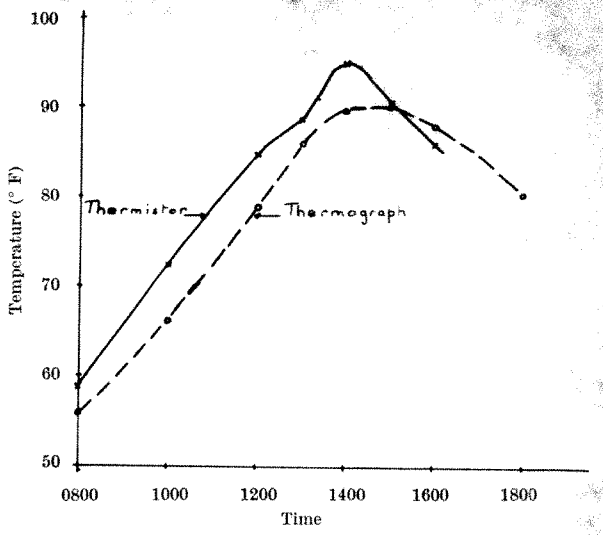

Fig. 3. Soil temperature records at 2 in. depth. August 25, 1965.

was less than 4 per cent and the remainder were less than 10 per cent. To check circuit performance under simulated field conditions the thermistors were placed in pots of plants in a greenhouse when temperature fluctuations were sufficient to obtain a fair proportion of time above the cut-in temperature—here 99° F. Each week differences between the temperatures of the three thermistors were obtained by changing the pots and their positions in the greenhouse. Hourly readings of the soil temperature were taken using the thermistors in the circuits and these were recorded graphically. The temperature–time integral was calculated from the graphs and compared with values from the voltameters (Table 1). Differences between the calculated values and the observed values over the 5-day periods were sufficiently low as to make the method useful in field studies.

The results obtained with thermistors were compared with thermograph records by taking hourly readings with thermistors placed alongside the thermograph elements in the field. Both had been calibrated against the same thermometer. Typical results are shown in Fig. 3 for elements 2 in. below the soil surface on a sunny day. The thermistor registered a temperature integral of 21 degree-hours above the cut-in point of 85° F as compared with thermograph record of 17 degree-hours. The low heat capacity of the thermistor made it the more sensitive instrument for measuring short periods at high temperatures, and higher results were always obtained with the thermistor circuits than thermographs in the field.

The circuit described has been used for one season in the field to record soil temperature integrals above selected values at many points in a soyabean crop[3]. A bank of fifty-four circuits connected in parallel were run from a 12 V battery. Sixty yard lengths of multi-core cable connected the thermistors with the remainder of the circuits which were housed in an adjacent shed. The battery required recharging every second day but during that period voltage changes were negligible.

We found that a modified form of the circuit could be operated from a.c. (220 V) mains by incorporating a rectifier. This necessitated a fixed resistor of 820 Ω for R_1 and the use of two fixed resistors of 27 kΩ and 56 kΩ with a variable one of 46 kΩ in place of R_3 in Fig. 1. The current–temperature ratio was higher but still linear.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, September 19—Friday, September 23

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (in the Renold Building of the University of Manchester Institute of Science and Technology, Manchester)—Conference on "High Voltage D.C. Transmission".

Tuesday, September 20

SOCIETY FOR ANALYTICAL CHEMISTRY, SPECIAL TECHNIQUES GROUP (at the Laboratory of the Government Chemist, Cornwall House, Stamford Street, London, S.E.1), at 3 p.m.—Mr. R. C. Chirnside: "Special Techniques, Past, Present and Future".

Tuesday, September 20—Thursday, September 22

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (joint meeting with the Plastics Institute and the Institution of the Rubber Industry, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2)—Conference on "Advances in Polymer Science and Technology".

Wednesday, September 21

MINERALOGICAL SOCIETY (at the Research and Development Laboratories, Pilkington Bros. Ltd., Lathom, near Ormskirk, Lancashire), at 10 a.m.—Symposium on "Reflected Light Methods in the Study of Refractories and Ceramics".

SOCIETY FOR ANALYTICAL CHEMISTRY, MIDLANDS SECTION, AND THE BIRMINGHAM AND MIDLANDS SECTION OF THE SOCIETY OF CHEMICAL INDUSTRY (in the Haworth Lecture Theatre, Chemistry Department, The University, Edgbaston, Birmingham)—at 3 p.m.—Symposium on "Determination of Organic Acids".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at the School of Pharmacy, University of London, Brunswick Square, London, W.C.1), at 6 p.m.—Dr. J. R. Vickery (C.S.I.R.O., Australia): "The Scope and Status of Food Science" (First Food Group International Lecture).

Wednesday, September 21—Thursday, September 22

CHEMICAL SOCIETY (at the University of Sussex, Brighton), at 9.20 a.m. daily—Autumn Meeting.

Thursday, September 22

INSTITUTE OF PETROLEUM, EXPLORATION AND PRODUCTION GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Address by Mr. Michael T. Halbouty (American Association of Petroleum Geologists).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN THE SUB-DEPARTMENT OF COMPUTATION—The Registrar, The University, Hull (September 23).

ASSISTANT LECTURER (preferably candidate who has worked in the field of insect physiology) IN ZOOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (September 26).

ASSISTANT LECTURER or LECTURER in either: (*a*) SOCIAL PSYCHOLOGY or (*b*) SOCIOLOGICAL ANALYSIS—The Registrar, The University, Keele, Staffordshire (September 28).

LECTURER IN BIOCHEMISTRY IN RELATION TO VETERINARY STUDIES—The Secretary of the University Court, The University, Glasgow (September 28).

ASSISTANT EXPERIMENTAL OFFICER (graduate) IN THE ENTOMOLOGY DEPARTMENT to work on the ecology of soil animals—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1052/92 (September 30).

ASSISTANT LECTURER IN PHYSICAL CHEMISTRY—The Deputy College Secretary, Westfield College (University of London), Kidderpore Avenue, Hampstead, London, N.W.3 (September 30).

EXPERIMENTAL OFFICER (with a degree, H.N.C. or equivalent qualification) IN THE PEDOLOGY DEPARTMENT to assist in research on soils—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1052/91 (September 30).

GEOLOGIST, GRADE 2 (with a university degree with geology as a major subject, and preferably some experience), for geological investigations throughout Western Australia—The Public Service Commission, 184 St. George's Terrace, Perth, Western Australia (September 30).

HEAD (with a good honours degree and experience of research on methods of weed control, preferably in the field of horticulture) OF THE HORTICULTURAL SECTION, for work on the uses of herbicides in horticultural crops—The Secretary, A.R.C. Weed Research Organization, Begbroke Hill, Kidlington, Oxford (September 30).

LECTURER IN THE SCHOOL OF ELECTRICAL ENGINEERING (in the field of automatic control systems), University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

SENIOR LIBRARY ASSISTANTS (2) (with experience of classification and cataloguing, and competence in Russian would be a strong recommendation for one of the posts)—The Librarian, University of Essex, Wivenhoe Park, Colchester, Essex (September 30).

UNIVERSITY LECTURER (or possibly, initially, a Departmental Demonstrator) IN PALAEONTOLOGY IN THE DEPARTMENT OF GEOLOGY AND MINERALOGY—The Professor of Geology, Department of Geology and Mineralogy, University of Oxford, Parks Road, Oxford (September 30).

ASSISTANT LECTURER (preferably with interests in historical geography) IN THE DEPARTMENT OF GEOGRAPHY—The Secretary, University College, Gower Street, London, W.C.1 (October 1).

ENTOMOLOGIST (with a good honours degree or equivalent qualification, preferably in zoology, with specialization in entomology) for research on, and development of, biological control—The Secretary, Glasshouse Crops Research Institute, Worthing Road, Rustington, Littlehampton, Sussex, quoting Ref. N/22 (October 1).

JUNIOR RESEARCH FELLOW IN GEOGRAPHY—The Registrar, The University, Sheffield (October 1).

SENIOR LECTURER IN BIOTECHNOLOGY in the Faculty of Food Science and Biotechnology, Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mal, London, S.W.1 (New Zealand and London, October 1).

CHAIR OF MECHANICAL ENGINEERING—The Secretary, Heriot-Watt University, Edinburgh (October 3).

SENIOR LECTURER, LECTURER (Grade I or II) or ASSISTANT LECTURER IN EDUCATION with special reference if possible, to the psychology of education at the University College of Rhodesia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (October 3).

RESEARCH ASSISTANT (graduate in a biological science) to Dr. J. D. Dodge in the Department of Botany, to collect and culture marine dinoflagellates and examine them by light and electron microscopy—The Assistant Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (October 7).

EXPERIMENTAL OFFICER (with a degree or considerable experience of preparative organic chemistry) IN THE DEPARTMENT OF CHEMISTRY IN THE FACULTY OF SCIENCE to be attached to the Polymer Group—The Registrar, The University, Manchester, 13, quoting Ref. 206/66 (October 8).

CHAIR OF SURGERY AT UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 10).

CHAIR OF ANIMAL HEALTH AT MASSEY UNIVERSITY OF MANAWATU, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 15).

CHIEF TECHNICIAN OR LABORATORY SUPERINTENDENT IN THE DEPARTMENT OF CHEMICAL PATHOLOGY—Prof. G. H. Lathe, Department of Chemical Pathology, School of Medicine, The University, Leeds, 2 (October 15).

LECTURERS (3) IN COMPUTING (for one post a knowledge of numerical analysis would be an advantage)—The Assistant Registrar (Science and Engineering), The University of Birmingham, P.O. Box 363, Birmingham, 15 (October 15).

PROFESSOR (preferably with specialist interests in civil or mining engineering); and SENIOR LECTURERS or LECTURERS in the School of Engineering, University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (October 15).

READER IN CHEMICAL ENGINEERING—The Secretary, Royal College of Advanced Technology, Salford, 5, Lancs, quoting Ref. No. CH/49 (October 17).

SENIOR LECTURER or LECTURER in VETERINARY HISTOLOGY IN THE DEPARTMENT OF VETERINARY ANATOMY, University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (October 22).

LECTURER IN HYDRAULICS or HYDROLOGY IN THE DEPARTMENT OF CIVIL ENGINEERING—The Deputy Secretary, The University, Southampton (October 24).

SENIOR LECTURER/LECTURER IN PHARMACOLOGY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, October 31).

PROFESSOR OF PHYSIOLOGY (Zoology) IN THE INSTITUTE OF BIOLOGY—The Dean of the Faculty of Science, The Hebrew University of Jerusalem, Jerusalem, Israel (January 1).

ASSISTANT PROFESSOR IN BIOCHEMICAL PHARMACOLOGY or BIOCHEMISTRY—The Dean, Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada.

BASIC GRADE BIOCHEMIST (with an honours degree in biochemistry, chemistry or A.R.I.C.) for the hospital laboratories—The Secretary, Dudley Road Hospital, Birmingham, 18.

HEAD OF THE DEPARTMENT OF MATHEMATICS AND PHYSICS; and HEAD OF THE DEPARTMENT OF MECHANICAL ENGINEERING—The Secretary, Wolverhampton College of Technology, Wolverhampton.

PHYSIOLOGIST/BIOPHYSICIST to study physiological response to controlled changes in environmental conditions—D. C. Page, Head of Personnel Services, The Electricity Council, Research Centre, Capenhurst, Chester, quoting Ref. N/28.

PROFESSOR and HEAD OF THE DEPARTMENT OF OPHTHALMIC OPTICS—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff.

PROGRAMMER IN THE COMPUTER UNIT—The Acting Registrar, University College of Wales, Aberystwyth.

RESEARCH ASSISTANT (graduate, preferably with experience of Atlas Autocode and ABL) IN THE DEPARTMENT OF SOCIAL AND PREVENTIVE MEDICINE, to take part in the further development of a compiler for analysing surveys—The Registrar, The University, Manchester, 13, quoting Ref. 202/66.

RESEARCH ASSISTANT (honours graduate in electrical engineering) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING for a project concerned with a study of the distribution of electromagnetic fields in conducting media—The Academic Registrar, Loughborough University of Technology, Loughborough, Leicestershire, quoting Ref. 18A/F.

RESEARCH ASSISTANT to work with Prof. A. G. Gaydon on spectroscopic study of excitation processes in shock-heated gases—Prof. A. G. Gaydon, Chemical Engineering and Chemical Technology Department, Imperial College of Science and Technology, London, S.W.7.

RESEARH ASSISTANT (with a good honours degree in geology or chemistry and an interest in crystalline rocks and/or phase equilibrium studies) IN THE HIGH PRESS/HIGH TEMPERATURE EXPERIMENTAL UNIT, GEOLOGY DEPARTMENT—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire.

RESEARCH FELLOW or RESEARCH ASSISTANT (with a good mathematics degree, or a degree with a high mathematics content, and preferably some knowledge of computer programming and statistical analysis techniques) IN THE DEPARTMENT OF CIVIL ENGINEERING, to take part in basic research in the design of materials for mechanical properties—The Deputy Secretary, The University, Southampton.

SCIENTIFIC OFFICER (with an honours degree, or equivalent, and preferably some research experience) to undertake research on reproductive physiology—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge.

SENIOR LECTURER or LECTURER to teach Zoology full-time—The Registrar, Regional College of Technology, P.O. Box 143, Leicester.

SENIOR PHYSICIST to take charge of the Physics Department, Radiotherapy Centre, St. William's Hospital, Rochester—The Group Secretary, Medway and Gravesend Hospital Management Committee, Medway Hospital, Gillingham, Kent.

TECHNICIAN (with H.N.C. in electronics and preferably experienced in radio frequency techniques) IN THE DEPARTMENT OF CHEMISTRY to work on research and development work—The Personnel Adviser, University of Birmingham, P.O. Box 363, Edgbaston, Birmingham, 15.

WHO STAYS HOME?

THE most recent fuss about the emigration of British doctors, chiefly to North America, has raised again a question which can never be far beneath the surface, but which is inevitably painfully obtrusive at times of economic crisis—is it possible, and is it even desirable, to try to prevent the drift of technically skilled people towards the countries in which they and their kind are already most plentiful and best used? The fact that the doctors are the centre of public attention in Britain just now is probably more a consequence of the row the medical profession is having with the British Government over the terms of service in the National Health Service than a sign that there has been a recent acceleration in the exodus of newly qualified doctors. Indeed, the scanty statistics which exist suggest that the loss has persisted for the best part of a decade. And what is true of doctors is likely to be true of other technical people in Britain and, to a smaller extent, from other countries in Western Europe.

The first thing to be determined, however, is the cause of this substantial exodus. Otherwise, attempts at a solution must necessarily be exercises in pot luck. The trouble is that there is no single reason why technical people emigrate, and often a temptation for them and those who watch them go to hide from the most obvious but most unpalatable truths. This, no doubt, accounts for the frequency with which departing scientists proclaim that they are going "not for the money, but because I shall have more scope in my new job". Of course there is a lot in what they say, but there is also something in the less rosy view that money and the things it brings can be a powerful attraction. Newly qualified people are particularly open to influence on grounds like these. Given similar electron microscopes, or equal chances of working with a big bubble chamber on a particle accelerator, people are likely to be influenced by the ease with which houses, or even motor cars, are to be had. To think otherwise would be to pretend that technical people are not human.

It follows from this that money by itself could do a lot to cure some of the problems of emigration. Certainly it would be a great advantage if some of the problems of emigration were translated into money terms. The doctors are an easy case to start with, for it is a fair guess that, by adding something like £20 million a year, or roughly 20 per cent, to the annual cost of paying British doctors, emigration would be reduced to a mere trickle. With care, and chiefly by seeing that younger doctors were well looked after, it might be possible to achieve the same result with less expenditure. To make this kind of calculation does not imply that the British Government should promptly foot the bill, even though it may only be a small proportion of the whole cost of running the National Health Service, but it is the kind of yardstick which it ought to keep in mind. The point is that the purely financial incentives to emigration could be extinguished at a fairly manageable cost, at least where doctors are concerned. It is obviously not necessary to go all the way to match salaries and other conditions in countries elsewhere, for even skilled people do not lightly pull up their roots. But it is necessary that governments should go in for more hard-headed calculations of the cost of keeping potential emigrants at home. Sometimes they might decide that it is cheaper to let the errants go. Sometimes they might have to reconcile themselves to the apparent paradox that comparatively poor countries may often have to pay disproportionately more to those skilled people whose services they wish more urgently to retain.

To say all this does not imply that the flow of emigrants from countries such as Britain is entirely a function of the cash rewards available in various countries, but merely that this is a much neglected feature of the process. The kind of career which a young man can look forward to is also an important consideration, in academic life as well as in industry. One of the attractions of the United States in recent years has been the way in which young people look forward to early responsibility, and the sense of freedom that accompanies it. American industry is fond of giving young people "their heads", as the saying goes. Then American universities are often more able to let a young person free in charge of his own work, partly because of the machinery for getting financial support, partly because of the technical assistance which is available, and partly because of the comparatively flexible organization of university departments. In industry and universities, there is an impression that American scientists move from one place to another more freely, so that promotion can be rapid—and the frustrations of marking time correspondingly painful. To take the edge off this kind of temptation to emigrate, of course, nothing but simple imitation will suffice, but imitation is necessary on other grounds than those of limiting emigration. Industry and universities in Western Europe, and certainly in Britain, would be better institutions if they were able to give young recruits a greater sense of freedom and opportunity. They would be much healthier and more effective if their technical people were helped along by technical and other assistance as good as any to be had. There is no point in keeping cadres of scientists in half-employment for lack of equipment or other necessary facilities. Better to let them emigrate than that.

No amount of organizational imitation will entirely halt the emigration of scientists from countries such as Britain, however. There are many occasions on which people of all ages decide that they will move from one

country to another because they will then be able to work in fields which are, to them, more exciting. No doubt the space programme in the United States has served to lure some scientists from Western Europe, though its influence has probably been exaggerated. The plentiful supply of particle accelerators has certainly been a magnet for nuclear physicists. And, of course, a young man wishing to work on aircraft development and construction will be attracted almost irresistibly towards the great aircraft plants of the United States. So does it then follow that smaller countries than the United States must enlarge their space programmes and aircraft industries? Arguments like these are common but invalid. Emigration is often the lesser evil, for there is no reason to believe that the numbers of people attracted away from smaller countries by temptations like these are in any way substantial. The costs of keeping them would usually far outweigh the potential benefits.

In any case, of course, emigration is not the simple and distasteful scourge which it is often supposed to be. For one thing, emigration works in both directions. In Britain, for example, there is probably one Irish doctor working for every Englishman recently flown overseas. Britain is probably making still greater demands on the potential medical resources of India and Pakistan—both of them countries much more in need of doctors. But, in the long run, these transfers of skill and training from one country to another are beneficial and, up to some point, are to be encouraged. For emigration is not always permanent. British medicine has probably as much to gain from a better working knowledge of American practices as India, in the long run, will benefit from the return of a proportion of the Indian doctors now working in Britain. In academic science and in industry, these comings and goings are even more to be welcomed. Moving a person from one place to another is, after all, the most effective way of letting one place know what the other is doing. In this sense, emigration can be the life-blood of scholarship. No country can tolerate indefinitely a steady outward flow of bright young people, but by seeing that the conditions of work for technical people, in universities and elsewhere, are those which the criteria of good management in any case suggest, the inward and outward flows of migrants would be reasonably in balance. That, and not demographic isolation, should be the goal.

PUGWASH AFTER PUGWASH

THE Pugwash organization has long since become familiar and even respectable. It has survived the overexcited ballyhoo which attended its creation a decade ago, and which tended to imply that the goodwill and innocence of a handful of scientists would create sweetness and light throughout the world, and especially in foreign ministries. If Pugwash is now less ambitious—and less innocent—than it used to be, it is also more useful. There is good reason to think that the meetings which now take place are modestly valuable and informal means of exchanging information on matters related to arms control between the military powers. The only tangible achievement in this field consists of the work of the informal meetings which preceded the signing of the present test-ban treaty in 1962 and 1963, and which were of some value at least to officials in the United States, but there is also continuing value in the opportunities provided by the larger Pugwash meetings for letting nationals of one country learn more about the policies of others on matters of disarmament. In other words, the value—or the potential value—of Pugwash is not that it can make the problems of disarmament melt away, but rather that it can enable its participants to appreciate why even apparently trivial measures of arms control can be exceedingly difficult to implement. Though its participants would not always appreciate this, Pugwash should be as much a means of ventilating disagreement as of winning agreement.

From this point of view, unfortunately, the published statements of the Pugwash meetings are usually a great disappointment. With respectability, Pugwash has also acquired a kind of folk-lore of received doctrines which cloud its judgment on the affairs with which it wishes chiefly to concern itself. The formal communiqué still contains proposals for arms control which have no relevance to contemporary problems—or even to the problems of a decade ago, when they first made their appearance. The non-aggression pacts and the nuclear-free zones which once more make their appearance may sometimes—though not always—be ways in which security might be increased, but they are no longer central problems. The assertion that the main obstacles to a comprehensive ban on nuclear tests are "political rather than technical" has turned up again, though this time it is accompanied by a fuller discussion than usual of how the technical obstacles—by no means unreal—might be overcome. Then there is some wide-eyed complaint about the remoteness of "General and Complete Disarmament" without much evidence that the participants are aware of the size of the windmill at which they are tilting. This is where the proceedings of Pugwash are most open to criticism. Seeking as they do to influence public opinion, the participants in Pugwash would be much more effective if their pronouncements could give the technicalities of disarmament some hard-headed perspective. The Pugwash communiqué, in other words, should aim to convince those who read it that somebody has made a thorough technical examination of the problems, and has hit on what promises to be a practical solution. To ask all this is possibly to ask that Pugwash should give continuing attention to problems in between major conferences, and there is some encouraging news of attempts to set up permanent working groups. Evidently there is still a great deal to be done.

NEWS AND VIEWS

Small Comfort about Particles

THERE is more relief than disappointment about the news that CERN has failed to confirm an announcement from the United States in June this year that the laws of particle physics are invariant under charge conjugation. To be sure, after the principle of parity conservation was abandoned a decade ago, nothing has seemed inviolate. Three years ago a hint that there might be something wrong with the common assumption of invariance under charge conjugation was provided by some anomalous observation of the decay of K mesons. Among all the troubles which beset the theoreticians, however, there is nothing to suggest that life would be simpler or more reasonable if the laws of physics dealt differently with particles and anti-particles—electrons and positrons, protons and anti-protons. This is why there was consternation in some quarters when a group from Columbia University, working with a hydrogen bubble chamber at the 30 GeV accelerator at Brookhaven, announced evidence that the principle of charge conjugation is invalid. Among a gigantic collection of photographs from the bubble chamber it had been possible to find 1,441 representing the decay of the neutral eta meson into three pi mesons, and statistical analysis suggested that the decay process was unsymmetrical with respect to the electrical charge of the particles. Briefly, the positive pi meson has a statistically greater velocity than the negatively charged pi meson. Since this was precisely the behaviour that would have been expected if the trouble about the K meson decay is indeed a consequence of the invalidity of charge conjugation, it is perhaps not surprising that the Columbia group tended to throw its hat a little in the air (*Phys. Rev. Letters*, **16**, 1224; 1966).

The CERN experiment has also been concerned with the decay of eta mesons, but the technique has been somewhat different from that used at Brookhaven. Instead of having to hunt for significant information in a welter of bubble chamber pictures, the CERN group has used a counter technique and has therefore been able to accumulate significant information quickly. The conclusion that there is no significant asymmetry in the decay of neutral eta mesons is based on seven times as many events as the Columbia group had to work with. Though it will obviously be some time before the matter is fully resolved, the chances are that the CERN view will eventually prevail. Meanwhile, those who may be sensitive to the charge, sometimes heard in recent years, that CERN is always second, will now be quoting the old fable about the tortoise and the hare. Those who want to see even bigger accelerators built quickly will be urging the advantages of duplication in this field. There remains the problem of the K meson and its anomalous decay.

Pugwash in Poland

THE sixteenth Pugwash Conference held in Sopot, Poland, last week seems to have been chiefly concerned with problems of disarmament. In this respect the sixteenth conference differs from its immediate predecessor, when matters concerned with the use of science in developing countries took up a great deal of time. In Poland, four groups of people seem to have devoted themselves to problems of disarmament and the politics of disarmament. On the proposal that there should be a freeze on nuclear weapons in central Europe, the Pugwash committee emphasized the difficulty of controlling the movement of small nuclear weapons and delivery systems, and said that a treaty on non-proliferation of nuclear weapons would help to pave the way for an agreement on the freeze. The same section of the conference was in favour of a reduction of conventional troops in Europe in present circumstances. The traditional Pugwash assertion that a non-aggression pact between the NATO and Warsaw Treaty powers would be a boon was accompanied this time by a statement that some participants saw this as a step towards German reunification and that others considered that the problem of the German Democratic Republic and its legal status could be overcome by the same devices as those which enabled it to adhere to the Partial Test Ban Treaty. Another of the working groups agreed that the issue of recognition for the German Democratic Republic should not prevent the growth of collaboration between the two Germanies in economic, scientific and cultural affairs. In the same spirit the Pugwash statement urges more collaboration between European states on matters such as the exploitation of water resources, energy, transport and the like. The group seems also to have considered that educational collaboration might eventually lead to "common textbooks" in international relations, international law and other fields.

This year's Pugwash seems to have had little to say about general and complete disarmament except to recognize, perhaps more realistically than before, that this is a difficult problem. On more particular schemes for arms limitation, the conference was apparently in agreement that the nuclear test ban treaty should be extended to cover underground tests, though the statement also adds its previous view that the obstacles to a comprehensive test ban treaty are "political rather than technical". The conference suggested that a move towards a comprehensive test ban treaty might be brought about by a treaty incorporating a threshold below which nuclear explosions would be permitted, on the understanding that the threshold would be gradually lowered. To this device could be added commitments undertaken by particular states to refrain from testing nuclear weapons except under various circumstances, the provision of unmanned seismic detection stations and even on-site inspection under a "request and invitation" procedure. In this connexion the statement commends the proposal that there should be a "detection club" of countries willing to collect and to publish seismic data on the basis of which underground explosions might be identified.

Among other less carefully worked out proposals in the statement is a commendation of the non-proliferation treaty, the establishment of nuclear-free zones in places such as South America, Africa and the Middle East, and proposals to refrain from deploying anti-ballistic missile systems and the like. Pugwash commends the efforts of the International Atomic Energy Authority to control the uses made of plutonium and other fissile materials arising from civil uses of nuclear power.

More Discord about Concord

THE Committee of Public Accounts of the House of Commons has added to the public criticism, in Britain and in France, of the Anglo-French project to develop the supersonic aircraft called Concord. In a report now published (*Second Report of the Committee of Public Accounts*, H.M.S.O., 3*s*.) the committee draws attention to the way in which the estimated cost of the Concord project has risen from between £150 millions and £170 millions in 1962 to £275 millions in May 1964 and has now reached the present approximation of £500 millions to the final cost. The total cost is to be shared equally by the two governments. Increases of cost in the past four years have been necessary because of substantial changes of design, primarily intended to increase the range of the aircraft, but the general upward drift of industrial costs has also played some part. It seems plain that the Public Accounts Committee, which is one of the most persistent of the public bodies empowered to inquire into the spending of public money in Britain, intends to press a reluctant Treasury to agree that there should now be a thorough review of the procedures for forward estimating in collaborative aircraft projects, chiefly because the committee has decided that "the Concord project provides a severe test of the Ministry's system for controlling research and development projects".

The committee's report has directed public attention to a number of important features of the Concord contract. In the first place, the sum of £500 millions now estimated as the final cost includes £80 millions for the development work which, it is expected, will continue after a certificate of airworthiness has been granted to the prototype machines two years from now. (There is also a sum of £50 millions labelled "contingencies".) It also appears that the contracts which are being negotiated between the governments and the aircraft manufacturers will make it possible for the governments to recover some of the initial outlay on research and development. Even on an "admittedly optimistic forecast of the number of aircraft to be sold", however, it is apparently considered improbable that as much as a third of the initial cost will be returned to the treasuries of Britain and France by means of levies.

In line with its reputation as a watchdog over public expenditure, the Public Accounts Committee is understandably anxious that there should be much better arrangements for negotiating contracts for the development of aircraft. One of the most worrying features of the present position is that so far only £90 millions of the total expenditure has been incurred. Obviously there is plenty of time yet for the cost to rise still further. It is small wonder that the Public Accounts Committee promises to return to this theme.

Laboratory Work Study

THE report of the Public Accounts Committee which drew attention to the financing of the Concord aircraft (see above) has also raised a more modest protest about the way in which the Ministry of Aviation—soon to be abolished—has apparently resisted for sixteen years the attempts of the British Treasury to see that research scientists in government laboratories are being used to the full. Arrangements were apparently made in 1949 to see that each department of government should be responsible for inspecting the use made of its own staff, and for seeing that it is employed efficiently. When the Treasury pointed out, in 1963, that the Ministry of Aviation had not sent its inspectors into the laboratories, the Ministry replied that it was short of inspectors. By 1965, however, research staff in some though not all of the Ministry's laboratories were inspected, and it was apparently decided that of 160 scientific posts at the Radio Department of the Royal Aircraft Establishment, Farnborough, 24 were in some way open to criticism and 7 could actually be abolished. (The same inspectors also approved the creation of three additional posts in the same department.) To judge from what the Public Accounts Committee has to say, the Ministry is hoping to decide, on the basis of inspections at several establishments, whether the game is worth the candle. Everyone seems to agree "that there are limitations on the value of inspection in the scientific field compared with its value in the clerical and office field", but here again the Public Accounts Committee promises—or threatens—that it will not let the matter drop.

Industrialized Building

ON-SITE battery production of the basic units of large buildings, such as blocks of flats, has been used extensively in Europe and especially in the Soviet Union. The system offers considerable savings in manpower and costs, but has not been widely used in Britain, where the building trade is still very much dominated by a traditional approach. In co-operation with the Building Research Station, the Edmonton Borough Council undertook in 1964 to build a 17-storey block of flats using the industrialized system and casting walls and floors on site. The results of the experiment are reported in *Building Research 1965* (H.M.S.O., London, 1966).

The internal structural units were produced by vertical casting between concrete panels, the moulds being in groups of up to sixteen units. The external cladding panels had to be produced by horizontal casting and needed far more labour. The total labour required for the erection of the shell of the building was 570 man-hours—it is hoped to reduce this substantially in the future when more experience with the technique has been gained. Among the problems to be overcome is the battery casting of the cladding panels, and simpler panels have now been designed which can be cast in this way.

The technique has aroused considerable interest and is now being used by a number of firms. The report expresses concern, however, that the relative ease with which the process can be adopted should not lead to a deterioration in the standards of design. If past experience is anything to go by, this fear is only too well founded.

Synchronized Training

THE Council of Engineering Institutions, comprising the twelve British engineering institutions and the Royal Aeronautical Society, has finally designed a single examination for all engineers to replace the individual examinations previously administered by each engineering institution separately. The new examination will be conducted at degree level and, like the previous individual exams, will provide another

avenue to engineering qualification equivalent to a university degree or sandwich course.

Mr. F. E. Warner, chairman of the education and training committee responsible for the change, feels that the majority opinion among engineers is in favour of a comprehensive engineering education. It was only when setting the papers that various engineers discovered, to their surprise, the similarity of their problems. The examination is in two parts, the first consisting of one paper in each of six subjects—properties of materials, applied thermodynamics, fluid mechanics, applied mechanics, applied electricity and mathematics—corresponding to a level half-way through a degree course, and the second including one compulsory paper on "the engineer in society" and five others from a choice of thirty-seven. The first paper covers such areas as government, economics and business management; it is not expected to encompass a full business course but, Mr. Warner said, "to make engineers aware of the properties of men and money and their interaction with engineering". This new system will become mandatory by January 1974, but timetables for incorporating all or part of the examination will differ for various groups.

The committee has also worked to revise the other membership requirements of all the institutions, and there is a growing belief that there is a need for engineers and engineering administrators to do a stint in the universities so as further to broaden their outlook—and that of university students. While the CEI is justly proud of the new examination and feels it is an important step away from overspecialization, it is also aware that it will become less important as more and more students enrol in full-time and sandwich courses. The great increase in the numbers of technical and training colleges has meant that fewer students are studying part-time while holding down jobs as well. The examination may, however, remain important as an internationally acceptable standard.

Demographic Revolution

A POPULATION Conference sponsored by the Council of Europe was held in Strasbourg at the beginning of September. The justification of yet another conference so soon after that organized by the United Nations in Belgrade last year is that Europe is the only area now reaching the third and final stage of the 'demographic revolution'. The fertility rate is declining to the point at which it just offsets a very low death rate—a state characterized by controlled fertility and mortality. In his opening address to the conference M. Jean Bourgeois-Pichat, chairman of the organizing committee, said that "it is in Europe that solutions will first have to be found to the economic and cultural problems which the end of the demographic revolution will bring. Perhaps it is no exaggeration to say that it is in Europe that the future of the human race will be decided".

By bringing together 174 participants from 25 countries the conference attempted to emphasize the increasing need for co-operation in research and data collection by all European nations. Besides holding general meetings on such subjects as "developments in mortality", "developments in fertility" and "trends in population structure and their consequences", the conference adopted a series of recommendations—on comparative research into fertility, studies of the changing needs of elderly people, the training and housing of migrant workers, the standardization of population statistics, and the international aspects of regional planning, particularly in areas close to national frontiers.

Fish for Food

WHAT can the intensive production of freshwater fish contribute towards the world dietary deficiency of protein? This was discussed at an international meeting of 160 fishery biologists at the University of Reading during the first week of September. The meeting was convened to survey the biological basis of freshwater fish production and to prepare a handbook of methods for use in the Productivity of Freshwaters section of the international Biological Programme—a document which should be both authoritative and up to date and an invaluable aid to further research on a world-wide basis.

The first stage in evaluating a fishery is to determine the size of the exploited population, its age structure and rates of mortality and recruitment. It was clear that methods for estimating these vital statistics are now well advanced, although populations in tropical waters, where the seasonal rhythm of growth and reproduction is not well defined, present special difficulties. For the efficient management of production it is also necessary to know the food consumption of the fish and the efficiency with which the food is being converted to flesh. In this field much more work is needed, for though it is relatively easy to determine the efficiency of food utilization of fish reared on artificial foods in small ponds, it is not yet possible to calculate with any certainty the food consumption of natural populations. An important Russian school favours indirect calculations based on measurements of metabolic rates, while in North America the emphasis is on extrapolation from feeding experiments in aquaria. The influence of behaviour patterns on food consumption and hence production has more recently been appreciated—among species which are territorial in habit, for example, the number of individuals an area will support is limited by interspecific competition for territory, so that the production of a particular stretch of stream remains approximately constant whatever the density of stocking above a certain figure.

Those concerned with practical aspects of fishery management tend all too readily to assume that predators are undesirable and should be exterminated. The meeting at Reading was warned that natural predators may serve a useful purpose, for example by removing weak or deformed individuals from the breeding stock. It was also told about techniques for the management of freshwater fisheries in ponds and in natural habitats. It appears that the most impressive yields are to be obtained from ponds, since these afford the greatest degree of control at all stages of the production process. In many parts of the world the potential of an acre of fresh water for the production of high grade protein is far greater than that of an acre of land, so that a policy of controlled flooding might well be advantageous. A speaker from FAO, after presenting a rough protein budget for the year 2000, suggested that it might be possible to increase the production of freshwater fish in ponds by a factor of fifteen to thirty. Increasing production from the

land, already heavily exploited, might well be more difficult.

Physical Research in Africa

DR. B. N. C. AGU of the Department of Physics, the University of Ibadan, Nigeria, writes in retrospect of the problems discussed at the eighth annual conference of the Science Association of Nigeria earlier this year:

Most indigenous scientists, including those who graduate at home, tend to do their postgraduate research abroad for two main reasons. One is because of the limited facilities in most parts of Africa for research in the branches of physical sciences in which the students wish to work, including nuclear physics, electronics, metallurgy, solid-state physics, health physics and radio-astronomy. Another group of postgraduate students goes abroad in search of a doctorate from a reputable university in the United Kingdom or North America. Many of these will eventually return to take up teaching assignments in the local universities.

Most of the scientists who take postgraduate degrees abroad soon find in Africa that the convenient set-up on which they worked in the older universities abroad is no longer available to them. Should they attempt to maintain a tenuous umbilical cord with their mother universities abroad in order to continue research, or try to make a fresh start in African universities?

This latter procedure requires years before any progress is made and large sums of money which are not usually readily available. The purchase, replacement and repair of research equipment can be very frustrating. Orders for equipment take several months to arrive and the replacement of defunct parts takes even longer. The problem of getting and retaining competent technicians is almost insurmountable. Without enough local experience the repair and maintenance of research equipment become a major operation which can hold up important work for months.

In recent years, several countries and international organizations have been showing interest in developing research in Africa. However, a quick survey of the fields in which research is supported by these bodies shows a bias towards agriculture and veterinary science, African studies, population problems, child health, medicine and malnutrition problems in the developing countries. For the five year period 1961–1965 the distribution of foreign benefactions to the various departments of the University of Ibadan and its Teaching Hospital was as follows:

Medicine and Child Health	£483,361
Agriculture	£250,810
Education and African Studies ..	£246,910
Chemistry	£32,100
Physics	£7,650

The share of the physical sciences in these funds is meagre. One explanation may be that since these benefactions come from highly industrialized and developed countries, none of the organizations is interested in encouraging basic physical science research in developing countries. Except during the International Geophysical Year and the International Year of the Quiet Sun, when some equipment and limited funds were provided for collecting data from outstations in Africa, all the burden of research in the physical sciences has had to be borne by the resources of the particular developing country. Given the need to provide social amenities, very little money will in fact be available from the governments for any form of research. The very few industries in these countries are usually operated by foreign companies which have their headquarters in the developed countries. Most of their research can usually be done better in their home countries and therefore they will have little interest in encouraging research in the universities of the country in which they are operating.

The Quality of Radiation

A REPORT is about to be published by the International Atomic Energy Authority, Vienna, of an international panel meeting held in Vienna last year to discuss the biophysical effects of ionizing radiations of various kinds and properties (Technical Report Series No. 58, *Biophysical Aspects of Radiation Quality*, I.A.E.A., Vienna, 1966). The subject is important not merely because of its practical value in assessing the hazards due to radiation which is not simple in character, but also because of its interest in fundamental radiobiological research. One of the conclusions of the panel at Vienna was that there is a need of more systematic measurement of energy dissipation in biological material by ionizing radiation of various kinds. The intention is that the activity of the group shall be continued within the framework of a research programme co-ordinated by the international agency, and it is expected that the programme will be more clearly defined at a meeting to be held under the auspices of the agency in 1967.

Much of the discussion of the technical panel was concerned with the survival curves for cells of various kinds, and with the interpretation of the available experimental evidence. On one model, the results were interpreted in terms of the amount of energy required to produce critical molecular damage in small regions of the nucleus from a mammalian cell possibly not greater than 50 Å in diameter. In the same vein, a model of genetic damage supposing that critical effects are produced by one ionization in each of the very small structures situated more than 100 Å apart, showed that more heavily ionizing atomic particles have a greater probability of doing damage. Other interpretations of cell survival curves described at the meeting of the panel consisted of a model in which the damage done by alpha-particle radiation can be accounted for by the dissipation of between 350 and 500 eV in a small volume of a mammalian cell. (From this discussion it also emerged that the proportion of single-hit killing by X-rays in kidney cells is between 10 and 20 per cent.) Other interpretations of the effects of ionizing radiation on single cells were based on various stochastic models.

Replant Problem

THE "replant problem" is only one of many which face fruit growers, but solving it could lead to a spectacular increase of yield on many farms. It turns up when fruit trees are planted in ground previously planted with trees of the same species—for example, when apple trees are planted in old apple orchards. The cause is not yet clear, but the result can be a considerable retardation of growth in the first year of the life of a tree and proportional losses throughout. Clearly

something in the soil has an effect on the roots, which have a characteristic stunted appearance and cover a much smaller volume than normal roots.

The consequences of the replant problem have now been convincingly demonstrated by a series of experiments at the East Malling Research Station. Apple trees planted in an old apple orchard are small and poorly developed compared with similar trees planted after treating the soil with chloropicrin. This substance obviously gets rid of whatever it is that stunts growth, but it is dangerous, expensive and unpleasant to handle. Acidifying the soil is also effective but is much more expensive. Research is continuing at the root laboratory of the station to identify the cause—organism or substance. Although nematodes and viruses have been more or less ruled out, bacteria may be the culprits. In any event, the work has produced interesting new results on the growth of fruit tree roots and on the habits of the nematodes which prey on them.

Weizmann Institute

THE Annual Report of the Weizmann Institute shows that the establishment of the institute at the end of 1965 consisted of 300 scientists and engineers. At the same time there were 89 visiting scientists in residence. During the year £952,000 was contributed to the institute's budget by agencies, foundations and other organizations in Israel and elsewhere, and supported roughly a quarter of the work being done.

Index to Food Safety

THE vigour of the Food and Drug Administration has given the United States a fine reputation on food safety. The National Academy of Sciences has now done its bit to help by the publication of a comprehensive definition of standards of identity and purity for some 500 food additives now in use in the United States (*Food Chemicals Codex*, National Academy of Sciences—National Research Council, $25.00). The volume is the result of five years of work by a Committee on Specifications under Dr. Henry Fischbach, of the Food and Drug Administration. Draft specifications prepared by the committee, and with the help of an advisory panel under Mr. R. B. Smith, President of the Medical College of Virginia, were criticized by interested parties in industry, research and government before being cast in final form. The principal value of the new publication will be the way in which it will enable food manufacturers in the United States to interpret and abide by the necessarily laconic regulations which embody the ways in which the U.S. Government has sought to control the use in American foodstuffs of the 575 chemicals considered to be safe.

Professor E. A. Guggenheim

THE University of Reading is about to lose Professor E. A. Guggenheim, who retires on September 30. He has been head of the Department of Chemistry at Reading since 1946, and during this period has made his principal contributions to thermodynamics and statistical mechanics. During the same period he has built up a vigorous School of Physical Chemistry at the University. He will be succeeded as head of the Department by Professor G. W. A. Fowles, at present Professor of Inorganic Chemistry. Guggenheim has been nominated Emeritus Professor.

University News: London

DR. J. M. HINTON, first assistant in the Academic Department of Psychiatry in the Middlesex Hospital Medical School, has been appointed to the chair of psychiatry tenable at that school.

Appointments

MR. W. J. BRAY has been appointed director of research at the Post Office in succession to Dr. G. H. Metson, who retired in August.

Announcements

THE United States National Academy of Sciences and the National Academy of Engineering has announced the appointment of John C. Kohl as executive secretary of the Division of Engineering of the National Research Council, effective September 15. The NRC is the operating agency for both Academies.

Mr. Kohl, a civil engineer with broad experience in the field of urban transportation, became executive vice-president of the American Transit Association in March this year, after serving since 1961 as assistant administrator (transportation) of the Federal Housing and Home Finance Agency, responsible for its urban transportation programme including capital grants and transit demonstration projects authorized under the Urban Mass Transportation Act of 1964. He held that position on leave from the University of Michigan, where he was Professor of Civil Engineering and Director of the Transportation Institute.

Mr. Kohl succeeds Louis Jordan, who is retiring as executive secretary of the division after 24 years as a member of the NRC staff. Mr. Jordan will continue to serve the division as special consultant to its chairman, John A. Hutcheson.

The Division of Engineering, one of eight NRC Divisions, includes in its membership representatives of more than 20 national professional organizations as well as members-at-large drawn from various engineering specialties; more than 1,200 engineers and scientists from the academic community, industry and government participate in the Division's activities

AWARDS for postdoctorate research on the biochemical and physiological mechanisms of fertility and early stages of reproduction in various forms of life are being offered by the Lalor Foundation, Delaware, U.S.A., for tenure during 1967. They are open to scientists of all nationalities and may range up to $8,000 per year depending on the scope and duration of the projects approved. Preference will be given to younger members of university and college faculty and staff with an upper age limit of 41 years. The work may be carried on at the applicant's own institution or elsewhere. The foundation will also grant postgraduate summer or short-term research awards at the Marine Biological Laboratory at Woods Hole, Massachusetts. These awards will normally not exceed $1,200 for a single man or a woman, $1,400 for a married man working at his home institution, and $1,600 for a married man with principal programme at another institution. Requests for information and for application forms should be directed to the Lalor Foundation, 4400 Lancaster Pike, Wilmington, Delaware 19805.

THE International Association for Plant Physiology has prepared an International Directory of Plant Physiologists associated with its fifteen constituent national organizations. Copies may be purchased for $1.00 from the secretary-treasurer, Prof. Arthur W. Galston, Department of Biology, Yale University, New Haven, Connecticut.

THE journal *Respiration Physiology* (*Nature*, 211, 901; 1966) is published by the North-Holland Publishing Company.

WHAT NEXT AT BERKELEY?

THE University of California at Berkeley, one of the finest academic centres in the United States, was torn by a campus upheaval in the autumn of 1964 that was unprecedented in an era of campus conformity for the majority and Vietnam and civil rights protests by the vocal minority. Were they 'Reds' and 'Chinese communists'? Or were the participants in the Free Speech Movement at Berkeley intelligent students revolting against the impersonality of a university the size of Berkeley—27,000 students in 1965—and their own lack of motivation? Prompted in part by the unrest represented by the Free Speech Movement, the university's Emergency Executive Committee appointed in March 1965 a Select Committee on Education to examine in detail the problems of the university and present possible solutions. The committee, under the chairmanship of Prof. Charles Muscatine, has now submitted its report, and many of its recommendations should be implemented during the present academic year (*Education at Berkeley*, University of California Press and Cambridge University Press, March 1966).

The report does not present a broad, sweeping programme, nor does it attempt completely to revolutionize any large segment of the university; what it does try to do is establish an atmosphere of change and adaptation and at the same time to present a number of proposals aimed at specific problems. "Our ideal for the student is that he be provided with rich opportunities, generous guidance, and plenty of room for experiment, and that he be enabled to make for himself as many of the important decisions about his own education as possible".

The complaints that were levelled against Berkeley by the Free Speech Movement included claims that students were ignored and even deprived of their right to speak, that they were treated as IBM numbers rather than individuals, and that professors were more interested in research than teaching and had no contact with their students. The select committee admits that some of these charges are valid and has attempted to offer some solutions. To be sure, the committee does conclude, from a number of surveys among students, that most students consider they are getting a good education. In spite of this, the supporters of the Free Speech Movement were not simply a small minority but the hard core of intelligent and articulate students who wanted a cause with which they could identify.

But the problems at Berkeley stem not only from its size but from its composition. Berkeley students are as mobile as most Californians. Of the class entering as freshmen in 1961, only 50 per cent graduated by January 1966 or were still on the campus. Of the class that graduated in 1965 from the College of Letters and Science —the largest school in the university—38 per cent had completed their first two years elsewhere; only one-fifth of the graduate students come from Berkeley, so there are also more than 3,000 new students in the graduate schools each year.

An unstable, fragmented body of students, many of whom commute for between two and six hours each week, does not make for ease of contact in a large university, and many of the committee's proposals centre on this problem. It wishes to see the advising system, especially for freshmen, changed from an empty formality to a more personal though voluntary opportunity for students to seek out an adviser of their choice when they need help and not, as at present, merely to acquire the signature of a teacher who neither knows nor has time to care about what he is signing. The report says that the present system "is based on the doubtful assumption that a spontaneous and genuine relationship will develop between a student and a faculty member within the short periods officially required for advising twice a year. There are probably few men who are capable of forming meaningful relationships with dozens of students on short notice". To help new students the committee would like to see a summer orientation and guidance programme so that incoming students can learn what choices are available and map out a tentative schedule well before they register.

The complaint of many students at large universities that their professors have little interest in them and are more concerned with their research than with teaching can and has been made at Berkeley. At a university where more than one-third of the students are graduates, it would be very easy for teachers to neglect their undergraduate students, but, in fact, this does not seem to be generally the case. From a study of the distribution of faculty time-tables, it appears that the average teacher spends 24 hours on courses and lectures, 10 on undergraduate consultation and advising, 7 on graduate research instruction, and only 10 on individual research.

Size is a problem for classes in the lower division courses in the first two years, where classes average seventy. It seems clear, however, that the problem of student–faculty contact has not arisen from a neglect of teaching in favour of research on the part of the faculty. Even so, the committee recommends an eventual increase of the teaching staff with the student enrolment held constant. In the meantime, it considers that the proportion of lecture courses should be decreased in favour of discussion sections, seminars and tutorials, and that students be given more opportunity for supervised but independent study.

The report would also like Berkeley to reverse the increasing importance of course grades. Both students and faculty have often expressed dissatisfaction with a point-grading system—a student survey showed that 35 per cent of honours students believed that their grades did not reflect their actual knowledge and understanding of a subject—but the committee did not feel prepared to offer a comprehensive alternative. It does, however, propose that students should be allowed to take one course apart from their major each term on a pass or fail basis, and that some courses should be offered in a sequence of two or three quarters with a grade given only at the end.

Possibly the most important and far-reaching recommendation outlined in the report is for the establishment of a Board of Educational Development. As the committee says, "we believe it is important to establish machinery, not to implement any single curricular change, but to give continuing consideration, encouragement and financial support to all worthy proposals for educational development". The committee visualizes a permanent board of seven, each member serving for three years, to determine policy, implement projects, carry out studies and attempt to establish priorities for educational development.

None of these proposals will bring about any radical changes in education at Berkeley, but they do reflect and bow to the general unrest that has hamstrung the campus for the past few years. They betoken a willingness to experiment and to consider new concepts. Whether any innovations will be able to cope with the problems of size and composition that face such a State university remains to be seen, but Berkeley's pragmatic and gradual approach looks like making a practical start.

INSTEAD OF COSMOLOGY

By PROF. OSCAR KLEIN
Ringen 21, Stocksund, Sweden

THE attempt outlined in this article, to consider the origin and evolution of the system of galaxies—our metagalaxy—in a similar way to that of smaller stellar systems, is not a new cosmology but is essentially based on a somewhat detailed criticism of the various branches of cosmology of which some indications will be given below. On the other hand, it depends largely on the considerations developed in connexion with relativistic cosmology, the aim of which—apart from its philosophical foundations—has been real enough, namely, the interpretation of some remarkable results of astronomical observation, in the first place the characteristic red-shift of the spectral lines from other galaxies in its dependence on their distance, as discovered by Hubble; second, the tendency towards an even distribution of galaxies and galaxy clusters, when sufficiently large volumes are considered and, further, the recently discovered electromagnetic radiation apparently corresponding to a temperature equilibrium of a few degrees above absolute zero.

On the other hand, present day cosmology also has much in common with an age-old inclination of the human mind appearing in early creation myths and later giving rise to world systems based on *a priori* arguments, either theological—the universe being worthy of the wisdom of the Creator—or philosophical—so-called necessities of thought. Thus the system ascribed to Aristotle but also influenced by *The Bible* reigned on the whole, though not without modifications, throughout the Middle Ages.

In contrast to such grand world systems, physical science developed from a thorough study of certain simple classes of experience : the equilibrium conditions for solid bodies and liquids and the motion of falling and thrown bodies—not to mention the experience behind Euclidean geometry. This gradually led to the disclosure of general laws behind phenomena such as the principle of virtual work, the law of inertia and the principle of relativity, which in extended and modified form still belong to the foundations of physics. This search for general principles by means of well-chosen characteristic features of gradually more extended classes of experience is still the leading stimulus in physics, as illustrated by the development in the present century of relativity theory and quantum theory.

In earlier work of this kind, such as Newton's discovery of the law of general gravitation and his development of what we now call classical mechanics on the foundation laid by Galilei and his predecessors, the contrast with the "cosmological" trend was very conspicuous. This appears in Newton's general statements in his *Principia*, of which the claim of using the same explanation for analogous things was far from trivial, when things were the fall of earthly bodies and the motion of celestial planets. It may be said that the mentioned results of Newton's researches first gave substance to the concept of the universal laws of nature, which since then has been the leading idea behind physical investigation.

Although in formulating his law of general gravitation Newton had to rely on astronomical experience as embodied in the Keplerian laws, the later disclosure of general laws in electromagnetism and quantum physics has been mainly based on "earthly" experience. Conversely these laws have come to play an increasingly important part in astronomy the problems of which, apart from size and time, are well within the range of what can be studied in the laboratory. Scientists who wish to introduce new laws of nature in order to make the universe satisfy their *a priori* claims have, however, a certain advantage over Newton's contemporaries, who believed in the short time-scale of *The Bible*.

It is of interest in this connexion to consider the statement called "the cosmological postulate" by the defenders of the steady state cosmology : *that on the average the universe is the same everywhere and at all times.* Taken as the background for the hypothesis of a spontaneous creation of matter at a rate just sufficient to compensate for the rarefaction of the metagalaxy as a result of its observed expansion this is certainly an extreme example of cosmological thinking. On the other hand, the statement itself is a natural induction from astrophysical experience concerning the validity of the laws of gravitation, electromagnetism and atomic physics at the most distant places and early times so far accessible to observation. Thus, just as a sufficiently large sample of a population living under unchanging natural conditions and human legislation will show a constant distribution of ages and professions, we should expect that a sufficiently large region of the universe would present a constant distribution of stellar systems with respect to types and stages of evolution. Because the metagalaxy is in fact changing we conclude that—despite its enormous size—it is too small to be representative of the average situation in the universe. Moreover, we assume that it is just one of a multitude of similar systems in different stages of evolution, some of them expanding and some contracting.

On this assumption, our metagalaxy would not be a singular case but, like the smaller stellar systems, a regular occurrence in a very much larger—perhaps infinite—universe, very thinly populated by stellar systems, so as to avoid the well known paradox of infinite gravitational fields and infinite starlight illumination in the way suggested by Charlier and others. Such considerations lead us to assume that the metagalaxy once started as a very extended and very thin collection of the simplest stable particles—protons and electrons—which contracted by means of mutual gravitation.

As we shall see, these assumptions are further supported by a closer comparison of the foundation of Einstein's general relativity theory with the arguments behind his cosmology. Also, a tentative interpretation based on the view just mentioned of the origin of the metagalaxy of the relationship noticed by Eddington between the size and mass of an Einstein universe (adapted to the average density of the system of galaxies) to the so-called radius of the electron and the mass of the proton seems to offer some clue as to the manner of its transition from an earlier contraction to its present expanding state.

After some preliminary attempts on this basis it occurred to me that it would be extremely improbable for the huge

cloud under consideration not to have contained as many antiprotons as protons and as many positive electrons as ordinary electrons. The evidence obtained from experiment as well as theoretical studies points to an equal *a priori* probability of a particle and its antiparticle. This hypothesis of equal amounts of matter and antimatter in the original cloud made it necessary to assume that some natural mechanism of separation has been in action during the evolution of the metagalaxy. Questioned about this point, Professor Hannes Alfvén soon proposed some such mechanisms. This was most stimulating and led us to consider seriously the possible role of matter–antimatter annihilation as a hitherto neglected force in cosmical physics, the first result of which was a sketch of the evolution of the metagalaxy from its start to the present expanding state (published in a joint paper, where his separation mechanism was also briefly considered).

The great progress made during the past twenty years in interpreting the many new discoveries in elementary particle physics is based on the combination of quantum theory and special relativity theory. This has given rise to the opinion shared by many physicists that, while special relativity is one of the most fundamental principles in physics, the concepts of general relativity are limited to the realm of very large dimensions—gravitation being not only the weakest but also the least understood kind of interaction. I believe that this opinion has arisen from a misunderstanding of general relativity partly caused by Einstein himself in connexion with his cosmological considerations. Thus I believe that elementary particle physicists are right in assuming that the fundamental laws of physics are those found in the limiting case of negligible gravitation. But far from being contrary to the theory of general relativity, this view is a consequence of what Einstein called the "equivalence principle", the very cornerstone of his general theory.

It is of interest that the concepts on which this fundamental principle is based depend on experience well known since Newton's time and already known to Galilei —namely, that all bodies undergo the same acceleration in a gravitational field—and from which follows an explanation of the now well known weightlessness inside a satellite. In Newtonian theory, however, this applied only to mechanical phenomena. But Einstein—starting from special relativity, emanating in its new form from a thorough study of electromagnetism and optics—saw in this old fact a deep law of nature applicable to any physical phenomenon. Already in Newtonian mechanics the fact mentioned implies that an inertial frame of reference—that is, a frame in which the law of inertia is directly valid—can be introduced locally anywhere and at any time in any gravitational field. The word "locally" here means that such a frame can be used in the neighbourhood of a certain point during a certain time interval, sufficiently small for the variation of the gravitational field to be negligible. Mathematically this is related to the replacement of a small part of a curved surface by a bit of the tangent plane. But just as a lake—despite the curvature of the Earth's surface—can be considered as plane for most purposes, this kind of frame will in most cases have a practical validity within a quite large space–time region.

Einstein's principle of equivalence states that any physical law, when referred to an inertial frame, will hold in circumstances where gravitation may be neglected —that is, will be a law of special relativity theory. Conversely, any such sufficiently well known physical law can be generalized so as to describe the effects of gravitation on the phenomena in question.

Two important implications of this principle which are often forgotten will be emphasized here. The first is that this principle provides the physical interpretation of the mathematical formalism of general relativity theory; measurements of physical quantities—most directly those of length and time—being in principle referred to an inertial frame, that is, a frame freely falling in the local gravitational field and having zero velocity with respect to the practical rest frame at the time of the measurement. The other, which is a consequence of the first, is that there is no essential difference between so-called inertial forces—such as the centrifugal force—and "true" gravitational fields.

We shall now consider briefly the properties of an approximately isolated system—for example, its mass—from the point of view of the principle of equivalence. The use of an inertial frame implies the practical removal of all gravitational fields other than that due to the system itself. Thus, in order to measure the mass of the Earth by means of the gravitational field it produces, a frame has to be used in which the gravitational field from the Sun is removed as far as its lack of homogeneity permits, that is to say, a frame freely falling in the field of the Sun. This field is sufficiently strong to influence appreciably the direction of gravitation but is compensated by the inertial force as a result of the accelerated motion of the Earth around the Sun. As is seen, this compensation is automatically taken care of by using the aforementioned frame.

A similar case is provided by the Copernican frame, in which the centre of gravity of the solar system is at rest, and which is freely falling in the gravitational field due to the remainder of the galaxy. Here the average field is very weak, which means that this frame deviates very slightly from one at rest with respect to the sphere of fixed stars, a frame which was assumed to give a practical definition of Newton's concept of absolute space. In a frame of reference at rest or in uniform motion with respect to absolute space there would be no inertial forces. Referred to such a frame and using the corresponding concept of absolute time the true laws of physics would hold—in the first place the law of inertia.

These Newtonian concepts were strongly criticized by Mach, the famous physicist-philosopher, in his admirable book on the evolution of mechanics. Regarding them as metaphysical in the worst sense of the word, he took the view that only the motion of a body with respect to other bodies could be physically meaningful. He concluded that inertial forces must be gravitational effects resulting from accelerated motion with respect to the multitude of distant bodies in the universe. This idea appealed strongly to Einstein in his search for a generalization of special relativity and became—under the name of "Mach's principle"—one of the main incitements to his cosmology.

While Mach's apparently well founded criticism of Newton's concepts was actually based on preconceived ideas of the meaning of words like "body" and "empty" space, Einstein's principle of equivalence was, as we have already seen, an induction from empirical facts. Thus, it is not so surprising that this principle and not Mach's idea concerning inertia is in best agreement with relativistic quantum theory, where the words "matter" and "vacuum" have obtained a new and richer content, their everyday meaning being correspondingly limited.

We shall now summarize the relation between the equivalence principle and the Mach principle. According to the former the mass of a body—which could be anything from an elementary particle to a stellar system—is referred to an inertial frame, which is better defined the better the body is isolated, its surroundings approaching the physical definition of an empty space. In practice such a frame has no direct relation to the structure of the universe. With Mach's principle, on the other hand, a body would have zero mass in an empty universe, the mass being smaller the less matter there is.

As is well known, the deviations from Euclidean geometry—which are very small in the applications of general relativity to ordinary problems, such as the motions of the planets—play an important part in cosmology. Their general background is by no means mysterious, being the fact that the different points of a gravita-

tional field in general require different inertial frames. In this connexion Einstein's field equations which replace the Newtonian law determining the gravitational field arising from a given distribution of matter should be mentioned. Because there is no gravitational field in the limiting case of special relativity these could not be derived by means of the equivalence principle in its usual form. Einstein found them by means of the idea of "general covariance" with respect to the choice of the four co-ordinates used for the mapping of a finite region of space and time, together with the requirement of greatest possible simplicity. Because these equations have been used in connexion with speculation exceeding by far the range of our experience it should not be forgotten that their derivation is probably less fundamental than the part of the theory which is based on the principle of equivalence. None the less, they represent an important advance in several respects from Newtonian theory.

Einstein's original attempt to describe the average situation of the universe by the famous "closed world" solution of his somewhat modified field equations depended strongly on his hope of satisfying the Mach principle. Another important aspect was the avoidance of the boundary condition valid in the Newtonian case as well as in ordinary solutions of his own equations: *that the gravitational field vanishes asymptotically towards infinity*. As has already been shown, this condition (although, in practice, infinity here means distances from the system under consideration) is automatically fulfilled in the inertial frame, where any gravitational field other than that due to the system itself is removed. Einstein, however, regarded the use of such a frame as running against the claim of general covariance. Strangely enough, both these arguments are contrary to the spirit of the principle of equivalence discovered and used most ingeniously by him in the development of a theory of general relativity.

A third assumption—the static nature of the solution—was based on the belief of astronomers before Hubble's discovery that even distant stellar systems have very small velocities with respect to our galaxy. Later Einstein abandoned this assumption in favour of a class of expanding solutions discovered by Friedmann and later, independently, by Lemaître, who together with Robertson and others developed the relativistic cosmology mentioned in the introduction.

As was mentioned at the beginning of this article, the average mass density as obtained by counts of galaxies and galaxy clusters together with more or less reliable estimates of the average masses of such stellar systems tends to become spatially constant, when sufficiently large volumes are considered. There is a simple sub-class of the expanding solutions just mentioned which satisfies the condition of pressureless matter of spatially constant density. Moreover, these solutions give a generalized red-shift law, which for moderate distances agrees with Hubble's empirical law: *the red-shift of the spectral lines from a given galaxy proportional to its distance from our galaxy*. Thus as a result of the slowing down of the expansion because of gravitation, the coefficient of the Hubble law decreases in the course of time. Taking any point, for example our own galaxy—all points being equivalent—as the origin, the position of any other galaxy may be described by means of three time-independent co-ordinates, one radial co-ordinate η and two angles representing latitude and longitude. The distance of a point from the origin is then a function of η multiplied by a time-dependent factor a of dimension of length, η being chosen dimensionless. Thus a describes the expansion of the system, and its relative time-derivative $1/T$ is the Hubble law coefficient at the time under consideration. (T is frequently, but rather inadequately, referred to as the age of the universe.)

There are two subclasses of the solutions under consideration characterized by the value $+1$ and -1 respectively of a parameter ε; the first represents an infinite universe, the second a finite, closed universe of the Einstein type. In order to satisfy the gravitational field equations and the condition expressing the conservation of particles (doubtlessly well satisfied at the present time), a, T and the density μ have to fulfil two conditions which, because they are very simple we shall give explicitly, namely

$$\frac{8\pi}{3}\gamma\mu T^2 = \frac{a_0}{a_0 + \varepsilon a}, \quad \frac{4\pi}{3}\mu a^3 = \frac{c^2}{2\gamma}a_0 .$$

Here γ is the ordinary gravitational constant, a_0 an integration constant of the same dimension as a, and c the vacuum velocity of light. T is the reciprocal of the Hubble coefficient, and is well known for the present time; the estimates of μ, however, are rather less certain. Thus, $T = 1{\cdot}3 \times 10^{10}$ (thirteen thousand million) years and $\mu = 10^{-30}$ g cm^{-3} (that is, 1 g in a cube, the side of which is a hundred thousand kilometres) seem to be reasonable estimates This gives for the left hand side of the first formula a value considerably smaller than unity (0·09), which can, however, be reconciled with the right hand side only if $\varepsilon = +1$. Solving then for a and a_0 we obtain a value for a_0 of about 10^9 light-years and $a \sim 10\, a_0$.

Assuming that these estimates are not very far from the best fit that can be obtained between relativistic cosmology and our metagalaxy at the present stage of evolution, we shall now proceed to a model of the kind mentioned at the beginning of the article which represents a bounded expanding solution to Einstein's equations of spatially constant density, and which satisfies the ordinary boundary condition. Such a solution can be constructed from the cosmological solution stretching to infinity by allowing the matter distribution to end at a certain finite value η_0 of the radial co-ordinate η, the space outside of the expanding spherical surface, thus defined, being empty. This is the three-dimensional analogue to the cutting out of a circular cap around a point on a spherical surface. Thus we obtain a spherical expanding cloud of spatially constant density, which satisfies the foregoing equations —the boundary condition leading to the following relation for its total mass M:

$$M = \frac{4\pi}{3}\mu a^3\eta_0^3 = \frac{c^2}{2\gamma}a_0\eta_0^3$$

Thereby M is defined by means of the external gravitational field due to the system. It should be pointed out that the centre is now a meaningful point, and its distance from our galaxy is an observable quantity. Because η_0 together with a determines the radius of the system, it is possible that an estimate of η_0 could be obtained by a survey of the distribution of stellar systems of high red-shifts with respect to direction. Such a survey is still lacking but the highest red-shifts so far known correspond to about four-fifths of the velocity of light when interpreted as Doppler effects. This would correspond to an η-value of the source slightly greater than unity, if our galaxy (for this calculation) is put at $\eta = 0$. On the other hand, an upper limit for η_0 may be obtained by means of the so-called Schwarzschild limit applied to the system at the time when the observed light was emitted. For an expanding or contracting system such as that under consideration, this limit is the state where the velocity of the boundary is equal to that of light. For densities beyond that state there is no natural way of satisfying the boundary condition. In the present case this state is reached for $a = a_0\eta_0^2$, which means that this is the smallest value a could possibly have had according to the model. Bearing in mind that the present expanding state of the galaxy should, according to our programme, have been preceded by an earlier contracting state, this value of a is probably smaller than the smallest value for which the expansion was fully established. Now, a red-shift

corresponding to a Doppler effect velocity of 4/5c means that a at the time when the light was emitted was as large as one-third of the present value of a. This and the estimate of the η-value which belongs to such a red-shift would point to a value of η_0 in the neighbourhood of unity.

It is of interest to compare the solution under consideration with the corresponding solution of Newtonian theory. In the latter case we have a common time for the whole space, which in the present case corresponds to the time of the external inertial frame. An important difference between the two solutions is involved with the Schwarzschild limit, which does not exist in the Newtonian theory, where c is regarded as infinite. In the present solution—using the inertial frame time—a contracting solution will approach this limit asymptotically but never reach it. Apart from this the classical formulae are valid for $\eta_0 \ll 1$. In the classical case, $a\eta$ is the distance of a point from the centre, while in the relativistic case this is the first term of a series expansion in powers of η—the approximation being quite good up to η-values not much smaller than unity.

Now, in the classical case, $\varepsilon = +1$ means that there is a surplus of kinetic energy beyond that needed to bring the expansion to infinity, while $\varepsilon = -1$ means a corresponding deficit—a_0 being in that event the largest value which a can take. This is quite similar to the situation in the relativistic case, where Mc^2 is the total energy including the rest mass energy of the system, while M_0c^2, the sum of the energies of its sub-systems (galaxies and galaxy clusters), is equal to the volume integral of the density μ. Thus for $\varepsilon = +1$ $M > M_0$, while $M < M_0$ for $\varepsilon = -1$. Thereby the ratio M_0/M is a function of η_0, which for $\varepsilon = +1$ is given by

$$\frac{M_0}{M} = \frac{3}{2\eta_0^3}\left(\eta_0\sqrt{(1+\eta_0^2)} - \ln(\sqrt{(1+\eta_0^2)} + \eta_0)\right).$$

With $\eta_0 = 1$ this gives $M_0/M = 0{\cdot}8$, and the surplus energy $Mc^2 - M_0c^2$ is 20 per cent of the total energy.

Assuming that all these estimates, although necessarily uncertain, are reasonably realistic we shall consider the last result from the point of view of our basic hypothesis: *that the metagalaxy began as a very large and very thin cloud of practically zero temperature.* This means that its total energy $M'c^2$ (M' being the original mass of the cloud) was practically equal to the sum of the rest mass energies of its particles. Suppose now that during its evolution up to the present state an amount of energy $c^2\Delta M$ has been lost by radiation including neutrinos, together with the amount $c^2\Delta M_0$ of the rest mass energy. Then we shall have

$$M' = M + \Delta M = M_0 + \Delta M_0,$$

or

$$\frac{M - M_0}{M} = \frac{\Delta M_0 - \Delta M}{M}.$$

It thus follows from the above estimates that ΔM_0 must be more than 20 per cent of M; how much more depends on the amount of energy lost.

To gain some further clue as to how the transition from the original state of the metagalaxy to its present state occurred, we shall consider the strange empirical relations noticed by Eddington for the linear dimensions and the total rest mass of an Einstein universe adapted to the observationally estimated density. Their essence is the appearance of the large number N of the ratio between the electrical and gravitational attraction between a proton and an electron, when macroworld quantities are compared with their counterparts from the microworld. Instead of the Einstein universe, we shall consider the bounded solution with the value of a_0, already estimated, and the corresponding mass M.

With

$$N = \frac{e^2}{\gamma m_e m_p} = 2{\cdot}27 \times 10^{39},$$

e being the elementary electric charge, γ again the gravitational constant and m_e and m_p the masses of electron and proton respectively, the above estimate of a_0 fulfils almost exactly the relation

$$a_0 = 2Nd,$$

where

$$d = \frac{e^2}{m_e c^2} = 2{\cdot}82 \times 10^{-13}\ \text{cm}$$

is the so-called radius of the electron. Assuming $\eta_0 = 1$ it follows that

$$M = N^2 m_p.$$

Although the exact form of these relations should not be taken seriously, we shall see that their order of magnitude is probably meaningful.

Thus, considering the metagalaxy from the present point of view, it does not seem unreasonable that the mechanisms responsible for its evolution also determine its natural average size; it is feasible that in so large a system the relative fluctuations from this "natural average size" are quite small. If we tentatively assume that the turning of the original contraction into its present expansion resulted from radiation pressure on the electrons of a cloud by means of scattering according to the well known Thomson formula, well valid in the visible and infra-red part of the spectrum, the mean free path of a photon—determining the degree of opacity of the matter

—would be equal to $1 : \frac{8\pi d^2}{3} n_e$, where n_e is the number of electrons in each unit volume. It follows from the foregoing estimates that this length is of the same order of magnitude as the radius of the cloud in its densest state, where $a = a_0$ (the Schwarzschild limit), if n_e is comparable with the number of protons in each unit volume. The meaning of this is suggested by the fact that the contraction of the cloud to the density in question—about 10^{-27} g cm^{-3}—would lead to annihilation of a sensible fraction of its total mass.

The formation of electromagnetic radiation needed to break the motion during the contraction of the cloud is still far from clear; the possible sources would be collisions of the particles of the cloud with each other and with electrons as a result of annihilation, the increase of already present radiation through the process resulting in braking and, finally, synchrotron radiation as a result of the presence of magnetic fields. The last type of radiation has been studied by Alfvén *et al.* in an attempt to consider annihilation as the main energy source in the newly discovered so-called quasars. This process, however, would scarcely be important in the present connexion, because the relevant wavelengths would be very large compared with the average distance of the particles in the cloud, and this would mean high transparency because of the equal amount of positive and negative electrons.

Short of a detailed theory for the formation of radiation, it may be worth while to estimate its spectrum under the assumption that at this turning point the system is not too far from a temperature equilibrium. The temperature would then be determined by the energy available from the contraction of the system from its beginning state of very low density to a state approaching the Schwarzschild limit.

With a mass of the order of magnitude estimated here the temperature in question would be somewhere around 50° K, and practically all the thermal energy would then be in the form of electromagnetic radiation (the particles would contribute almost nothing, even if their temperature were many orders of magnitude higher). The average wavelength at that temperature (smaller than 1/10 mm) would be well within the region of validity of the Thomson formula and sufficiently small with respect to the average distance of the particles in the cloud (more than 100 mm).

Looking somewhat more closely at the possibility—suggested by the above estimates—of explaining the transition to the present state of the metagalaxy, it would seem that although the orders of magnitude are promising there is too little annihilation as well as opacity, if one makes the simplest assumptions : that the homogeneity of the cloud is conserved during the contraction and that the number of electrons is equal to that of the protons. There is no necessity, however, for the latter assumption—electrical neutrality being upheld by protons and antiprotons separately and positive and negative electrons separately—while a moderate increase of n_e (the number of electrons in each unit volume) would give sufficient opacity. The limit would probably be given by the highest permissible value of n_e in the present state of the system, taking into consideration the decrease of this quantity resulting from expansion and annihilation. Verification of the approximate temperature equilibrium as well as of the explanation of the expansion by means of radiation pressure can perhaps be seen in the observed low-temperature radiation mentioned at the beginning of the article. Thus, if the radiation expands in doing work on the electrons, the opacity being sufficient, its temperature would decrease approximately in the same proportion as the linear dimensions increase, that is, by about a factor of ten according to the estimates of a and a_0. Within the uncertainties this would agree well with the temperature (about 3° K) of the present radiation.

As to the other difficulty, it would be removed if a sufficient number of inner condensations appear inside the cloud during its contraction, their time scale being shorter than that of the general contraction, as a result of their higher density. Such an occurrence produced by inner instabilities seems highly probable. Assuming a mass of such a condensation of the order of magnitude of a galaxy, considerable annihilation would occur quite long before its opacity is sufficiently great to stop the contraction and very long before the Schwarzschild limit is reached.

Here also another point should be mentioned, namely the transfer of the momentum given to the electrons from the radiation to the protons of the cloud. According to Alfvén this would be brought about by the magnetic fields necessarily present in a thin plasma of electric particles.

Thus, as already mentioned, a considerably smaller mass would develop in a manner differing widely from that of a metagalaxy, the lack of sufficient opacity impeding largely the braking of the contraction by means of radiation pressure. Here one would expect that the magnetic fields—implying the Alfvén separation—would become important and lead to the development of a galaxy or a galaxy cluster but not to a metagalaxy. A much larger mass, on the other hand, would scarcely suffer any significant annihilation before inner condensations had appeared because the Schwarzschild limit density is inversely proportional to the square of the mass.

BOOK REVIEWS

ORIGINS OF INVENTIONS

A Social History of Engineering

By W. H. B. Armytage. Second edition. Pp. 378+36 photographs. (London: Faber and Faber, Ltd., 1966.) 50*s*. net.

THE aim of this book is "to chart technological developments with special reference to Britain, to indicate how they have affected and been affected by social life at certain stages and to offer some clues as to the origins of innovations and motivations". This is a far from modest aim for a book of less than 400 pages which starts its story in 3000 B.C. and ends with the problems posed by space, high energy physics and the power revolution.

The book is one of a series designed for the student and professional scientist and technologist, and for such a public the treatment of technological developments and of the relevant scientific discoveries is sketched in with a fine sense of perspective and economy. It is not a book for the general reader, for whom inevitably, in a book of the size, there is not enough description of the inventions listed.

The treatment of how technological developments affected and were affected by social life is less satisfactory. The analysis of the interaction between technology and education, and also of the ways in which, from time to time, necessity has mothered inventions is well done. But in dealing with the effects of technological developments on social life Professor Armytage has been much less successful. If a third edition of this book is published it is to be hoped that Armytage will have more to say about the social impact of changing war technology, about the effects of changing technology on family life, social mobility, the location of industry, the distribution of income, the forms and concentration of economic and political power, and so on. Attention to such analysis, deriving from Marx, Weber, Sombart and Durkheim, should help to add to the engineer's understanding of the "social, political and philosophical implications and consequences of his work and influence in society at large".

The final aim of the book—to offer some clues as to the origins of innovations and institutions—is fairly well accomplished. In a book on the social history of engineering, however, it is a little disappointing not to find rather more discussion of the relations between science and engineering and, in terms of economic development, possible conflicts between them. How many countries have been successful in both together? Armytage touches on this problem in his treatment of Greece and Rome but does not take it much further. In contemporary Britain he simply treats research as the key to innovation, without much attempt to examine the problem of the best allocation of scarce scientific and engineering manpower between alternative uses. Here too I hope that the third edition of this book will include a discussion of the complex economics of research, development and innovation.

BRUCE WILLIAMS

ARCHAEOLOGICAL FINDINGS

The Annual of the British School at Athens

No. 60. Pp. 345+36 plates. (London: The British School at Athens, 1965.) 105*s*. net.

THE British School of Archaeology at Athens enjoys a high reputation in archaeological circles, not only for the general competence of its research and excavation organization but also for providing a wide range of papers

in its annual journal. The *Annual* for 1965 illustrates this scope of the School's interests in Aegean archaeology. Of some fifteen papers, more than half provide catalogues of regional or typological material; the range of subjects is varied, and includes bronze coinage in central Greece of A.D. 1,000, the provenance and identification of the Knossos sealings, and Late Helladic IIIA2 pottery from Mycenae. Also of importance is a paper on the geographical distribution of Minoan sites in western Crete. One excavation report, on work done at Palaikastro, VI, and one or two papers on specialized research subjects also find places in the *Annual*; of the latter, a detailed assessment of the *Battle of Oinoe* in the Stoa Poikile attempts to show how far Greek art and history can be reconciled in solving the problems raised by accepting that the battle of Oinoe occurred during the Pentekontaetea. Several difficulties cannot be resolved.

Although a majority of papers in the *Annual* deal with the typological and other problems of coinage, sealings and pottery from Greek and Cretan sites, two articles are concerned with the application of newer techniques of study and classification to material remains. The first of these is a study of composition patterns of Mycenean pictorial pottery from Cyprus, using optical emission spectroscopy, and following on earlier work on Mycenaean and Minoan pottery in the *Annual* for 1963. Almost all the twenty-five samples investigated correspond to a group previously shown to be of a fabric typical of much of the Peloponnese, and fourteenth and thirteenth century shipments of pottery from Peloponnese ports to Cyprus are therefore attested. Difficulties over sampling methods have apparently been eliminated.

Spectrographic analysis has also been used in the investigation of other materials from the Aegean, and a full report appears on obsidian, a material not particularly important to peoples living in Greece or the islands in the second or first millenia, but of considerable importance to their predecessors through some four or five thousand years. Obsidian as a raw material for the production of tools and weapons was traded extensively in the Mediterranean world, and every piece on the mainland of Greece had to be imported from regions where recent volcanic activity under certain conditions had produced obsidian that was glassy and could be fractured conchoidally. Only Melos, Antiparos and Giali in the Aegean possessed this material, although other areas to the west, north and east were also available. Spectroscopic examination and analysis have revealed various groups, with barium and zirconium important as trace elements, and the Melian obsidians are separated conclusively from those of Lipari in this way. The archaeological implications for this work, work which has been considerably extended since the paper was written, are varied. Perhaps the most striking is the very early use of Melian obsidian in Crete and Greece, in the late seventh millenium B.C. In fact, Melos was virtually the only supply of obsidian throughout the prehistoric period, and its trade and exchange in the area is particularly well attested in the late Neolithic and Early Bronze Age of the south Aegean. One of the interesting aspects of this study lies not in the material traded, but in its significance for early transport. Sea travel over great distances was clearly well within the capabilities of these people, although until recently it was assumed that only primitive forms of sea-going vessels would have been available. JOHN M. COLES

BINARY LOGIC

Logique Binaire et Commutation

Par J. Brunin. (Bibliothèque de l'Automaticien.) Pp. xvi+548. (Paris: Dunod, 1966.) 128 francs.

THIS book forms Volume 11 of a series of books by various authors (by no means all French) entitled "Bibliothèque de l'Automaticien" edited by Pierre Naslin, a well-known figure in the world of automatic control. The author, Jean Brunin, is a specialist in telephonic circuitry, and has published widely in the field of electromagnetic relay systems and the use of Boolean algebra in their analysis and synthesis. More recently he has devoted attention to the realization of such systems by electronic means. After a few examples on the use of truth tables for solving logical problems, including a particularly disarming one showing how a (quite exceptional) detective tracks down the perpetrator of some felony, the book thereafter clearly reflects the author's interest in relay circuits and their description in terms of Boolean functions. Thus the first ten chapters, occupying the first 450 pages, are exclusively devoted to such circuits and their synthesis from specified Boolean expressions, and only the last, admittedly longest, chapter treats electronic (that is, diode, transistor and ferrite) logic circuits, and most of these are associated with telephonic requirements.

Although the book is intended as a teaching manual, the enormous number of relay circuits, with their truth table representations and the all-too-brief explanations of their action, while forming a useful compendium for the practising telephone engineer, would leave a newcomer to the subject somewhat bewildered. Undoubtedly the inclusion of some questions would have been helpful.

While it may not be inappropriate in the present context, the treatment of electronic switching circuitry is cursory, no consideration being given to switching speeds, leakage currents, effects of loading, and so forth. The design, even the circuits, of practical logical elements are not given, and the use of such elements is restricted to the simulation of relay circuitry. Strangely enough, the diagrams in this section are noticeably inferior to those of the first ten chapters, and tend to be cramped, the resistors in particular being "hand drawn". A quaint feature, which I have never seen before, is the cross hatching of the base of non-conducting transistors.

G. DE VISME

COSMIC RAYS

Proceedings of the Ninth International Conference on Cosmic Rays

London, September 1965. Vol. 1: Pp. i–xiv+1–606. Vol. 2: Pp. xv–xxvi+607–1113. (London: The Institute of Physics and the Physical Society, 1966.) 210*s*. the two volumes.

THE past decade or so has witnessed an enormous expansion of activity in all branches of geophysics, and a measure of the current interest in cosmic rays is afforded by these proceedings of a recent international conference. The two volumes, totalling more than 1,100 pages, contain some 300 papers covering the whole field of cosmic rays. The papers fall into three categories. Fourteen major invited contributions cover the following topics: cosmic rays and the interplanetary field, the magnetic field in interplanetary space and the magnetosphere, the theory of cosmic ray modulation, magnetic fields in the galaxy, the Earth's radiation belt, the origin of cosmic rays, X-ray and γ-ray astronomy, quasi-stellar objects and radio galaxies, long period variations, and high energy interactions. Some 293 short papers are grouped according to subject: acceleration modulation, spectral composition, geophysical effects, isotopic distribution, extensive air showers, high energy interactions, muons and neutrinos, techniques. Seven other survey papers review the papers presented at the Conference on particular topics. The editors have also included verbatim reports of the discussions which took place at the meetings. These are sometimes very brief and contribute little, but other discussion reports include quite useful additional

points, and on the whole the inclusion of this material enhances the value of the volumes. With such an extensive field to cover, and with so many papers contributed, it is a commendable feature of the publication that all contributions, apart from the invited papers, are limited to about two thousand words.

This was the ninth of a series of international conferences organized since 1947 by the Cosmic Ray Commission of the International Union of Pure and Applied Physics and the first of the series to be held in the United Kingdom. In his preface to the volumes, Professor J. G. Wilson, chairman of the Organizing Committee, calls attention to this fact and rightly goes on to comment on how appropriate it was that the conference should meet at Imperial College in the month which marked the retirement of one of the great figures of the cosmic ray world, Prof. P. M. S. Blackett.

All too often a just criticism of the proceedings of scientific conferences is that their publication is delayed many months, sometimes even years, after the conclusion of the meeting and it is not unknown for papers presented at conferences to be outdated long before the proceedings appear. In the present case the editors and publishers are to be congratulated on achieving early publication of such a substantial body of material. The volumes are excellently produced by a photo-offset process and the price is reasonable. W. J. G. BEYNON

ORBIT THEORY

Orbital Hodograph Analysis

By Samuel P. Altman. (American Astronautical Society Science and Technology Series, Vol. 3.) Pp. 134. (Baltimore, Md.: American Astronautical Society, 1965. Distributed by Western Periodicals Co., North Hollywood, California.) $11.25.

CLASSICAL theories of celestial mechanics depend on expressing the properties of orbits in terms of orbital elements, for example, semi-major axis, eccentricity, etc., and then investigating the changes in the elements. An alternative approach, which is the subject of this book, is to make use of the hodograph, that is, to focus attention on the velocity or acceleration vector of the body in orbit. Chapter 1 is introductory and shows that the velocity hodograph of an ellipse, parabola or hyperbola is a circle, the origin being inside the circle if the orbit is an ellipse, on the circle for a parabola, and outside for a hyperbola: the hodograph thus allows changes from elliptic to hyperbolic orbits without the discontinuities which bedevil classical analysis. Other forms of hodograph are also defined. Possible analytical transformations are discussed in Chapter 2 and trajectories of ballistic missiles in Chapter 3. Orbital transfer and its optimization are the subjects of Chapter 4, and Chapter 5 is concerned with orbital rendezvous. Chapter 6, on lunar landing, shows how numerical solution by hodograph methods is just as good as by normal methods, despite the fact that the landing point, with zero velocity, becomes indeterminate in the hodograph formulation. A final chapter offers suggestions on the future uses of hodograph methods, including optimization problems and the n-body problem.

Dr. Altman has provided a useful introduction to a theoretical method which may well prove important in the future, and it is a pity that the book has several annoying faults. To begin with, symbols are usually left undefined in the main text, and the reader has to keep on referring to the list of symbols at the end of the chapter, where the definitions are not always immediately comprehensible. The book appears to be printed photographically from a typescript: unfortunately the print is very faint on many pages and part of page 69 was quite invisible in the review copy. Also on some pages the print extends to within 5 mm of the stitching on the spine and is unreadable unless the book is almost torn apart. Finally, the standard reviewer's complaint that the book is too expensive really does seem justified when it is so short and so poorly printed. D. G. KING-HELE

CARBONYL CHEMISTRY

The Chemistry of the Carbonyl Group

Edited by Saul Patai. (The Chemistry of Functional Groups.) Pp. xii+1027. (London and New York: Interscience Publishers, a Division of John Wiley and Sons, 1966.) 220*s*.

THIS is the second volume to appear in the series of large monographs on individual functional groups edited by Prof. Patai, and it follows very closely the pattern of its predecessor on the alkenes. The resemblance extends even to the fact that a salient chapter—in this case the one on equilibrium additions to carbonyl groups—is missing because the manuscript did not materialize on time.

There is no question but that this is a useful compilation, its seventeen chapters containing an abundance of information and a wealth of references. One does, however, wonder a little at the balance of space allocated to various topics: whether, for instance, the photochemistry of aldehydes and ketones merits the longest chapter in the book, and whether in the chapter on chemical and physical methods of analysis the former should receive as much emphasis as the latter. Multiple authorship makes it very difficult to maintain uniform standards, with the result that some chapters tend to become catalogues while others present a reasoned, and even elegant, review of their topic. Examples of the latter are the chapter on general and theoretical aspects of the carbonyl group, and the one on the basicity of carbonyl compounds, though it is only fair to say that their rather general subject matter assists in achieving a more spacious view.

The book includes extensive surveys of methods by which carbonyl groups may be formed as well as the reactions that they undergo, but there is no formal treatment of the effect of carbonyl on adjacent groups. This is not unreasonable except perhaps as it effects α-hydrogen, though there is some discussion of aldol and kindred reactions in Chapter 12.

The book's production standards are relatively mediocre and, large though it is, its price puts it beyond the reach of all but institutional buyers. PETER SYKES

ORGANIC REACTIONS

The Investigation of Organic Reactions

By Ross Stewart. (Prentice-Hall Foundations of Modern Organic Chemistry Series.) Pp. xii+125. (Englewood Cliffs, N.J., and London: Prentice-Hall Inc., 1966.) 20*s*. paper; 44*s*. cloth.

Reaction Mechanisms in Organic Chemistry

By Blanca Tchoubar. Pp. xiv+197. (London: Iliffe Books, Ltd.; New York: American Elsevier Publishing Company, Inc., 1966.) 45*s*. net.

A SOUND appreciation of the mechanisms of organic chemical reactions requires a reasonable background knowledge of how these mechanisms are determined and this *The Investigation of Organic Reactions* provides in a clear and concise manner. A detailed and satisfying survey of equilibria, reaction intermediates, transition states, reaction paths, and catalysis is given in the course of five chapters to each of which there are appended some half a dozen problems. The treatment is stimulating and the book can confidently be recommended both to undergraduates approaching the subject for the first time and to more experienced chemists who wish to renew their acquaintance with this field.

The second work is complementary to the first. Its purpose is to describe the fundamentals of electronic theory of chemical structure and of reaction mechanism over a wide field of organic chemistry. There are two sections. The first outlines the electronic theory of valency and includes a description of the transmission of polar effects in conjugated and non-conjugated systems, while the second and larger portion of the book deals with the various types of heterolytic and homolytic reactions and their occurrence in aliphatic and aromatic substitutions, in elimination and addition reactions, in prototropic processes, and finally, in reactions involving carbonyl groups. The book is clear and readable but its presentation is marred by numerous misspelt words and misleading statements. As an example of the former, there is written in connexion with Mannich bases, "... the case with which they de-animate . . . " (page 154). The second example results from Tchoubar's failure to distinguish between conjugative effects in the ground state (mesomeric effects) and those in the excited, transition states (electromeric effects). He remarks (page 175) that in aromatic nitration the steric effects of dimethyl groups in the *ortho* positions reduce or wholly suppress the deactivating and *meta* directing effects of nitro- and sulphonic-acid groups by suppressing the associated negative conjugative effects. This cannot be so, because only inductive effects can operate in such cases, and, indeed, in 1964, E. Baciocchi and G. Illuminiti showed that there was no reduction in the deactivating influence of these groups. In my opinion these and other blemishes seriously diminish the value of this book for the general reader.

E. ROTHSTEIN

BASIC ORGANIC CHEMISTRY

Modern Textbook of Organic Chemistry

By G. P. Ellis. Pp. xii+466. (London: Butterworth and Co. (Publishers), Ltd., 1966.) 57*s*. 6*d*.

IT is most pleasing to have a good, well-written book on basic organic chemistry by a British author. In this book, aimed at the first two years of an honours course, or equivalent, the variations in reactions of the functional group for aliphatic and aromatic compounds are usefully considered together. The first chapter, which introduces fundamental concepts, is, as is the whole book, simply and informatively written. Each chapter, sub-divided into well-enumerated sections, includes rigorous adherence to the IUPAC system of nomenclature, most importantly even for simple compounds. Reactions are classified according to their type, for example, electrophilic substitution, addition which, with the emphasis on actual reactions with yields as examples, should enable the student to appreciate the subject. A summary at the end of each chapter outlines the various methods of preparation of the class of compound being discussed while other useful assets are spectral characteristics, surveys of economically important compounds, and selected questions, to which answers are thoughtfully provided. The superb cross-referencing, a highlight of the book, together with an excellent index ensure that the student can rapidly find any particular topic regardless of the lecture course he may be following.

The treatment of some reaction mechanisms does not reach the high standard maintained in other aspects; some intermediate steps are omitted and little explanation of the driving force is given. This is accentuated by the omission or complete misplacement of arrows to designate electron pair shifts and will only serve to further confuse the student (pages 229, 237). Again, tautomerism is not an intramolecular hydride shift as depicted (page 14), and the proposed mechanism for osazone formation is quite wrong (page 389). The badly distorted chair forms of *cyclo*hexane with axial bonds at 90° to those in the ring are of no help in an understanding of stereochemistry.

I hope that considerable attention will be directed to the correct placement of dots, charges, arrows, and three-dimensional depictions in any revised edition, for the typographical errors mar what is otherwise a most useful text-book.

ROBERT D. H. MURRAY

FERTILIZATION

Fertilization

By C. R. Austin. (Foundations of Developmental Biology Series.) Pp. x+145. (Englewood Cliffs, N.J., and London: Prentice-Hall, 1965.) 21*s*. paper; 40*s*. cloth.

C. R. AUSTIN has been interested in the biology of the gametes for a long time and he has courageously undertaken to write this account of the cytological, physiological and behavioural mechanisms concerned with their union. Nor does he speak only as a compiler; his 20 years or more of research on this aspect of biology qualify him unusually well for the undertaking. The result is a notably significant book.

Too often in the past cytological studies of fertilization have been primarily descriptive with little attempt to evaluate the functional significance of the mechanisms involved. In this study the approach is from the functional rather than the purely morphological standpoint and much emphasis is placed on the method of experimentation. This book not only provides concrete information on gamete physiology, but also adopts a realistic attitude towards the larger problems and responsibilities growing out of our increased knowledge in this field. But although it is valuable to have our present knowledge of the subject accurately summarized and evaluated, a most important contribution of this slender volume is the attention it attracts to the problems that remain to be solved.

The first part of the book includes an introductory chapter with a concise account of the structure and function of the cell. This part then continues with a discussion of meiosis, mitosis and cell division. Then follow chapters which are devoted to a comprehensive and thorough discussion of the significance of fertilization, the form, differentiation, approximation, contact and fusion of the gametes, as well as the immediate consequences of fertilization. The final chapter describes unusual and abnormal forms of fertilization; this is a restrained and reasonable account which forms an effective conclusion to a book which is outstanding for its clarity and simplicity.

To make the book more readable each of the chapters has subheadings which are valuable in organizing the information. In addition references are not included in the body of the text. These have been covered by the larger treatises mentioned in the adequate bibliography at the end of the book, which also includes a comprehensive list of the chief monographs, reviews and original papers devoted to the subject of reproduction or more specifically fertilization. Excellent figures are included in the text as well as photomicrographs, many of which are original.

If any critical comment were called for, it would merely be that the text had brought to light disproportionately few new insights into mammalian fertilization. Austin would probably agree. From intent, however, the discussion of this aspect of the problem has been limited so as not to obscure the contributions made by the less commonly investigated species. Where there is a genuine paucity of evidence, thinking such as this, soundly based on what is known, is the one thing most likely to stimulate the research that will produce evidence, either for or against. No student interested in the physiology of the gametes can afford to be ignorant of this gem.

E. C. AMOROSO

MARINE BORERS

A Survey and Illustrated Catalogue of the Teredinidae (Mollusca : Bivalvia)

By Ruth D. Turner. Pp. vii+265 (64 plates). (Cambridge, Mass.: The Museum of Comparative Zoology, Harvard University, 1966.) $8.

FROM the moment that seafaring man started to use wood for his boats and piers, shipworms demanded attention on account of their unseen but devastating effects, and when later he became a scientist they aroused admiration because of their unique adaptive features. Yet the systematics of the family Teredinidae have remained in a state of confusion. This is partly a result of the erroneous creation of new species from fragments of moribund or dried remains found in drift-wood or ships from distant water, and of the fact that no comprehensive study of the family has until recently been undertaken. Dr. Turner has now marshalled information from libraries and museums over the world and examined all available material.

The results presented in the first part of the book include illustrated descriptions of the gross anatomy of the soft parts of fourteen genera of the family; these prove to be important in classification. There are also drawings and descriptions of the valves, tubes and pallets on which the diagnosis of both living and fossil species is based. The genera are redefined and a key is compiled for the identification of fresh or well-preserved adult specimens which is easy to use and will minimize one of the most formidable tasks of those working on teredine borers. Moreover, the second part of the book eases the systematist's problems, for it comprises a catalogue of all the generic and specific names which have been used in the family, with their original citation, type locality and the location of the type specimen; the present status of the name is indicated wherever possible.

The author points out that this is a preliminary survey and indicates a number of lines of research for the systematist, physiologist or ecologist who is interested in shipworms. Much-needed monographic studies of the various genera are now being planned. V. FRETTER

CYTOPHOTOMETRY AND INTERFERENCE MICROSCOPY

Methoden und Ergebnisse der Zytophotometrie und Interferenzmikroskopie

Herausgegeben von Walter Sandritter und Günter Kiefer. (Acta Histochemica: Zeitschrift für Histologische Topochemie, Supplementband 6. Herausgegeben von Hermann Voss, Gerhard E. Vogt und Joachim-Hermann Scharf.) Pp. 459. (Jena: Gustav Fischer Verlag, 1965.) 99.30 MDN.

THE collection of sixty-six papers presented at the ninth symposium of the very active Gesellschaft für Histochemie is a mine of interesting and stimulating information. The volume consists of two parts: the first deals with cytophotometry, the second with interference microscopy. Each part is subdivided into a description of instruments, their parts and arising problems, inevitable errors and results obtained in histochemistry. Each paper is supplemented with a bibliography and a critical discussion by the present participants.

Quantitative histochemistry is growing rapidly and instruments for physico-optical investigations were the prevailing topic of the symposium. Caspersson presented a new universal microspectrograph, where X-rays, ultra-violet, visible and infra-red light could be used. Unfortunately, instruments of this kind are very complicated and expensive; their equivalents in different laboratories are often inadequate. Caspersson suggested that laboratories should be specialized and planned on the national, or even international, scale. Sandritter assembled a list of chemical components present in cells, which could be localized and estimated quantitatively with physico-chemical methods. The list is supported with references and a description and bibliography of new instruments designed for this purpose. Thorell analysed microspectrographically the respiratory system of the cell and defined the metabolic state from an area of 1·5 μm diameter in a single intact cell. The problem of measuring the thickness of a section is important in quantitative investigations. Hallén re-examined this old subject and came to the sad conclusion: "The only way to avoid the error is to avoid sectioned material". Fluorescence microscopy combined with photometry was the subject of several papers (Ruch, West and others). The method is particularly useful, as the fluorescent spectrum is proportional with respect to concentration of the examined material within the living or fixed cell.

The complexity of physico-optical methods is often the source of errors. There are a few important papers dealing with this problem. Sandritter and Schlütter, for example, pointed out the significance of the depth of the field. Changing the depth or defocusing produces differences in value as much as up to 45–55 per cent. On the other hand, a comparison of results obtained from the literature dealing with interference microscopy, X-ray and chemical estimation showed that the values of measured dry mass differ by only about 15 per cent (Sandritter). Cytophotometry of DNA, RNA and proteins of normal and malignant cells stained with Feulgen, gallocyanin or other methods, is the subject of several other papers.

In a short review it is impossible to mention everything, particularly when the specification of the instruments is concerned. The book can be recommended for all interested in physical methods applied to histochemistry. J. KRUSZYNSKI

MICRO TO ULTRA-MICRO

Introduction to Quantitative Ultramicroanalysis

By I. M. Korenman. Translated by Scripta Technica, Inc. Translation edited by Ronald Belcher. Pp. ix+234. (New York: Academic Press Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) $9.50.

Submicro Methods of Organic Analysis

By Ronald Belcher. Pp. ix+173. (Amsterdam, London and New York: Elsevier Publishing Company, 1966.) 55*s*.

BY title these two books are complementary and they do, indeed, give a good account of the present state of ultra-microanalysis. At first sight they appear to be quite different in approach and in the fields which they cover, but closer examination shows that this is more apparent than real. It is the result of the historical fact that although in the inorganic field methods which can be classed as ultra-microanalysis were used in the nineteenth century in inorganic chemistry, and have been increasingly studied since the early thirties, the much more exacting field of organic ultra-microanalysis has only been attacked relatively recently. The result is that Prof. Korenman's book, which in fact is inorganic, is an account of the work of a very large number of workers who have contributed considerably in important ways, and who include Korenman himself, Alimarin and Benedetti-Pichler.

Organic ultra-microanalysis, on the other hand, has mainly been developed by one school of analytical chemistry so that Prof. Belcher's book is in effect an account of one compact line of research, largely emanating from a single school. But it gives as fair an account of the present state of organic ultra-microanalysis as does Prof. Korenman's book in the inorganic field.

Probably one of the most telling arguments in favour of both books is that one realizes that ultra-microanalysis, whether in the inorganic or the organic field, has no longer that *noli me tangere* connotation that it used to have. Like microanalysis thirty years ago, it now has the right to be included in the equipment of any general analytical laboratory.

I cannot refrain from closing these reviews with an almost irrelevant comment. The attribution of "firsts", profitless though it may be, is intriguing to anyone with a historical bent, but must be handled with the greatest caution. Prof. Korenman, in saying that "as early as 1868, K. A. Timiryazev described some procedures for gas ultramicroanalysis", must surely be unaware that in 1855 Thomas Andrews described to the British Association the detection and measurement of hydrogen and oxygen from the electrolysis of water in amounts of approximately 10^{-4} cm^3. CECIL L. WILSON

The Origin and Evolution of the Universe

By Evry Schatzman. Translated from the French by Bernard and Annabel Pagel. Pp. 288+4 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1966.) 84*s*. net.

THIS is a translation of a book which first appeared in French in 1955. Some of the developments in astronomy and cosmology since then have been mentioned in the English version, but the rapid advances and discoveries of the past few years (such as quasars) have not been included. There is a fairly extensive account of the state of knowledge of stellar astronomy, and there are sections dealing with theories of the origin and evolution of stars, stellar systems and the solar system. The title of the book is perhaps a little misleading; cosmology as such occupies a relatively small proportion of the contents.

The overall planning of the book and the choice of subject-matter are excellent. In general, the treatment of the individual topics is quite good; the discussion, which is mainly non-mathematical, is readable. Unfortunately the book contains a rather large number of careless errors. Names are mis-spelt and references are incorrect. There are also some inconsistencies of a more serious nature. To name one, on pages 36 and 37, short-period variables are assigned to the spherical component of the Galaxy without further comment; however, on pages 46 and 47 it is stated that the disk population includes *RR* Lyrae variables. In reality, only some short-period variables are of the *RR* Lyrae type; *RR* Lyrae variables are probably represented in both the disk and in the spherical components. J. B. ALEXANDER

Plasma Physics

(Lectures presented at the Seminar on Plasma Physics organized by and held at the International Centre for Theoretical Physics, Trieste, from 5–31 Oct., 1964.) Pp. 649. (Vienna: International Atomic Energy Agency; London: H.M.S.O., 1965.) 273 schillings; 78*s*.; $13.

APPROXIMATELY half of *Plasma Physics* is devoted to a series of introductory lectures. In these the important aspects of plasma physics are discussed by various authors both from the macroscopic points of view using the magnetohydrodynamic equations, and from the microscopic one. The latter includes a discussion of the self-consistent Vlasov approximation and of the transport corrections. These lectures are individually of a high standard and give a comprehensive introduction to plasma physics but inevitably lack continuity.

The other half of the book contains lectures given by experts discussing work in which they are actively engaged. Although these lectures were given nearly 2 years ago they contain much material which is still relevant.

One topic of current interest is the theory and experimental work on the stabilization of plasma to low-frequency (small compared to the ion cyclotron frequency) instabilities. A detailed discussion is presented of the stabilizing effects of Joffe bars, the concept of minimum B and its generalization to toroidal systems.

Another topic which receives considerable attention is the problem of plasma turbulence. In the limit of weak turbulence the basis of quasi-linear theory and its extension to include mode–mode coupling terms is described and the application of these theories to the problems of enhanced diffusion and the structure of collisionless shocks discussed.

Two lectures, one on fully developed turbulence and the other on the kinetic theory of weakly unstable systems, give a clear indication of the more fundamental aspects of plasma physics.

These lectures, particularly those in the second half of the book, provide a very stimulating exposition of some of the present-day problems of plasma physics. The printing is of a high quality which makes the book easy to read though, of course, not necessarily easy to understand. This collection of lectures is to be thoroughly recommended both as an introduction to plasma physics and as a reference book to the present-day problems in this field. G. ROWLANDS

Testing of Polymers

Vol. 1. Edited by John V. Schmitz. Pp. xiv+479. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1965.) 147*s*.

IN materials science and technology, testing is an essential requirement: it provides an experimental description of the material as a means for the objective appraisal and comparative evaluation of its performance. As a result of the diversity and explosive growth of synthetic polymers and the limitless chemical possibilities of providing tailor-made polymeric products of desirable properties, a unification and co-ordination of the wide variety of testing procedures has become desirable. In this series of publications an attempt has been made to provide an authoritative discussion of all aspects of testing and in a form suitable for use by polymer chemists and physicists, material scientists, engineers and manufacturers, all of whom need to understand and apply test data.

Volume 1 of the series consists of fourteen chapters each of which covers some significant aspect of the testing of synthetic polymers. Most chapters review methods for evaluating individual properties, but other articles present background information or methods of evaluating individual properties, as well as service tests for end use purposes. The opening chapter discusses the purpose and the importance of standards, sources of standards, specification of materials and classification. This is followed by an account of the conditioning equipment for polymer testing. Chapters 3 and 4 which deal with the mechanical relationships in testing for the mechanical properties of polymers are concerned only with the basis of the tests and do not describe types and procedures for mechanical tests. The next five chapters (Chapters 5–9) cover in detail the wide subject of electrical property test methods and include d.c. dielectric conductance and conductivity, dielectric constant and loss measurements, electrical resistivity techniques and high voltage testing. The remaining chapters deal with specialized topics, testing for odour and taste, indentation and compression tests for floor coverings, cavitation erosion, and testing of gas and vapour permeation. The final chapter provides a useful literature coverage of selected references on sources of standards and tests for polymers.

This first volume is certainly a most valuable reference book and will be widely used by all interested in polymeric materials and their applications.

MEETINGS

THE CELL NUCLEUS

DURING May 9–11, 1966, a meeting was held at the Radiobiological Institute of the Organization for Health Research TNO in Rijswijk, the Netherlands, on "The Cell Nucleus: Metabolism and Radiosensitivity".

J. Brachet opened the meeting with a paper on the crucial question of control of nuclear function. He pointed out that in many life forms the nucleus plays a key part in the production of RNA throughout life, but that the nucleus was, in fact, very sensitive to the activities of the cytoplasm and its function was intimately related to the cytoplasmic products. Brachet considered the type of cell substance that would influence the function of the nucleus, and pointed out the possibility that *s*RNA and possibly the derivative of *s*RNA without the -CCA terminus might be responsible for control of nuclear activity.

D. Mazia discussed the functions of cells in mitosis, and in particular the nature of the protein involved in the mitotic spindle and in mitotic contraction. He indicated that this protein contains a number of substructures of which at least two, the 4*S* and 2·5*S* units, are probably linked through disulphide bonds. He suggested that spherical elements of spindle fibres might be "popped out" of the strand, thereby producing shortening without thickening. J. H. Frenster discussed the hypothesis that heterochromatin (dense) and euchromatin (less dense) might be inactive and active forms of chromatin. He claimed that the euchromatin in the thymocyte is uncoiled and is therefore less dense.

In the next session, E. C. Henshaw discussed the isolation, purification and characterization of messenger RNA. An effort to isolate and purify this substance was undertaken with cytoplasmic RNA, particularly with liver polysomes. The rapidly labelled cytoplasmic RNA was studied and stimulatory activity for amino-acid incorporation into protein was found in the RNA fractions with sedimentation constants ranging from 6 to 14.

C. E. Sekeris dealt with the hormonal stimulation of *m*RNA synthesis. Much attention has recently been focused on the possibility of hormonal stimulation of *m*RNA synthesis, but it has yet to be shown that an increased amount of a specific type of messenger RNA does, in fact, produce a specific readout characteristic of a hormonal effect. Some hormones produce an increased RNA synthesis in some cells, but others do not.

M. Sluyser brought forward some evidence that the histones of the ventral prostate are different from the histones of other tissues. He suggested that hormones might combine effectively with histones and that this combination would produce changes in the activity of the genome. Cortisone may bind to acidic proteins and to histones in the cell and possibly more strongly to "arginine rich" (AR) histones. J. C. Sirlin reported labelling with ^{14}C-methionine of RNA components in *Smittia* larvae. He found that only the 4*S* peak of nucleolar RNA became labelled. This evidence, he suggested, supports the concept that the nucleolus synthesizes 4*S* RNA which has a transfer-RNA function.

M. Errera studied the DNA–RNA complexes of HeLa cells using a modified Sevag procedure and MAK chromatography. The DNA-linked RNase resistant RNA has a base composition similar but not identical to that of DNA. There is also present in this preparation an RNA which is of the poly *A* type although approximately 25 per cent quanylic acid was present after hydrolysis.

The second day of the meeting dealt with the control of gene function by histones and with the nucleolus. E. W. Johns reported that the new $f2a_1$ and $f2a_2$ fractions of the slightly lysine rich (SLR) histones made it possible to account for the histones of a given cell in five more or less equal fractions. He reviewed the evidence for the similarity and differences of histones of various species and pointed out that most animal histones are very similar, but those of plants differ considerably. Johns noted that the binding of DNA to histones varies considerably, and that the histones with the least affinity are the f_1 or very lysine rich (VLR) histones. The f_3 or "arginine-rich" (AR) histones have the highest affinity for DNA, but the histones that produce the most precipitation of DNA from a saturated solution are the VLR or very lysine rich histones.

G. J. M. Tonino discussed the yeast chromatin and found two species of histones present, one containing approximately 1·5 times as much lysine as the other (9·2 against 5·5 per cent). Further studies are being made on these fractions.

M. G. Ord showed that the f_3 "arginine rich" or AR histones contain some thiol groups but the other histones contain few or none. Efforts have been made to purify all these fractions to determine the amount of phosphate linked using labelled orthophosphate. Ord reported that the active, uncoiled chromatin or less dense chromatin contained less phosphate and the dense or coiled chromatin contained more labelled phosphate.

L. A. Stocken reported on the possibility that the thiol groups of nuclear proteins were responsive to X-irradiation. The effects of radiation on hexokinase, glucose-6-phosphate dehydrogenase and glutathione reductase were studied, but little effect was found on these sulphydryl containing proteins. Changes in conformation might, however, have occurred.

A. L. Dounce discussed the nativity of nucleoprotein gels. The methods for measuring the viscosity of nucleoproteins were discussed as a means of determining the stability of gels. Treatment of nucleoproteins with urea and dilute saline solutions was carried out to establish stability. Previous workers have reported that histones must be present with DNA in order to stabilize these gels. Dounce has found however, that DNA gels can be obtained, but these can be broken by sulphydryl reagents, such as dithioerythritol. Histones increased the rigidity of the gels, but a higher concentration of DNA also produces a rigid gel. The acidic proteins present in the chromatin or DNA preparation are probably essential to maintain rigid gels.

E. Harbers showed that the priming efficiency of chromatin from Ehrlich ascites cells was not affected by the presence of histones; moreover, X-rays, shearing and sonication did not alter the priming activity of the nucleoprotein preparations. Harbers reported that heterochromatin had a decreased binding capacity for histone in the presence of actinomycin and suggested that histones like actinomycin should be in the small groove of the DNA helix. In the liver and kidney 60–80 per cent of the chromatin occurred as euchromatin. One of the important questions about euchromatin is whether its presence is related to the activity of the DNA. Less than 5 per cent of the chromatin is probably active in most somatic cells, and the high values obtained by Harbers suggest that yet another mechanism must be involved. Frenster suggested that this may be the amount of single stranded DNA in the nucleus.

H. Busch has been concerned with isolation of nucleoli on a large scale in order to obtain sufficient material for satisfactory fractionation and characterization of nuclear components. Studies have been made on the 45*S* nucleolar RNA which is the precursor of 28*S* RNA of the ribosomes. Purification of 45*S* RNA by countercurrent distribution shows that much of the RNA belongs to a small number of species

W. J. Steele indicated that the turnover of RNA in the cytoplasm was increased in animals treated with thioacetamide. As a result, the synthesis of 55, 45 and 35*S* nucleolar RNA increases markedly, and along with this increment in synthesis there is both enlargement of the nucleolus and an increased amount of rapidly sedimenting RNA within the nucleolus. The lesion involved is not yet defined.

M. Muramatsu dealt with the order of biosynthetic events in the nucleolus and the lack of information of the biosynthesis of 18*S* RNA. Ultra-violet analyses of the base composition of nucleolar RNA have shown that 45, 35 and 28*S* nucleolar RNAs have the same base composition, but this differs from that of 18*S* RNA.

R. B. Hurlbert presented studies on the effects of histones on biosynthesis of RNA in the RNA polymerase system of the nucleolus. He indicated that various histone fractions apparently produce different changes in the base compositions of the newly synthesized RNA. Moreover, trypsin, which probably attacks the histones and presumably other proteins of the perinucleolar chromatin, produces marked changes in the base compositions of the newly synthesized RNAs.

T. Y. Wang showed that extracts of the nucleus provide nucleoprotein fractions which take up labelled amino-acids into protein without a requirement for *s*RNA or ribosomes. The synthesis of protein in this fraction may proceed by very different mechanisms from those described for cytoplasmic systems. Wang also reported procedures for fractionating the acidic nuclear proteins; the products formed differ primarily in their solubility at *p*H 6 and 5, and have a low content of glutamic and aspartic acids.

On the third morning of the meeting, G. Siebert discussed the energy metabolism of the nucleus. He indicated that a number of enzymes involved in oxidative phosphorylation are found in the liver nucleus but that a number of cytochromes and enzymes are not present. He pointed out the need to isolate nuclei under conditions in which the enzymes remain in the nucleus. R. Penniall showed that labelled orthophosphate was bound not only in pyrophosphate bonds to nucleosides and nucleotides in nuclear preparations, but also formed inorganic di- and tri-phosphates.

I. Betel presented evidence for the presence of a complete and functioning respiratory chain in isolated thymus nuclei. The inhibition of oxygen dependent nuclear ATP synthesis by carbon monoxide is light reversible, suggesting the involvement of cytochrome oxidase in this process. He also showed that thymus nuclei are capable of oxidative phosphorylation coupled to a respiratory chain.

D. Klouwen has studied the occurrence of nuclear oxidative phosphorylation in other cell types. Nuclear oxidative phosphorylation was demonstrated in various lymphosarcoma cells and a myeloid leukaemia cell. He brought forward evidence that the exhaustion of ATP synthesizing capacity can be regarded as a biochemical basis for early cell death after radiation (interphase death).

J. F. Scaife indicated that a primary lesion of radiation might be the effect on nucleohistones or deoxyribonucleoprotein. He suggested that there is some form of labilization of DNA followed by liberation of histones from these macromolecules.

H. Grunicke reported that there is a decrease in glycolysis following administration of alkylating agents which might be related to the effects on NAD, inhibited biosynthesis of enzymes or increased degradation enzymes or blocks in transfer reactions.

In the final paper of the meeting, K. Rees dealt with the effects of the carcinogens aflatoxin *B*, thioacetamide and dimethyl aminoazobenzene on the rat liver cell. Dimethyl aminoazobenzene interacts with the protein associated with DNA, while aflatoxin reacts directly with DNA in an analogous manner to actinomycin *D*.

H. BUSCH

OBITUARIES

James Anderson Scott Watson

THE death of Professor Sir James Anderson Scott Watson, C.B.E., M.C., on August 5 is a loss to agricultural science in Britain and elsewhere. Scott Watson was born in 1889 on his father's farm in Angus. After a year working on the farm he went up to the University of Edinburgh at a very young age and graduated D.Sc. in agriculture in 1908. He won nearly all the class medals and was awarded the Vans Dunlop postgraduate scholarship, which took him for one year to Berlin and the second to the Iowa State College of Agriculture.

He was appointed a lecturer in agriculture in the University of Edinburgh in 1910, and served in the Artillery during the First World War and was awarded the M.C. He succeeded Professor Robert Wallace in the chair of agriculture in Edinburgh in 1922. In 1925 he went to Oxford and followed Sir William Somerville in the Sibthorpian chair of rural economy and held that post until 1944.

The Government created, for the first time in 1942, a post of Agricultural Attaché to the British Embassy in Washington combined with agricultural adviser to the High Commissioner in Canada. Scott Watson was the first occupant and he soon won the respect of American and Canadian farmers.

It had been decided as the result of the Luxmoore Committee on agricultural advisory work to create a National Agricultural Advisory Service for England and Wales, and Scott Watson was asked in 1944 to return to London and inaugurate the service. Many will share the view that not the least of Scott Watson's contributions to British agriculture was that he achieved the preliminary work and launching of the N.A.A.S. in October 1946 so successfully. His reputation, ability, integrity and the universal respect in which he was held quietened many fears and smoothed out many difficulties —it is doubtful if anyone else at that time could have accomplished it so quickly. He was the first director of the Service, and when in 1948 he was appointed chief scientific and agricultural adviser to the Ministry of Agriculture, a new post of director general of the N.A.A.S. was created for him. He held both posts until he retired in 1954.

Scott Watson had a wide and intimate knowledge of farming and farming conditions and an equally wide knowledge of the sciences on which agriculture is based; he was an omnivorous reader and had a prodigious memory. By some of his colleagues he was regarded as the "universal provider". He was a "born" teacher, equally effective with undergraduates, scientific gatherings or meetings of practical farmers. His great gift was in being able to express his vast knowledge in simple, clear and fluent language suitable to his audience. He was also an effective broadcaster, and his talks in pre-war days on rural Britain, subsequently published in book form, were a joy to listen to and to read. Before he left Edinburgh he published with J. A. Moore, one of his former students and then his colleague, the first edition of *The Science and Practice of British Farming*, which has run into many editions and is the standard text book in many countries of the world. For some fifteen years he also acted as editor of the journal of the Royal Agricultural Society.

As a man he was a most lovable personality, always kind and considerate; if he was aware of his great gifts he carried them easily and they were never paraded. To any request for his services or for his help the answer was invariably yes if it was humanly possible. He hated to have to return no for an answer. He had a vast multitude of admirers and friends, and to the large group of those who had been his students at Edinburgh and Oxford was added a deep bond of affection—to them he remained to the end simply Jimmy Watson.

LASER RADAR PROBE FOR THE MEASUREMENT OF METASTABLE NITRIC OXIDE IN THE UPPER ATMOSPHERE

By L. J. NUGENT
Electro-Optical Systems, Inc., Pasadena, California

THE application of the pulsed gas laser in an optical radar probe for the remote determination of the location and concentration of molecular and ionic species in metastable state populations in the upper atmosphere has recently been proposed by Young[1]. In this technique the probe operation is in part similar to that of conventional *A*-scope radar. In addition, the gas laser emission comes from the same chemical species to be investigated in the atmosphere and it is necessary that the laser transition should terminate on an excited state which is metastable with respect to the ground state. The laser output pulse is transmitted into the upper atmosphere where a small fraction of the energy is absorbed by the species to be detected. The latter subsequently produces resonance emission with high efficiency in the low pressure region above 50 km, and this scattered radiation signal is detected at a receiver with an optical field of view aligned along the direction of the transmitted pulse. From an oscilloscope display of signal intensity against time, species concentration can be determined as a function of position in the atmosphere. In particular, such measurements of metastable state N_2 and N_2^+ by this type of laser radar are considered to be possible.

The detection of the concentration of nitric oxide (NO) in metastable $a^4\Pi_i$ state in the atmosphere appears to be impractical for the gas laser radar technique because of a difficulty inherent in the nitric oxide gas laser. An optical radar approach to this measurement could be attempted, however, if specially selected giant-pulse Raman laser sources[2] are used in place of the nitric oxide gas laser. Accordingly, the sensitivity of a metastable state NO* optical radar probe using the giant-pulse Raman laser was examined, and estimates of the minimum detectable NO* concentrations made as a function of altitude and sky radiation background conditions. The results indicated that this technique is feasible under certain background conditions and that it should provide the means of obtaining new information about metastable state nitric oxide in the upper atmosphere.

Several of Gilmore's[3] lower lying potential energy curves for nitric oxide are presented in Fig. 1. The metastable state of interest here is $a^4\Pi_i$ with lowest lying vibrational state quantum number $V'' = 0$. Transitions terminating on $a^4\Pi$, the allowed Ogawa $b^4\Sigma^- - a^4\Pi_i$ bands[4,5], and transitions originating from $a^4\Pi$, the forbidden $a^4\Pi - X^2\Pi$ bands[6,7], have been observed in emission. The lifetime for radiative decay from the lowest lying $a^4\Pi_{5/2}$ multiplet to the ground state has been measured to be 156 msec in a solid neon matrix at 4° K[7]. The effective radiative lifetime of $a^4\Pi$, however, may be somewhat shorter at the higher temperatures in the upper atmosphere because the slightly higher lying multiplets $a^4\Pi_{3/2}$, $a^4\Pi_{1/2}$, and $a^4\Pi_{-1/2}$, which have shorter expected lifetimes, could be significantly populated by molecular collisions. Nevertheless, the effective radiative lifetime in the environment of the upper atmosphere should be at least of the order of milliseconds, which is long enough to permit build-up of the $a^4\Pi$ state population, through photodissociation and molecular reactions, to many orders of magnitude greater than the populations of the other higher lying electronic states.

Absorption and resonance emission in the Ogawa bands provide the mechanism by which these metastable state populations could be investigated most easily in the upper atmosphere using the laser radar technique. The possibility of obtaining laser emission in the Ogawa bands or in any other bands of nitric oxide in a gas discharge has been discussed by Young[8], however, and it appears that the reaction $NO + N \rightarrow N_2 + O$ with rate coefficient $k \approx 2 \times 10^{-11}$ cm³/sec may considerably decrease, if not completely eliminate, the output that would otherwise be expected. Even if laser emission is obtained in the Ogawa bands, therefore, the intensity will most likely not be high enough for application in an atmospheric probe.

It is a fortunate coincidence that the Ogawa band heads expected to be strongest in absorption in the upper atmosphere, namely those corresponding to transitions involving initial vibrational state quantum number $V'' = 0$ and terminal state vibrational quantum numbers $V' = 2$ or 3, occur in spectral regions where detector sensitivity and atmospheric transmission are high and where giant-pulse Raman laser radiation can be efficiently generated. Optical radar probe operation in the spectral region 11,447–11,577 cm^{-1} for the band heads corresponding to $V' = 2$, and in the spectral region 12,595–12,719 cm^{-1} for the band heads corresponding to $V' = 3$, is therefore most suitable for the proposed nitric oxide measurements.

Giant-pulse Raman laser radiation at any narrow wavenumber-band in the above spectral regions can be obtained. First the means is provided for coarse-tuning the giant-pulse ruby laser radiation to within ± 14 cm^{-1} of a desired NO* Ogawa band head by

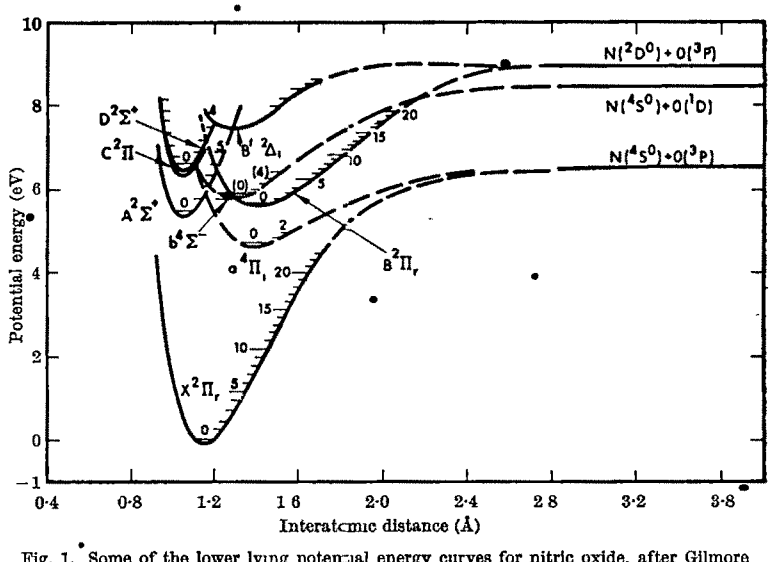

Fig. 1. Some of the lower lying potential energy curves for nitric oxide, after Gilmore (ref. 3). Estimated error: ———, < 0·02 eV; ± —, < 0·2 eV.

using the coherent Raman technique[9]. Then fine tuning is provided on a pulse by pulse basis by temperature tuning the ruby: ruby temperature control to within ±0·6° K over the range 77–357° K provides giant-pulse output selection over 14,418–14,391 cm^{-1} to within ±0·06 cm^{-1}. The coherent Raman technique for coarse tuning is more complex. The giant-pulse ruby radiation is Stokes-shifted, with about 10 per cent first-order conversion efficiency, by focusing it inside a cell containing a liquid, or a gas at pressures of 10 atmospheres or higher. The material is selected so that the frequencies and corresponding wavenumbers of totally symmetric molecular vibrations have the following restriction: the difference between the wavenumber of the ruby laser radiation and the wavenumber of the molecular vibration must be within temperature tuning range of a desired NO* absorption band head.

The following are examples of molecules with totally symmetric carbon–hydrogen (C—H) stretching frequencies such that they can be used to Stokes-shift the ruby radiation wavenumber to within temperature tuning range of the absorption region of some of the $V' = 2$ NO* band heads: CH_3I (gas) 2,969·8 cm^{-1}, CH_3Cl^{35} (gas) 2,966·2 cm^{-1}, CH_3F (gas) 2,964·5 cm^{-1}, CH_3Cl (liquid) 2,955 cm^{-1}, CH_4 (gas) 2,914·2 cm^{-1}, C_6H_6 (liquid) 2,899 cm^{-1}, C_2H_6 (liquid) 2,890 cm^{-1}, H_3CCN (liquid) 2,942 cm^{-1}, and CH_3COCH_3 (liquid) 2,925 cm^{-1}. Similarly, the following are a few examples of molecules that have totally symmetric carbonyl (C=O) stretching frequencies such that they can be used to Stokes-shift the ruby radiation wavenumber to within temperature tuning range of the absorption region of some of the $V' = 3$ NO* band heads: CH_3COH (liquid) 1,716 cm^{-1}, D_2CO (gas) 1,700 cm^{-1}, and H_2CO (gas) 1,744 cm^{-1}. In addition many other molecules fitting into either of these categories may be selected.

It is worth noting that giant-pulse coherent Raman emission has already been reported[10] for CH_4 at 11,488·9 ±0·5 cm^{-1} using room temperature ruby giant-pulse excitation, and this wavenumber exactly matches one of the band heads reported by Brook and Kaplan[4] for the Ogawa NO* system in emission. Although coherent Raman emission from the other substances above has not been reported yet, there is little doubt that it can be achieved with high efficiency in most cases. Typical output characteristics for the conventional giant-pulse ruby and for the corresponding giant-pulse Raman laser are presented in Table 1. It is safe to assume that lasers with the operating characteristics shown in this table can presently be made available for the NO* atmospheric probe.

Table 1. TYPICAL PARAMETERS REQUIRED FOR THE ESTIMATION OF THE MINIMUM DETECTABLE CONCENTRATION OF NO*

Source parameters	
Ruby laser	Raman laser
Output power, 33 MW	2–8 MW in first Stokes line
Output energy, 1 J	0·25–0·05 J
Pulse duration, 30 nsec	30 nsec
Bandwidth, < 0·1 cm^{-1}	< 0·5 cm^{-1} (liquid), 0 1 cm^{-1} (gas)
Beamwidth, ~ 1 mrad	~ 1 mrad
Repetition rate, ~ 15 cycles/min	~ 15 cycles/min

Detection parameters

Required voltage-signal-to-noise ratio = 5.
Number of times each measurement is repeated and the results integrated = 16.
Detection response time = 10^{-5} sec (resolution distance = 1·5 km).
Quantum efficiency of photodetector = 0 003 (*S*-1 photosurface with λ = 8,700Å).
Diameter of photon collector = 40 cm.
Estimated cross-section for absorption in the strongest Ogawa band heads of NO*, $\sigma = 10^{-13}$ to 10^{-14} cm^2.
Photodetector dark current = 1 8 × 10^{-14} amp (for *S*-1 photocathode cooled to −78° C and with a 2 cm^2 area).
Sky background irradiance,
$H\lambda$ = 6 × 10^5 photons/sec/cm^2/ster/Å (clear night).
$H\lambda$ = 10^9 photons/sec/cm^2/ster/Å (aurora at night)†.
$H\lambda$ = 4 × 10^{15} photons/sec/cm^2/ster/Å (day sky).
Detector bandwidth = 5 Å.
Detector field of view = 10^{-4} ster.

† Chamberlain, J. W., *Physics of the Aurora and Airglow*, 571 (Academic Press, New York, 1961).

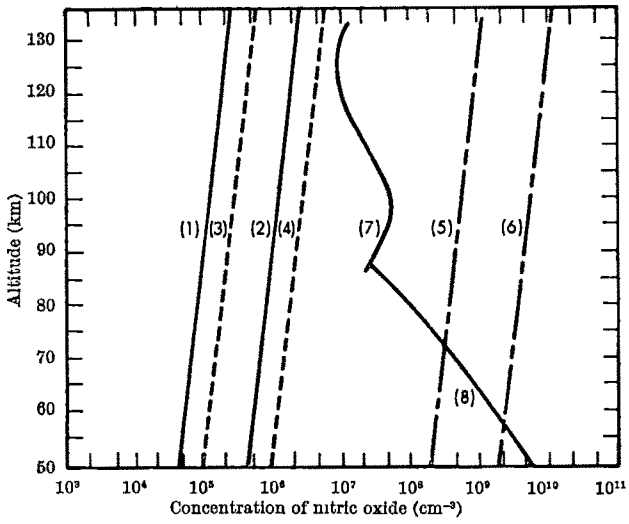

Fig. 2. Distribution of nitric oxide and calculated detectable concentrations of NO* at various altitudes in the atmosphere, where (1) and (2) are calculated using irradiance $H\lambda$ for a dark night sky and $\sigma = 10^{-13}$ and 10^{-14} cm^2, respectively. (3) and (4) are the same but refer to an auroral night sky. Similarly, (5) and (6) refer to the day sky. (7) is the distribution of total nitric oxide (refs. 12 and 13), and (8) the distribution of total nitric oxide (ref. 14). (1) to (6) are represented with sufficient accuracy as straight lines.

The sensitivity criterion for the NO* atmospheric probe is the minimum number density of NO* molecules that can be detected at a range h from the laser radar. Values of the parameters required for a sensitivity evaluation are listed in Table 1. Most of these numbers are accepted figures, but the estimated range for σ, the cross-section for absorption in the strongest Ogawa band heads of NO*, warrants special comment. Typical oscillator strengths for each vibrational band of formally allowed electronic transitions of nitric oxide lie between 0·002 and 0·02 (ref. 11). Because the Ogawa bands of nitric oxide are formally allowed and since it appears from the potential energy curves of Fig. 1 that the $V'' = 0 \rightarrow V' = 2$ and the $V'' = 0 \rightarrow V' = 3$ bands will have the strongest intensity, it is assumed that the oscillator strengths for these transitions lie at least within the above limits. Now there are six band heads in each Ogawa band and some of these overlap others. Furthermore, the Raman laser output has about the same bandwidth as each Ogawa band head and it can be tuned to overlap each band head. Therefore, it is reasonable to estimate the effective absorption cross-sections for each NO* band head as 10^{-14} to 10^{-13} cm^2, understanding that the absorption cross-section is proportional to oscillator strength and that an oscillator strength of unity corresponds to an absorption cross-section of 10^{-11} cm^2.

Values for the minimum detectable concentrations of NO* as a function of range for three representative background conditions and for the estimated factor-of-10 range in σ were calculated from the typical operating parameters listed in Table 1 (see ref. 1 for discussion of this type of calculation). These results are presented in Fig. 2, with recent estimates of the total nitric oxide concentration as a function of altitude above the Earth's surface, where the optical radar range is taken to be altitude. The total nitric oxide concentrations were taken from Nicolet[12] and normalized to agree with the measurements of Barth[13] for the region from 85 to 135 km. For the region between 50 and 85 km, they were taken from the *Handbook of Geophysics*[14]. It can be seen in Fig. 2 that for a night sky observation a signal would be obtained from an altitude of 50 km if the concentration of NO* is of the order of 10^{-4} of the total nitric oxide concentration, and that the corresponding fraction at 50 km for a day sky observation is of the order of 10^{-1}. Similarly, for an altitude of 135 km these numbers are 10^{-1} and 10^{2} respectively.

From this it appears that the chances for an NO* measurement of the day sky are not good; at best they are marginal at the stratopause and clearly out of the question at higher altitudes. The chances for an NO* observation of the dark night sky, the night sky with an aurora, or the twilight sky, however, appear to be very promising. Furthermore, the outlook for the future is even more promising because the probe sensitivity could be appreciably improved if a larger collecting mirror and/or the recently developed gigawatt-pulse ruby laser were used. Thus, the giant pulse Raman optical radar may become a tool for monitoring the concentration and chemical kinetics of metastable state nitric oxide in the upper atmosphere during the night or twilight hours, and will at least provide a means of setting upper limits on these unknown concentrations as a function of altitude and time.

ELECTRON SPIN RESONANCE STUDIES OF THE REACTIONS OF NITRIC OXIDE AND NITROGEN DIOXIDE WITH POLYMETHYL METHACRYLATE

By J. LAW*

Paterson Laboratories, Christie Hospital and Holt Radium Institute, Withington, Manchester

AFTER exposure to nitric oxide, polymethyl methacrylate (PMMA) exhibits an electron spin resonance (ESR) spectrum, and its response to radiation is modified[1]. Ebert and Law[2] found the same ESR spectrum after exposing PMMA to nitrogen dioxide and inferred that the spectrum produced by each gas arises from its reaction with small amounts (of the order of 1 per cent) of methyl methacrylate monomer (MMA). Exposure of PMMA containing MMA to either gas inhibited the formation of the well-known 5 + 4 line ESR spectrum when the gas was pumped off and the PMMA irradiated in a vacuum. If purified PMMA is exposed to either gas, no ESR spectrum is developed and in the case of nitric oxide, subsequent irradiation of the PMMA in a vacuum produces a normal response.

This article describes an investigation of the effects of nitric oxide and nitrogen dioxide both on PMMA containing MMA, and on pure MMA, using the ESR technique. Various possible reaction schemes and mechanisms will be discussed.

PMMA was prepared from purified MMA by irradiation as described elsewhere[2] and was allowed to retain small amounts of MMA. Nitric oxide was obtained from cylinders supplied by Matheson and Co., Inc., and was purified by passing through aqueous potassium hydroxide and two cold traps of solid carbon dioxide and acetone. Nitrogen dioxide was prepared by heating lead nitrate ($Pb(NO_3)_2$); oxygen was present in the mixture of nitrogen dioxide and nitrogen peroxide in the proportion indicated by the reactions quoted below. A trace of nitric oxide may have also resulted from decomposition of nitrogen dioxide at high temperatures, but in the presence of oxygen this would have rapidly formed nitrogen dioxide at room temperature. Samples of PMMA for treatment were prepared by filing from a block of the polymer and evacuating the resulting filings with a diffusion pump for about 20 h to pressures of the order of 10^{-5} torr. The samples were prepared in glass tubes of the type shown in Fig. 1, and each sample contained approximately 0·1 g of PMMA filings in a gas volume of about 50 c.c. The volume of filings was more than sufficient to fill the part of the tube entering the resonant cavity of the ESR spectrometer. All experiments were done at room temperature.

The pressures of the gases on admission to the samples were measured with a mercury manometer. All pressures of nitrogen dioxide quoted are partial pressures of nitrogen dioxide in mm of mercury, not of dinitrogen tetroxide mixtures, and were calculated from the observed pressure of a mixture of dinitrogen tetroxide, nitrogen dioxide and oxygen on the assumption that lead nitrate decomposes on heating according to the reactions

$$2\,Pb(NO_3)_2 = 2\,PbO + 4\,NO_2 + O_2$$
$$2\,NO_2 \rightleftharpoons N_2O_4$$

The dissociation constant of dinitrogen tetroxide was taken to be 0·18 at 25° C.

Electron spin resonance signals were observed using a Hilger and Watts 'Microspin' *X* band spectrometer. All such signals described here appeared to be of the same shape (except where otherwise described in the text) and this shape did not alter on reduction of microwave power fed to the cavity. Relative intensities of such signals were measured from the peak-to-peak amplitude

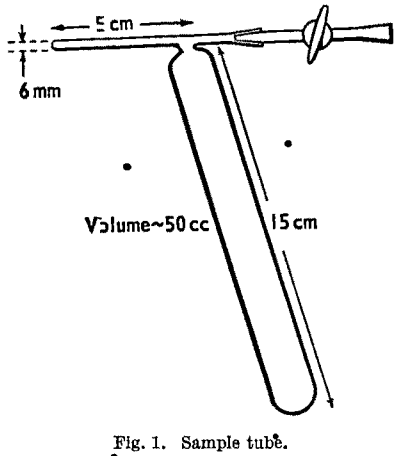

Fig. 1. Sample tube.

* Present address: Department of Medical Physics, The Royal Infirmary, Edinburgh.

of the main feature of the first derivative absorption signal.

Immediately after filing, the PMMA samples showed a weak asymmetric signal of the kind usually attributed to ROÓ, but this disappeared within a few minutes. Some samples were kept at 80° C for 24 h before exposure to nitric oxide or nitrogen dioxide, while others were kept in air for a similar interval of time before evacuation and exposure. These variations in initial treatment had no effect on their response to nitric oxide or nitrogen dioxide.

(*a*) Exposure of PMMA to nitrogen dioxide. Samples of PMMA filings continuously exposed to nitrogen dioxide at a pressure of 137 mm of mercury showed a very weak ESR signal within a few minutes of the start of the period of exposure. This signal decayed and disappeared within about an hour. Samples exposed to a lower pressure of nitrogen dioxide showed a larger signal which decayed more slowly. The signals were all of the form shown in Fig. 2, and had *g* factors close to two (ref. 2). Average curves for the growth and decay of the signals were plotted against time after admission of gas to the samples, for various gas pressures (Fig. 3). At the lower concentrations the gas was replenished at intervals of about 2 h by evacuation and immediate refilling, to maintain an approximately constant pressure. The gas remained in excess throughout each run at all concentrations. At all pressures a maximum was reached in the ESR signal intensity, after which the signal decays. Below 20 mm of mercury the decay rate was very low and at 9 mm of mercury it was not detectable. The relative values of these maxima are plotted in Fig. 4 against concentrations

of nitrogen dioxide. If the gas was pumped off when the maximum signal intensity was reached, the signal was stable, in air or in vacuum, for several months. If samples which had been exposed to high concentrations of nitrogen dioxide for long enough for the ESR signal to disappear were then exposed to low concentrations of gas, no further signal was developed. If, on the other hand, samples which had first been exposed to low gas concentrations, and had developed strong signals, were then exposed to higher pressures of gas, the strong signals decayed within a few hours.

This procedure was adopted to investigate the rate of decay of the ESR signal in the presence of excess nitrogen dioxide. Several samples were first exposed to nitrogen dioxide at 9 mm for 48 h and then to nitrogen dioxide at pressures varying from 68 to 128 mm of mercury. Relative decay rates were plotted against concentration of nitrogen dioxide (Fig. 5).

(*b*) Exposure of PMMA to nitric oxide. Samples of PMMA exposed to nitric oxide developed ESR spectra apparently identical with those developed using nitrogen dioxide. Typical growth curves are shown in Fig. 6, where it will be seen that in the early stages the curve is concave upwards—that is, the growth rate of the signal increases. The

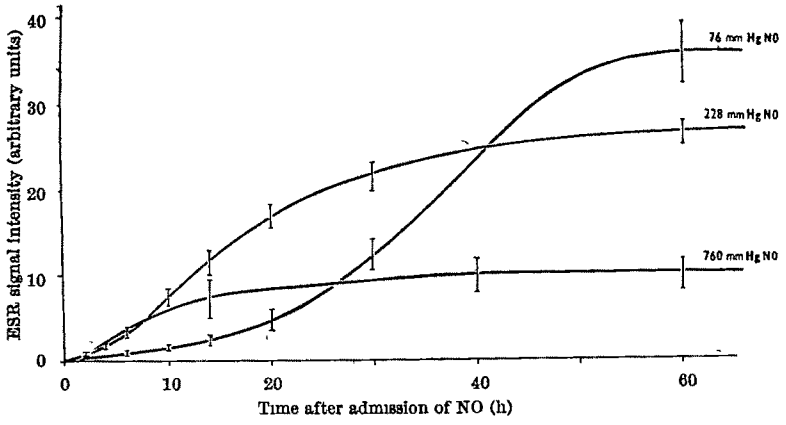

Fig 6. Growth of ESR signal intensity in PMMA exposed to nitric oxide. Uncertainties are standard deviations of means. Ordinate: ESR signal intensity (arbitrary units). Abscissa: time after admission of nitric oxide.

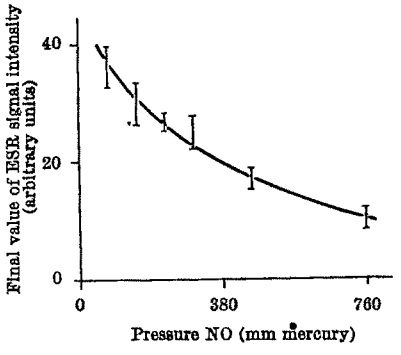
signal in all cases reached its final value within 60 h or less after admission of nitric oxide and then remained stable. At this time, a surplus of nitric oxide was still in contact with the PMMA at all concentrations. The signal was also stable in vacuum and in air for several months, as were signals produced by nitrogen dioxide. The relative intensity of this stable signal was plotted against concentrations of nitric oxide (Fig. 7).



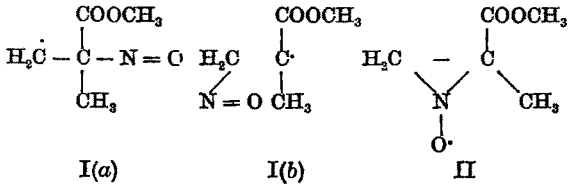


Fig. 7. Final values of ESR signal intensities in PMMA exposed to nitric oxide. Uncertainties are standard deviations of means. Ordinate: final values of ESR signal intensity (arbitrary units). Abscissa: pressure nitric oxide.

When samples are exposed to nitric oxide at atmospheric pressure and develop a stable ESR signal, they show no change in signal intensity if the nitric oxide pressure is later reduced. This is in line with the results from nitrogen dioxide. On the other hand, samples which are first exposed to nitric oxide at lower pressures and develop a larger signal show no reduction in that signal if the pressure of nitric oxide is subsequently increased, that is, the radicals are stable in nitric oxide at atmospheric pressure for periods of at least a week, in strong contrast to their rapid decay in nitrogen dioxide at 137 mm of mercury.

(c) Exposure of PMMA to nitric oxide and nitrogen dioxide alternately. Samples of PMMA were exposed to nitrogen dioxide at 137 mm of mercury for a few hours, until the ESR signal had disappeared. The gas mixture was then removed and nitric oxide at atmospheric pressure substituted. The sample turned blue but developed no ESR spectrum. Other samples of PMMA were exposed to nitric oxide at atmospheric pressure for 48 h until the ESR signal had reached a steady value. The nitric oxide was then removed and replaced by nitrogen dioxide at 137 mm of mercury. The samples lost their ESR signals and did not change colour. If nitrogen dioxide was used at 9 mm instead of 137 mm of mercury, no change in the ESR signal intensity was observed. Thus each gas attacks the same site

The two main aspects of this work which must now be considered are: (i) the chemical identity of the radicals, and (ii) the reaction systems giving rise to the kinetics described above. Ebert and Law[2] found that PMMA only showed an ESR spectrum after exposure to nitric oxide and nitrogen dioxide if it contained small amounts of MMA, regardless of the method used to prepare the PMMA. This result showed that the radicals arose from reactions involving only MMA and the gases, and it was suggested that the gases reacted with the C=C bond in the MMA. It was also established in the same paper that the nitrogen atom was closely associated with the orbit of the unpaired electron and little if any proton splitting was observed. This suggests radicals of type II rather than of type I.

After nitric oxide had been bubbled through pure MMA, and any PMMA which resulted had been filtered off, the radicals formed in the liquid could be extracted with ether; this suggests that the molecule exists as a monomer. In an attempt to convert these radicals to a more stable form, the reaction mixture was reduced by hydrogen over platinic oxide as catalyst, and the group $\begin{matrix} C-C \\ \diagdown\diagup \\ NH \end{matrix}$ looked for. It is known, for example, that di-methyl ethyleneimine has absorption bands at 425 and 303 mμ. The reduced radicals showed a band at 425 mμ but also an end absorption below 310 mμ, possibly from unreduced radicals, or unreacted MMA, which may have obscured the 303 mμ band. A Liebermann test gave a weak positive result for a secondary amine.

An attempt was made to isolate the resulting reduced compound by vacuum distillation. A viscous yellow residue resulted, which could not be distilled without decomposition at 120° C/3 mm of mercury. The residual liquid did not form a picrate, but gave a positive test for nitrogen. The infra-red absorption spectrum of the ether-extracted material contained a peak at 1530 cm^{-1}, suggesting nitroso groups. This peak disappeared on reduction of the radicals, but the spectrum of the reduced compound was difficult to interpret. Although no definite identification of the radicals can be made, the balance of evidence certainly favours type II.

An interpretation has been made of the kinetics of the reactions between PMMA and nitrogen dioxide. It must first be established that the kinetics are not limited by the rate at which the gases diffuse into the PMMA particles. The particle size in the PMMA samples was such that all the material was within 100μ of a surface. Powder samples of PMMA made up in the same way and irradiated in a vacuum developed the well known 5 + 4 line ESR signal which was removed with a time constant of a few minutes, or less, when either nitric oxide or nitrogen dioxide was subsequently admitted. Thus nitric oxide or nitrogen dioxide was available to all the material in the PMMA samples within a few minutes of admission of the gas, that is, in a time which was short compared with the time

scale of the growth curves (Figs. 3 and 6). A reaction model which is consistent with the observations in nitrogen dioxide can be put forward without the exact identity of the radicals requiring to be established first. Let us suppose that the reactions are of the general form

$$\text{MMA} + \text{NO}_2 \rightarrow X \quad (1)$$

$$X + \text{NO}_2 \rightarrow Y \quad (2)$$

where X is a radical (possibly, for example, Type II above) having the ESR spectrum of Fig. 2, and Y has no ESR spectrum. Either reaction may proceed by more than one stage. The weak component of the ESR signal, referred to by Ebert and Law[2], is disregarded in this analysis, as it was never responsible for more than 2 per cent of the observed signal intensity.

It is assumed that reaction (1) proceeds at a rate proportional to the concentration of nitrogen dioxide, N, which is constant in any single experiment, while reaction (2) proceeds at a rate proportional to some power α of N. (It may be seen later that if $\alpha = 1$ we should get a series of growth curves for different values of N which would have the same shape and would differ only in their time scale. This would conflict with the data in Figs. 3 and 4.)

If M is the concentration of reactive sites in MMA and x the concentration of radicals X at time t, then

$$\frac{dM}{dt} = -k_1 NM \quad (3)$$

$$\frac{dx}{dt} = k_1 NM - k_2 N^{\alpha} x \quad (4)$$

where k_1, k_2 and α are constants. k_1 and k_2 refer to reactions (1) and (2) respectively. The initial conditions governing these equations are

$$\text{at } t = 0,\ M = M_0$$
$$x = 0$$

The solution of the equation is then

$$x = M_0 \left(\frac{k_1 N}{k_1 N - k_2 N^{\alpha}}\right)(e^{-k_2 N^{\alpha} t} - e^{-k_1 N t})$$

On this model the maxima of the growth curves in Fig. 3, X_m, are related to the times at which they occur t_m and N by the equation

$$\log_e\left(\frac{X_m}{M_0}\right) + k_2 N^{\alpha} t_m = 0$$

If estimates of X_m and t_m based on the observations shown in Fig. 3 for various values of N are substituted in this equation, a least squares fit method yields a value for α of $2{\cdot}7 \pm 1{\cdot}0$. An estimate of α can also be made directly from the experimental results, and this provides an indication of the validity of the reaction model. In the experiments to investigate the rate of decay of the ESR signal in different concentrations of nitrogen dioxide reaction (1) has been virtually eliminated by allowing a small gas concentration to convert nearly all the available sites M to radicals X. This removes the $k_1 NM$ term from equation (4). If N is then increased suddenly to a relatively large value, only reaction (2) occurs to an appreciable extent since M is small. As a consequence of this we can, under these conditions, plot the rate of decay of x for various values of N, as in Fig. 5, and get a straight line of slope α. The experimental value of α obtained directly from Fig. 5 is $3{\cdot}5 \pm 0{\cdot}3$, which is in excellent agreement with the value of $2{\cdot}7 \pm 1{\cdot}0$ predicted on the basis of the reaction model. The best estimate of α to the nearest integer is three. This might correspond to reaction (2) requiring three nitrogen dioxide groups to convert each X group to Y. Since X and nitrogen dioxide are both radicals and Y is not, an odd integer might be expected for α rather than an even one. It is not clear why three nitrogen dioxide groups rather than one should be required, but this should be useful in the eventual identification of X and Y.

The results shown in Figs. 3–5 are thus consistent with a simple reaction scheme of the type outlined here. If the pressure of nitrogen dioxide in contact with PMMA is varied, from a low concentration to a high concentration, the reactions proceed to the degree corresponding to the higher concentration, whereas if a high concentration is used first, all the reactive sites in the MMA are filled by nitrogen dioxide (twice over) and further radical production in the powder does not occur. Similarly if nitric oxide is used following a high concentration of nitrogen dioxide no signal would be expected, while nitrogen dioxide after nitric oxide removes the ESR signal produced by the nitric oxide.

With nitric oxide no simple reaction model of the type suggested for nitrogen dioxide will explain the observations in Figs. 6 and 7, because the radicals X are stable in nitric oxide, that is, no decay reaction of type (2) occurs in nitric oxide. The ESR spectrum is the same after exposure to either gas, with each feature having the same g factor. Moreover, pure MMA, when exposed to either gas, shows the same triplet ESR spectrum at room temperature, and this transforms to the spectrum of Fig. 2 at 77° K (ref. 2). This implies that the same radical is responsible in each case, and suggests that nitric oxide may react with oxygen to form nitrogen dioxide which then reacts with MMA as previously described. The growth curves in nitric oxide (Fig. 6) are concave upwards in their early stages—that is, the rate of production of radicals is increasing during this period. This is consistent with a reaction which proceeds in two or more stages. It is difficult to suggest any likely source of oxygen in the PMMA samples after evacuation, however, or in the MMA which had been de-gassed by repeated freezing, evacuation and thawing. The results represented in Figs. 3, 4, 6 and 7 (in which the ordinate units are the same) show that the effects observed with nitric oxide could not be due to traces of nitrogen dioxide present as an impurity.

The results reported here with nitric oxide and nitrogen dioxide are qualitatively similar to some radiobiological results involving nitric oxide, and the possibility that they might arise from a similar mechanism is of some interest. It is often found that nitric oxide reduces radiation damage in dry biological systems and increases damage in wet systems as compared with radiation damage in nitrogen[3–7]. Dale *et al.*[5] found that if the pressure of nitric oxide in contact with *Shigella flexneri* during irradiation was varied, the effect of the gas on the radiosensitivity of this organism (measured as the reciprocal of the dose required to kill 90 per cent of the bacteria) showed a maximum at a nitric oxide pressure of 76 mm of mercury. Russell and Davies[8] found the same effect in *Escherichia coli* and Johansen and Howard-Flanders[7] have recently confirmed these results. No explanation of them has yet been reached but work on simple systems such as that described here on MMA and PMMA may prove a useful step towards such an explanation.

I thank Dr. M. Ebert of this laboratory for his interest and for many discussions in the course of this work, and Dr. B. W. Fox, also of this laboratory, for valuable suggestions and advice in attempting to identify the radicals.

HIGH LOAD-PRESSURE MINERALOGICAL RELATIONS IN CHONDRITES

By Dr. M. J. LE BAS
Department of Geology, University of Leicester

An advance in the understanding of the mineralogical relationships in chondrites was made with the abandonment[1,2] of the hypothesis[3] that chondrites are formed at temperatures below 1,000° C and at high volatile pressures.

This had been based largely on the temperature relations of orthopyroxene at 1 atm. Recent data[4] show that the infrequent occurrence of clinoenstatite is no indication that the temperature of original crystallization was about 1,000° C because at load-pressures of more than 8 kbars those conditions necessary for the formation of clinoenstatite no longer exist. Although it is possible that a little iron in solid solution could affect these relations, this seems unlikely in chondrites. Boyd and England further show[4] that the field of stability of clinoenstatite lies in fact below 600°–700° C. It is, however, improbable that the clinoenstatite observed in chondrites is formed at such low temperatures, for clinoenstatite is most likely to occur by inversion from protoenstatite at load-pressures of less than 8 kbars and temperatures[2] of about 1,200°–1,300° C.

The presence of (100) lamellae in orthopyroxene (Figs. 1 and 2) may result simply from the exsolution of lime-rich portions from the orthopyroxene and can occur at any pressure; but the presence of (001) style lamellae indicates the former presence of a clinopyroxene, and therefore of load-pressure conditions of less than 8 kbars. Barwell, Bjurbole and Indarch chondrites are examples of the former. The clinopyroxene to orthopyroxene inversion textures are rarely seen in chondrites (for example, Chainpur chondrite[5]), and it seems likely that protoenstatite did not exist as a primary phase in the majority of chondrites. This implies that at the temperatures of 1,200°–1,300° C now suggested[2], the primary crystallization would have occurred at load-pressures of more than 5 kbars.

The term "load-pressure" is here used to indicate pressure resulting from the weight of a superincumbent load, in contrast to the pressure resulting from volatiles. Because pressure due to load, P_l (often misleadingly termed hydrostatic pressure), and pressure due to volatiles (or vapours), P_v, commonly have opposite effects on the temperature of crystallization of solids, it is desirable that the distinction be clearly made.

As a result of examining the hypersthene-chondrite which fell at Barwell, Leicestershire, recently[6], two aspects have aroused interest: (*i*) the effect of load-pressure on chondrites; (ii) the role of plagioclase and the significance of the platey and prismatic texture in many chondrules.

Various authors[7–9] have put forward examples in favour of the formation of chondritic material at high load-pressures, while others[2,10–12] prefer lower load-pressures. Although meteorites examined now show low load-pressure relationships, it does not eliminate the possibility that many meteorites may have initially existed in a high load-pressure regime but were subsequently equilibrated to lower pressures. There has been much discussion[2,9,11–14] of the recrystallizations said to occur in meteorites, and it is thought that in many cases recrystallization may be related to the changes of pressure suggested here. Fig. 3 illustrates an exception to this. The metamorphism described by Wood[13] implies processes associated with increases of temperature and perhaps of pressures (P_l or P_v)—that is, conventional geological metamorphism as well. In contrast, it is suggested here that many of the phase changes resulted from the release of load-pressure largely by adiabatic expansion, followed by a fall in temperature. The normal type of metamorphism may also occur, but to a lesser extent. This theory is related to Mason's[15] suggestion that chondrules are porphyroblasts formed by solid state thermal recrystallization.

It has been customary in the past to correlate load-pressure relationships observed in meteorites with depth below surface and thus with size of the parent body. Some[3,8,16] have inferred that this parent has lunar dimensions; others[10,12] prefer asteroidal or smaller dimensions. More recently, high pressures resulting from shock during impact in space or on landing such as Lipschutz and

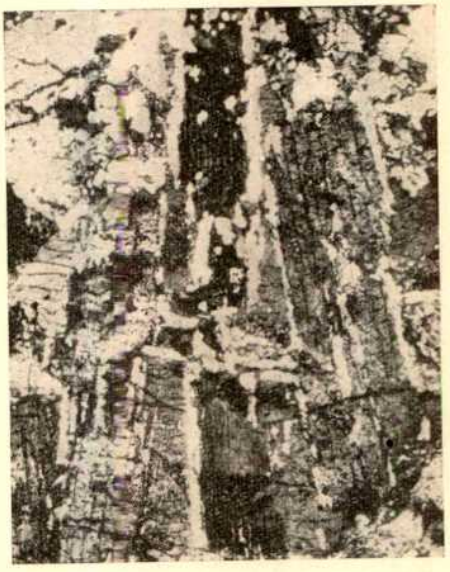

Fig. 1. Prismatic hypersthene crystals with (100) exsolution lamellae and rims of clinopyroxene. Chondrule in Barwell meteorite. (× c.35 crossed polars.)

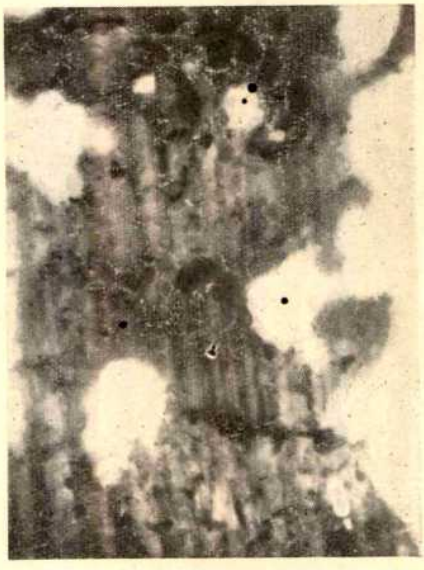

Fig. 2. Enlargement of portion of Fig. 1 showing the (100) exsolution lamellae in hypersthene. (× c. 720, crossed polars.)

Anders[17] have suggested for the origin of diamonds have been favoured[2,18] to account for the high load-pressure features.

It is difficult to reconcile existing ideas of processes involved in asteroidal or smaller bodies[2,19] with ideas which have been put forward to explain the relation between the various chondrites, achondrites and irons and their correlation with the structure of the Earth[1,9,20–23]. The latter ideas are currently accepted in one form or another by most mineralogists, and consequently theories must now be based on a real planetary model.

In subsequent paragraphs it is shown that load-pressures of 20 and 30 kbars may have been realized in the early history of chondrites. This would indicate on the above model a parent body or bodies of lunar or half lunar dimensions. (The central pressure in the Moon, radius 1,740 km, is about 47 kbars.) This raises the difficulty that, so far as is known, there is not enough asteroidal material to provide for one or more such large bodies.

The presence of plagioclase in chondrites has received scant attention[24], for plagioclase is often only represented by glasses and these need X-ray micro-probe methods to determine their composition[25]. In the Barwell meteorite, crystalline oligoclase plagioclase is present in the chondrules and in the matrix. It occupies a quarter of the volume of many chondrules, although it is absent from some which consist of orthopyroxene with exsolved clinopyroxene (Figs. 1 and 3). The plagioclase occasionally shows albite twinning (Figs. 4 and 5). This is unusual but not unknown elsewhere (for example, the Estacado chondrite[26]), and suggests that the Barwell meteorite has been more thoroughly re-equilibrated to lower temperatures than chondrites which show only cryptocrystalline plagioclase[14,24].

The examination of several chondrites under the polarizing microscope led me to recognize the similarity between the textures of barred and fibrous chondrules and the textures arising from exsolution seen in terrestrial pyroxenes. Grigoryev[27] has shown that chondrules occur in three simple textures: eccentrically radial, graticulate and porphyritic, and that they are related by recrystallization. Thus Harpum's comprehensive list[28] of twenty-five types of chondrules in Tanzanian chondrites can be reduced to Grigoryev's three classes.

These textures have been particularly well portrayed in the illustrations of the papers by Wood[19], Christophe-Michel-Levy[25] and Harpum[28]. Some examples of Barwell chondrules are shown in Figs. 1–9. Another textural

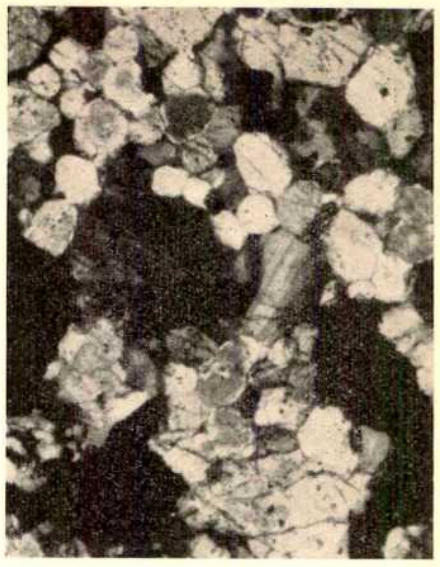

Fig. 4. Twinned oligoclase in part of a granular olivine-pyroxene-plagioclase chondrule from the Barwell meteorite. This chondrule is poorly defined and is texturally half-way between well defined chondrules and the matrix. (× *c.* 120, crossed polars.)

Fig. 5. Twinned oligoclase in olivine-plagioclase chondrule. Enlargement of portion of Fig. 6. (× *c.* 640, crossed polars.)

feature which has been noticed, particularly in the barred olivine-chondrules, is the polygonal outline (see Figs. 6 and 7) reminiscent of the shape of garnet crystals. A search of the literature showed this observation was not original, having been made by Sir Lewis Fermor[29] many years ago in the Khohar meteorite. He postulated[29] that garnet was converted to enstatite by a reduction in the pressure conditions. Later, he suggested[30] the existence of a new garnet called "khoharite" ($Mg_3Fe_2Si_3O_{12}$). The existence of "khoharite" was never substantiated, and Fermor's theory was abandoned.

The original observation of the polygonal outline of many chondrules can, however, be confirmed and needs to be explained. A modern interpretation might be obtained from the recent experimental work of Kushiro and Yoder[31], who have shown that garnet (pyrope : grossular = 2·1) stable at high load-pressures (> 20 kbars) and temperatures (1,200°–1,300° C) inverts on a reduction of the load-pressure to less than 8 kbars, and through intermediate phases of pyroxene, spinel and plagioclase, to a mixture of forsterite and anorthite plagioclase. They

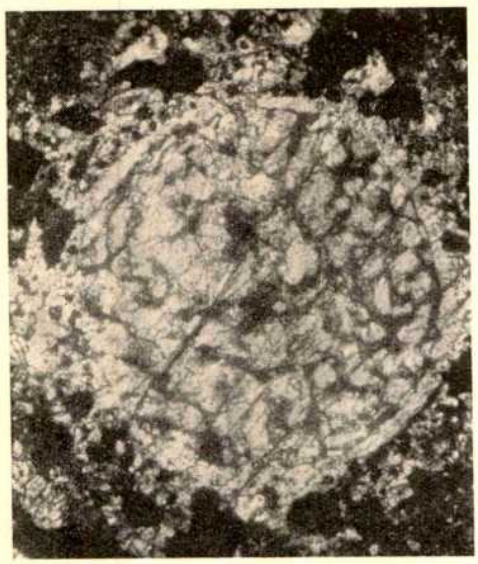

Fig. 6. Olivine-plagioclase chondrule with polygonal outline from the Barwell meteorite. The olivine is nearly all in optical continuity, but the plagioclase extinction is quite irregular. (× *c.* 75, crossed polars.)

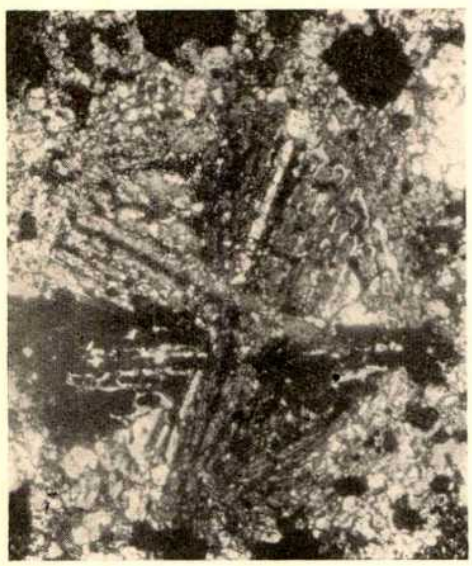

Fig. 7. Olivine-plagioclase chondrule from the Barwell meteorite with polygonal outline showing curious texture possibly related to the "hour-glass" structure. (× *c.* 45, crossed polars.)

have also shown[31] that similar garnet together with quartz at similar pressures and temperatures invert by way of a comparable sequence of events to enstatite and anorthite plagioclase. Because the plagioclase in chondrites is oligoclase, these experiments make the original presence of garnets in chondrites doubtful.

More recent experimental work by Kushiro[32] has shown that at 10 kbars load-pressure solid forsterite and liquid (albitic) co-exist at 1,400°–1,500° C, but that at load-pressures of 15–22 kbars at these temperatures, ortho-pyroxene, forsterite and liquid (albitic) become the stable phases. This assemblage bears a close resemblance to the minerals present in chondrules, even to the glassy representation of the albitic liquid. Kushiro also found[33] that at 22 kbars and 1,100° C, an albite–nepheline–forsterite composition glass crystallizes to give a jadeitic pyroxene. In other experiments, Yoder and Tilley[34] have shown that forsterite and jadeite co-exist at 33 kbars load-pressure and 1,250° C, and Bell and Davis[35] have shown that jadeite and diopside co-exist at 30 kbars load-pressure at 1,200°–1,300° C.

Coupled with these experimental data are the observations by Mason[24] and Wood[19] on the relative abundances of orthopyroxene and clinopyroxene in chondrites, and the fact that the absence of plagioclase can be correlated with the presence of lime-poor clinopyroxene (pigeonite). Together, these data suggest that jadeitic pyroxene with or without forsterite may have formed the primary material from which the chondrules formed. The jadeitic pyroxene would probably have been a pigeonite with a small amount of jadeite ($NaAlSi_2O_6$) in solid solution. Mason arrived at a similar conclusion from other considerations[24,26].

In some chondrules, a curious texture, as shown in Fig. 7, is seen. The angle between the adjacent sectors of the chondrule is about 75°. This is also the value of the angle between the x and z crystallographic axes of clinopyroxenes. Another chondrule (Fig. 8) shows a texture which is reminiscent of "herring bone" twinning,

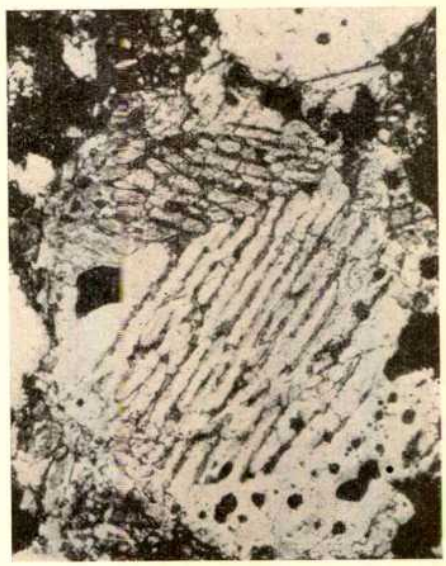

Fig. 8. Olivine-plagioclase chondrule from the Barwell meteorite showing texture related to "herring-bone" twinning. (× *c.* 120, crossed polars.)

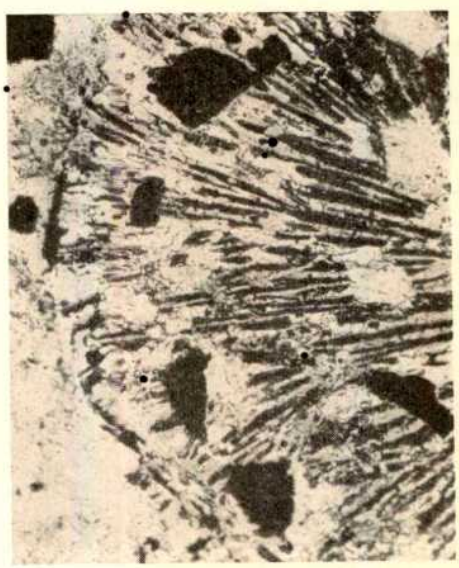

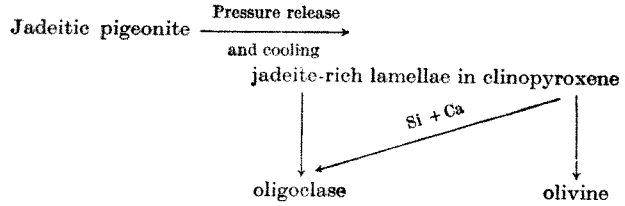

Fig. 9. Unusual chondrule from the Barwell meteorite formed of 50 per cent plagioclase, 25 per cent olivine and 25 per cent grey-brown turbid cryptocrystalline material (possibly pyroxene), and enclosing four crystals of unknown red-brown isometric mineral with high relief. (× *c.* 120, plane polarized light.)

a common feature of clinopyroxenes. It is considered that these textures are quite possibly crystallographic relics of a former clinopyroxene phase. The inversion stages could then be schematically represented as follows:

It is not yet possible to say whether or not individual chondrules may represent former pyroxene crystals. Too little is known of the habit and crystallography of jadeitic pigeonite, but jadeitic diopside (omphacite) commonly forms equidimensional crystals.

The data considered here suggest that it may be possible to distinguish chondrites formed at high load-pressure environments from those formed at lower load-pressures. In this way a model might be constructed of the original body or bodies. It would also contribute to the solution of the problem of whether or not the *H* and *L* chondrites[1] might have come from different bodies[16], possibly of different sizes, which came close enough to each other to cause their disintegration.

In conclusion, textures of chondrules in the Barwell and other meteorites are taken to indicate that some chondrites formerly existed in a high load-pressure environment in which dense minerals, such as jadeitic pigeonite, were stable. On release of the pressure, separation occurred to give the textures and mineralogy commonly seen in chondrules. It is suggested that the parent body or bodies may have been of lunar dimensions.

I thank Dr. M. H. Hey for permission to examine thin sections of meteorites in the British Museum (Natural History) collection, Dr. A. J. Meadows, Department of Astronomy, University of Leicester, for reading this note, and Mr. J. A. Dixon for assistance in the photomicrography.

MECHANISM OF OXIDATION OF DILUTE NICKEL—CHROMIUM ALLOYS

By Dr. G. C. WOOD and T. HODGKIESS

Corrosion Science Division, Department of Chemical Engineering, The University of Manchester Institute of Science and Technology

It is generally held that chromium additions to pure nickel progressively increase its high temperature oxidation rate until a concentration variously reported as 5–8 per cent is reached, whereupon further additions decrease the rate[1–6]. A widely quoted theory explaining this behaviour is that chromium in low concentrations increases the oxidation rate by increasing the number of cation vacancies in the NiO scale, whereas larger concentrations decrease it by also forming other phases of a more protective nature, namely $NiCr_2O_4$ or Cr_2O_3. The present communication describes results which prove that it is necessary to modify certain of these now classical views on the subject.

Electropolished and occasionally finely abraded specimens, 2·0 × 0·5 × 0·06 cm, of annealed pure nickel (99·97 per cent) and alloys containing respectively 1, 2, 3, 5, 7, 10, 15 and 27 per cent pure chromium were oxidized by immediate exposure at 1,000° or 1,200° C to pure dry, flowing oxygen in a silica spring thermobalance. After cooling relatively slowly for 10 min, they were prepared in cross-section by conventional metallography and examined in a Cambridge 'Microscan' Mark II electron probe microanalyser. Other scales from specimens of larger area were examined by X-ray diffraction.

Fig. 1(*a*) and (*b*) shows the kinetic growth curves for the whole range of alloys at 1,000° and 1,200° C respectively, plotted as the weight gain against the square root of time. Each curve was obtained by averaging the curves for several closely reproducible runs for each alloy. All the curves for alloys in the range 1–10 per cent chromium at 1,000° C and 2–10 per cent chromium at 1,200° C lie randomly within the narrow scatter bands indicated, there being no significant difference in oxidation rate in the composition ranges quoted. At 1,000° C, therefore, addition of 1–10 per cent chromium to nickel increases the parabolic rate constant from 2·93 × 10^{-10} to 1·73–2·13 × 10^{-9} g^2/cm^4/sec, precise adherence to the parabolic relationship being maintained for the full 25 h of the runs. The corresponding increase at 1,200° C is from 2·33 × 10^{-9} to 1·31–1·54 × 10^{-8} g^2/cm^4/sec for the first 8–10 hours. At this stage there is a positive deviation, scarcely detectable for pure nickel but pronounced for the alloys, probably because the alloy core is now very thin; localized thicker scale is observable at the ends, perhaps because of oxide disruption there. It is remarkable that at 1,200° C nickel containing 15 per cent chromium oxidizes as fast as the dilute alloys in the early stages and even at 1,000° C the initial rate is more rapid than for pure nickel.

Alloys of nickel with 15 and 27 per cent chromium eventually oxidize more slowly than the other alloys at both temperatures because of the development of a healing layer of Cr_2O_3 at the scale base[6]. Very small patches of similarly healed scale are observed with nickel–7 per cent and 10 per cent chromium at 1,000° C but have an insignificant influence on the growth curves. The curve for nickel containing 1 per cent chromium at 1,200° C is drawn for 5 h only because the growth kinetics for this alloy were highly irreproducible especially at long times. Indeed the curve shown represents only the average kinetics of the faster runs and even this is slightly lower than for alloys containing 2–10 per cent chromium. The general conclusion is therefore that there is no sharp maximum in oxidation rate, as previously reported. Instead, the rate increases with chromium content up to 1–2 per cent, whereupon it remains substantially constant with further chromium additions until scale healing by Cr_2O_3 occurs.

The morphology, structure and analysis of scales in section are summarized schematically in Fig. 2. Single quotation marks are used to denote single oxide phases containing low concentrations of the other element. On pure nickel, adherent, uniform single-layer scales were obtained at both temperatures, the oxide grain size increasing considerably towards the outer surface. On nickel with 1 per cent chromium at both temperatures and with 2 per cent chromium at 1,200° C, thicker, apparently single-layer scales of 'NiO', which lost adhesion to the alloy on cooling, were produced. A deeply penetrating layer of fine acicular 'Cr_2O_3' particles penetrated the alloy. Alloys containing 2–10 per cent chromium at 1,000° C and 3–10 per cent chromium at 1,200° C all developed scales with double layers in the sense that only the inner layer contained visible second-phase particles. On

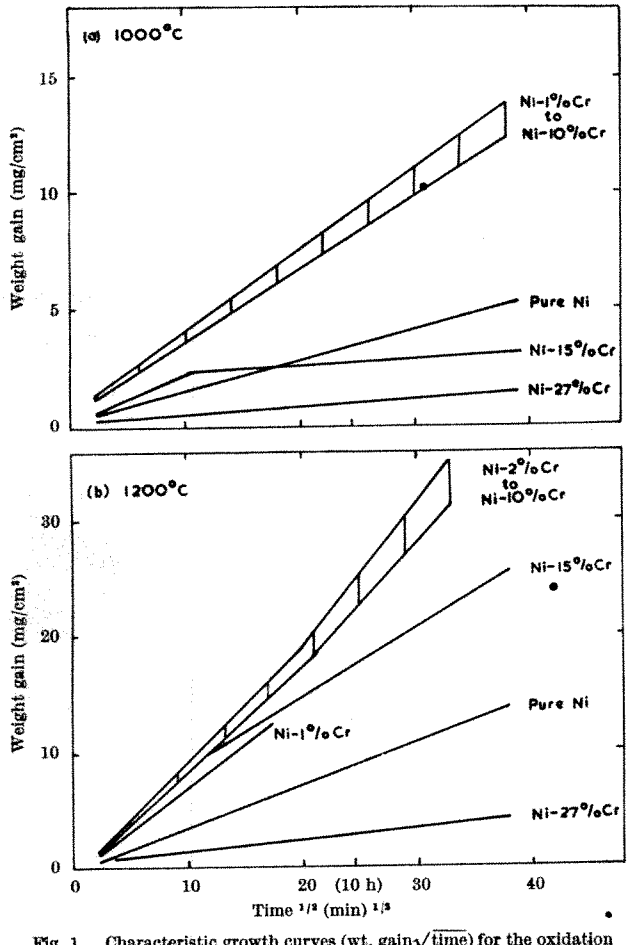

Fig. 1. Characteristic growth curves (wt. gain $\sqrt{\text{time}}$) for the oxidation of nickel–chromium alloys in oxygen at (*a*) 1,000° C, (*b*) 1,200° C.

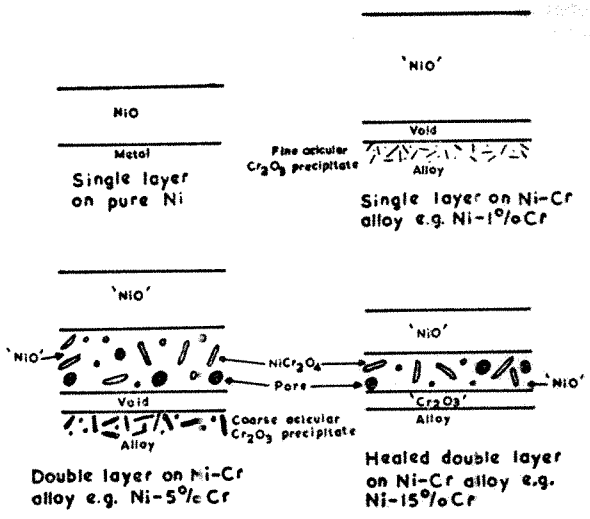

Fig. 2. Schematic diagrams of scales on dilute nickel–chromium alloys.

cooling, the two layers maintained excellent adhesion but the entire scale lifted from the alloy. The 'Cr_2O_3' internal oxide was of a coarser acicular nature, at least in the alloy range 2–5 per cent chromium, and penetrated less deeply into the alloy. The inner layer contained similarly shaped $NiCr_2O_4$ particles. There were also several large pores but it was difficult to decide whether a continuous porous network existed in the inner layer, especially as the 'pores' bore some resemblance merely to a relief-polishing effect when viewed in oblique illumination. The outer layer appeared completely compact, there being no obvious evidence of the pores developed in similar sulphide films by anisotropic dissociation[7]. It should also be emphasized that the demarcation between single- and double-layer growth was not clear-cut. Thus, although the alloy with 1 per cent chromium at 1,000° and 1,200° C and that with 2 per cent chromium at 1,200° C were adjudged from the lack of many visible pores and precipitate in the inner regions to have single layers, the large outer columnar grains ceased about halfway through the scale and traces of $NiCr_2O_4$ were detected by X-ray diffraction. Time appeared to have an influence on the structure. Scales on 15 per cent and 27 per cent chromium alloys adhered to the alloy because of the linking of the healing 'Cr_2O_3' layer to the alloy[8].

Concentration profiles through a characteristic single-layer scale formed on nickel-1 per cent chromium at 1,000° C and a double-layer scale on nickel–5 per cent chromium at 1,200° C are shown in Fig. 3(*a*) and (*b*) respectively. The curves are ultra-slow scanning traces corrected for absorption and fluorescence effects at the points indicated and confirmed by static probe measurements in vital locations. The apparent single layer on nickel–1 per cent chromium is clearly 'NiO' containing chromium, rising in concentration from the scarcely detectable level of 0·1 per cent or less at the scale/oxygen interface to 1·29 per cent at the alloy/oxide interface at 1,000° C; at 1,200° C the similar rise is typically from 0·2 or less to 2·10 per cent. Both values at the true inner interface should possibly be a little higher, but this is partly obscured by the voids. For nickel–1 per cent chromium at 1,200° C the chromium concentration near the alloy/oxide interface varied somewhat, possibly explaining the scatter in the kinetic curves. For nickel–1 per cent chromium at 1,000° C and nickel–2 per cent chromium at 1,200° C, a chromium plateau at about 1 per cent and 3 per cent respectively was sometimes achieved in the inner region, depending on the time. This suggests that the solubility of chromium in nickel oxide was being virtually satisfied there, so a few spinel particles could persist. Some lack of equilibrium due to the

slowness of diffusion of Cr^{3+} ions in 'NiO' may also have been involved.

The outer layers on nickel–5 per cent chromium show somewhat similar chromium concentration profiles, the values at the outer interface being the same as for the alloy with 1 per cent chromium. At 1,000° C the chromium concentration at the inner layer/outer layer interface is typically 1–2 per cent for this type of specimen and at 1,200° C it is consistently constant at 3·5–4·5 per cent for the whole range of alloy compositions (Fig. 3(*b*)). Since the latter value was also always found for the 'NiO' between the second-phase particles in the inner layer, it is considered to be the limit of solubility of chromium in NiO at this temperature. Spot analyses and X-ray diffraction showed the acicular second phase particles to be $NiCr_2O_4$, there being no 'Cr_2O_3' in the inner layer. Resolution of 'NiO' and $NiCr_2O_4$ was not possible at 1,000° C by microanalysis. Static probe microanalysis demonstrated that the internal oxide particles are 'Cr_2O_3' and additionally that the alloy between the particles, although much depleted in chromium, is by no means pure nickel. There is admittedly always some possibility of the X-ray source entering internal oxide particles buried beneath the surface but this would not always be expected to be the case, or alternatively some fluorescence of chromium radiation in the particles by nickel radiation excited in the matrix.

In explaining the results, it may be proposed that when the allow is exposed to oxygen, 'NiO' and 'Cr_2O_3' both form initially, but rapidly combine and coalesce, producing either an unsaturated or just saturated solution of chromium in 'NiO' for the very dilute alloys, or $NiCr_2O_4$ particles in a saturated solution of chromium in 'NiO' for alloys containing more than 1–2 per cent chromium. Partial dissociation of 'NiO' occurs at the alloy-oxide interface and oxygen diffuses into the alloy, provoking the precipitation by preferential oxidation of 'Cr_2O_3', thus causing considerable chromium depletion in the surrounding alloy. As the external scale develops, the 'Cr_2O_3' granules become incorporated into the inner layer where they, together with any chromium left in the oxidizing alloy, saturate the 'NiO' there with chromium and are converted into $NiCr_2O_4$ particles of a similar shape. For the very dilute alloys almost total dissolution of 'Cr_2O_3' in the 'NiO' tends to occur. Ni^{2+} ions diffuse from the alloy to build the outer layer at its outer surface. Cr^{3+} ions from the alloy or the 'NiO' in the inner layer can penetrate the outer layer but reach only a low concentration in it. This theory differs from that of Moreau and Bénard[9] in that the alloy between the internal oxide particles is apparently not almost pure nickel, presumably because equilibrium is never maintained in this region and chromium can still diffuse into it, and also because chromium ions can clearly diffuse well into the outer scale layer. Birks and Rickert[10] maintain that, in explaining the incorporation of the 'Cr_2O_3' internal oxide particles into the scale, it is necessary to postulate in addition that oxygen gas, obtained from dissociation of 'NiO' in voids in the inner layer, moves through a porous inner layer to form fresh oxide at the alloy/oxide interface. Without necessarily disputing this theory, the authors believe that it is still to be demonstrated that the inner layer does contain a complete network of pores. Consideration should also be given to the possibility of plastic 'NiO' relaxing around the 'Cr_2O_3' particles as the alloy is consumed, so detaching the 'Cr_2O_3' particle "markers". Evidently some stress is developed at the interface during the incorporation process, because of the lack of adhesion on cooling, but whether it is due to chromium reducing the plasticity of 'NiO' or directly to the internal oxide cannot yet be stated. Microhardness measurements at room temperature suggest that 'NiO' is harder than NiO.

It remains to be explained why all the dilute alloys generally oxidize at the same parabolic growth rate. Although the chromium is distributed across the scale in a complex manner, the concentrations in the 'NiO' at the alloy/oxide and oxide/oxygen interfaces are constant with time for nearly all the alloys at a given temperature. This presumably could mean that the concentration difference of cation vacancies across the film is constant with time, so a parabolic rate is maintained. The effect of chromium in increasing the rate ceases once the 'NiO' near the alloy is saturated with chromium and the profile through the 'NiO' in the film is established, any further additions being superfluous. As postulated by Hauffe[11], the chromium enrichment in the inner region of the scale may flatten the cation vacancy concentration profile across the scale rather than enhance it. The effect of chromium in increasing the rate must therefore be related to an increase in the total vacancy concentration rather than in the vacancy concentration difference. Additional problems in interpretation may exist because of present doubts about the defect structure of NiO and the applicability of the valency rules.

It is, however, a little surprising that the blocking effect of $NiCr_2O_4$ precipitate in the inner layer has an apparently negligible influence on the flux of outwardly moving ions. This would seem to suggest that oxygen flow through pores in the inner layer could be contributory, by the dissociative process[10], although this could not

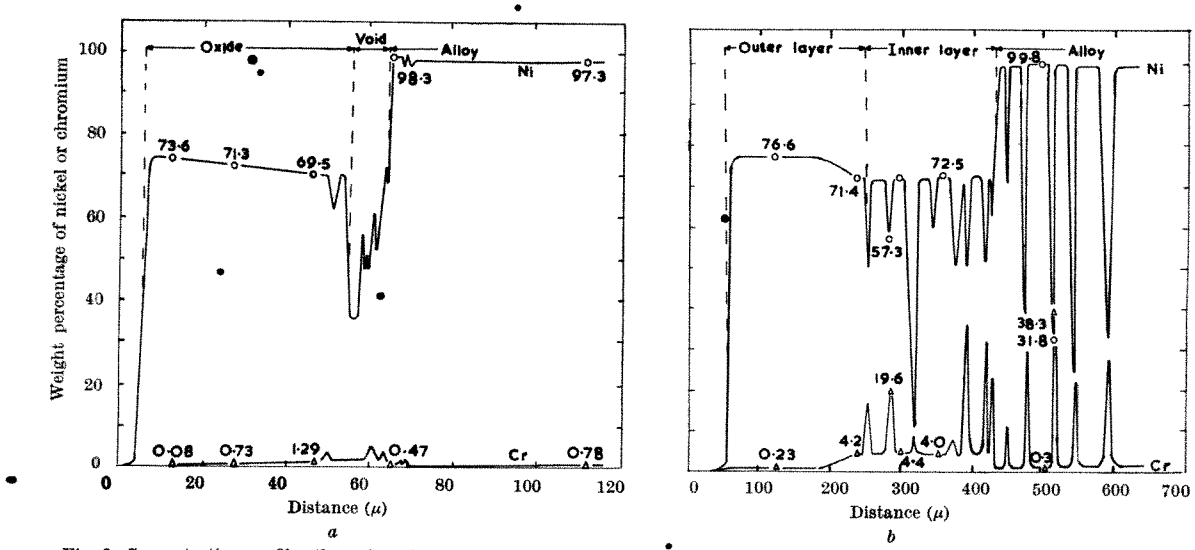

Fig. 3. Concentration profiles through scales and alloys after oxidation of dilute nickel–chromium alloys. (*a*) Nickel–1 per cent chromium for 5 h at 1,000° C; (*b*) nickel–5 per cent chromium for 25 h at 1,200° C.

hold if the inner layer does not exist on the very dilute alloys, and would be less likely if there is never a complete network of pores in the inner layer on other alloys. It might, therefore, also be argued that the outer 'NiO' layer (the entire layer for dilute alloys) is rate-determining, because the chromium concentration gradient across it is constant and the same for most alloys, the inner layer effectively being a short circuit. The authors will return to these matters elsewhere when additional data are available.

Rapp[12] has recently independently reported views tending in the same direction as ours, based on theoretical considerations, but has apparently not confirmed them experimentally.

We thank Prof. T. K. Ross for providing facilities, the International Nickel Company (Mond) Limited for the alloys and the Science Research Council for a maintenance grant to one of us (T. H.) and for providing the micro-analyser.

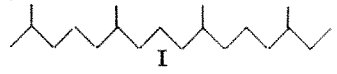
HYDROCARBONS FROM AUSTRALIAN OIL, TWO HUNDRED MILLION YEARS OLD

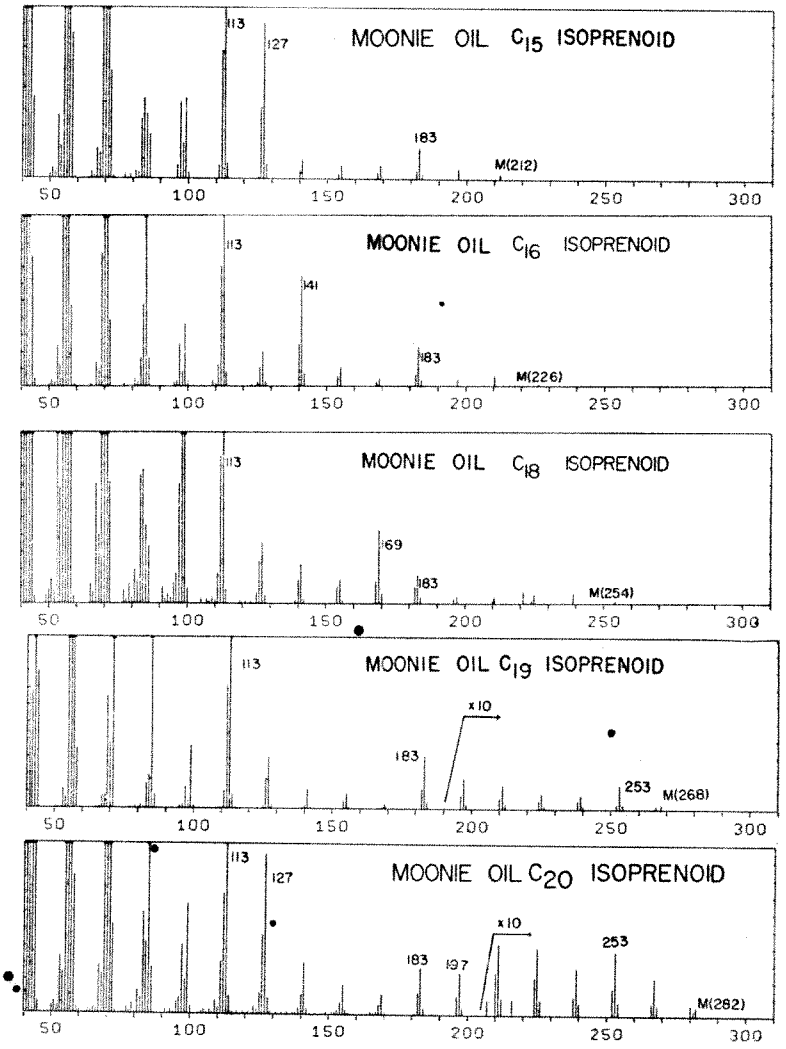
By WILLIAM VAN HOEVEN, PAT HAUG, A. L. BURLINGAME and PROF. MELVIN CALVIN
Department of Chemistry and Space Sciences Laboratory, University of California, Berkeley, California

IN an attempt to extend our investigation of the organic components of ancient sediments[1–4] to another continent and presumably a separate origin, we studied the hydrocarbons present in the Moonie crude oil from Queensland, Australia. It is believed that the source of the oil was in Permian rocks, probably sedimentary, and that later it migrated along an unconformity at the base of the reservoir basin into Jurassic and Triassic sandstone—dated on the basis of spores[5] (also A. S. Keller and R. C. McLaughlin, personal communications). A wide spectrum of analyses of sediments from various ages and from various places can be expected to provide data relevant to a solution to the question of when and how life evolved on earth. Such an approach may eventually shed some light on the ecology of a particular region at a given geological period.



The experimental procedure, already explained in detail elsewhere[1], involved the use of column chromatography (thin layer chromatography with grade neutral alumina eluted with *n*-heptane) to separate the "total" hydrocarbon fraction (1·46 g) from 3·89 g of crude oil. Using this "total" fraction, the "normal" (straight chain) hydrocarbons were separated by means of a 5 Å molecular sieve, from the "branched-cyclic" hydrocarbons, which represented about 42 per cent of the "total" hydrocarbons. Individual compounds of the "branched-cyclic fraction" were separated on a 3 per cent *SE*-30 gas-liquid chromatography column (10 ft. × ¼ in.) and purified successively on two columns (25 ft. × ¼ in.) containing 2·5 per cent 7-ring metapolyphenylether (PPE) and 3 per cent tetracyanoethylated pentaerythritol chromatographic phases. A modified G.E.C. 103 mass spectrometer was used to elucidate the structures of isolated compounds. Figs. 1–3 show the original mass spectra of the first three compounds isolated from the Moonie oil. These are sample spectra illustrating the purity attained by the isolation procedures described and proper mass spectrometric handling techniques. In Figs. 5–7 the bar graphs drawn from these originals are presented. (Relative intensities for all peaks which are off scale because of the choice of the base peak are given in Table 1.) All spectra published in this and preceding papers have been handled in the same manner.

The gas chromatograms (packed column, 10 ft. × ⅛ in. 3 per cent *SE*-30 programme rate of 6°/min) of the "total", "branched-cyclic" and "normal" fractions are presented

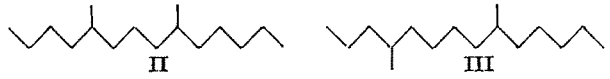


Figs. 1–3. Original mass spectra of Moonie oil C_{18}, C_{18} and C_{19} isoprenoids.

in Fig. 9. The normal alkanes can be seen to run from C_9 to C_{29} with maxima at C_{12} and C_{18} and negligible odd over even predominance. Particularly indicative of life processes are the isoprenoid alkanes, which possess a high degree of structural definition. The isolated C_{15}, C_{16}, C_{18}, C_{19} (pristane) and C_{20} (phytane) isoprenoids, the mass spectra of which are given in Figs. 4–8, appear to have a regular isoprenoid structure corresponding to that of phytane (Structure I).

I

Evidence was also obtained for the existence of a C_{21} isoprenoid but it could not be separated from other components. Also identified were representatives of three other homologies; Fig. 10 gives the mass spectrum of C_{15} *iso*-alkane (2-methyltetradecane), Fig. 11 that of C_{18} anteiso-alkane (3-methylheptadecane), and Figs. 12 and 13 those of C_{15} and C_{16} *n*-alkyl-*cyclo*hexane. Possible biological origins of these compounds have previously been discussed[4]. Figs. 14–17 give the mass spectra of four unidentified compounds X_1, X_2, Y_1 and Y_2, which are relatively pure by gas chromatographic as well as by mass spectrometric standards. Compounds X_1 and X_2 are



Figs. 4–8. Mass spectra of Moonie oil C_{15}, C_{16}, C_{18}, C_{19} and C_{20} isoprenoids.

Fig 9. Gas chromatograms of total, branched-cyclic and normal hydrocarbon fractions of the Moonie oil.

matographic phases. High resolution mass spectrometric studies verify that these are saturated branched hydrocarbons. Fig. 18, a gas chromatogram on a 3 per cent *SE*-30 capillary column (150 ft. × 0·010 in., programme rate 1°/min), reveals the actual complexity of these regions. A thorough mass spectrometric analysis of the C_{17} isoprenoid region (as determined by "co-injection" of the synthetic 2,6,10-trimethyltetradecane) indicates that this compound is not present in significant amounts. Mass spectrometric ambiguities in the identification of the exact structure of the C_{19} isoprenoid[4] have been eliminated (and the presence of pristane definitely established) by co-injection of pristane[6]. An investigation of the high mass region has not provided evidence of steranes or triterpanes, although high molecular weight unsaturated compounds are present.

Hydrocarbons from the Australian Moonie oil, which is two hundred million years old, therefore resemble very strongly the hydrocarbons found in other sediments varying in age from thirty million to two thousand seven hundred million years. Because we have found indications of isoprenoids, iso-alkane, anteiso-alkane, *n*-alkyl *cyclo*-hexane, and normal alkane series in the oils and sediments examined, as indicated in Table 3, it is becoming increasingly evident that among biogenic sediments, variations resulting from individual sediment history and ecology are to be found primarily in the relative amounts of these compounds present, and possibly in the hydrocarbons present only in small quantities, and not in the types of hydrocarbons present.

We thank Prof. J. B. Johns and Dr. H. K. Schnoes for many helpful discussions, A. S. Keller for samples of crude oil, D. Smith for helping in preparing the mass spectra and E. D. McCarthy for providing a sample of synthetic C_{17} isoprenoid, 2,6,10-trimethyltetradecane. This work was supported by the National Aeronautics and Space Administration and the U.S. Atomic Energy Commission.

ISOLATION OF A GLUCOSE-BINDING COMPONENT FROM HUMAN ERYTHROCYTE MEMBRANES

By DR. H. BOBINSKI and DR. W. D. STEIN
Department of Biological Chemistry, University of Manchester

GLUCOSE is transported across the human erythrocyte membrane by a relatively specific facilitated diffusion system, the kinetics of which have been extensively studied[1-3]. Attempts to isolate this system from the cell membrane[4,5] have not hitherto been successful. We wish to describe a sensitive column chromatographic technique for studying the binding of glucose by membranes and by membrane fractions and to describe how this technique has been used to monitor the isolation from the membrane of a glucose-binding component. The properties of this glucose-binding component suggest that it is closely associated with glucose transport.

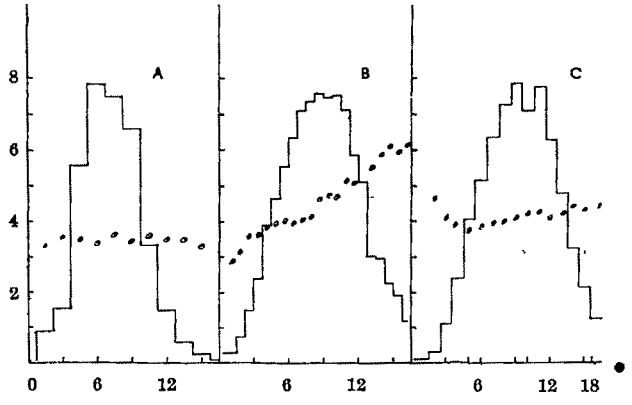

Fig. 1. Retardation chromatography on 'Celite' columns. *A*, 'Celite' alone. *B*, 'Celite' + membranes from 10 ml. of erythrocytes. *C*, as *B* but in the presence of 10^{-4} M phloretin. Solid line, radioactivity associated with glucose (abscissa scale; 1 unit = 0·1 counts/sec). Circles, ratio of tritium to carbon-14 counts (ordinate scale; 1 unit = unit ratio of tritium to carbon-14 counts), (abscissa scale: effluent volume in ml.). The sugar added was here 2 ml. of a mixture of 2 mM glucose (tritiated) + 2 mM sorbose (labelled with carbon-14) in a *tris*-succinate buffer at *p*H 7·4.

We prepare chromatographic columns in which the stationary phase is composed of membranes or of membrane fractions immobilized by adsorption on to 'Celite' or on to DEAE-cellulose. (The idea of making columns of cell membranes is due to Dr. S. Hunt and the further development of this technique has been greatly assisted by his collaboration—see the following communication.) After exhaustive washing, a procedure which removes all residual haemoglobin bound to, or occluded within, the membranes, the columns are loaded with a mixture of sorbose labelled with carbon-14 and tritiated glucose, both at the same concentration (generally 2 mM). The volume of the sugar solution is such that the concentration of sugar emerging from the bottom of the column attains a plateau value (Figs. 1–4). Fractions of the emerging solution are collected and analysed for radioactivity by liquid scintillation counting, the leading and trailing edges of the plateau being particularly carefully examined. If such a column bears a component which binds glucose in preference to sorbose, it would be expected that glucose will be retarded by the column and will appear after sorbose in the effluent. Thus the radioactivity counts in the emerging effluent will be initially low in tritium. In the plateau region the two isotopes will generally emerge together. In the trailing edge of the plateau, the counts due to glucose will be high. The amount of glucose retarded can be calculated from the difference in area between the sorbose and glucose effluent curves in the region up to the point where both curves merge in the plateau.

Although each glucose-binding component interacts with many glucose molecules during the passage of the sugar sample down the column, the total number of glucose molecules retarded will be equal to the number of glucose-binding sites. Yet this column procedure is apparently a very sensitive measure of glucose binding. Indeed, glucose binding by erythrocyte membranes has not hitherto been detected[6]. The sensitivity of the procedure depends (among other factors) on the volumes of the column and the solution; long, narrow columns will ensure that each glucose-binding site is used with maximal effectiveness.

Using this procedure with 'Celite' columns we have been able to show that (i) 'Celite' itself does not retard glucose in preference to sorbose (Fig. 1*A*), but that (ii) cell membranes adsorbed to 'Celite' do retard glucose (Fig. 1*B*), and that (iii) this retardation is largely prevented by the simultaneous presence of a low concentration

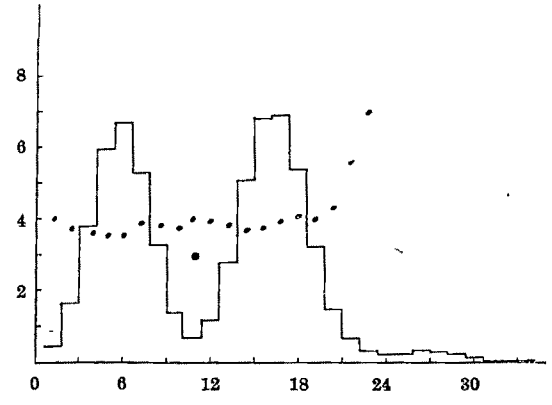

Fig. 2. Retardation chromatography on DEAE-cellulose columns, in the absence of membranes. Two successive samples (4·0 ml. and 5·6 ml.) of a mixture of 2 mM (tritiated) glucose and 2 mM sorbose (labelled with carbon-14) in 0·003 M phosphate buffer at *p*H 7·0 were added. Symbols and scale as in Fig. 1.

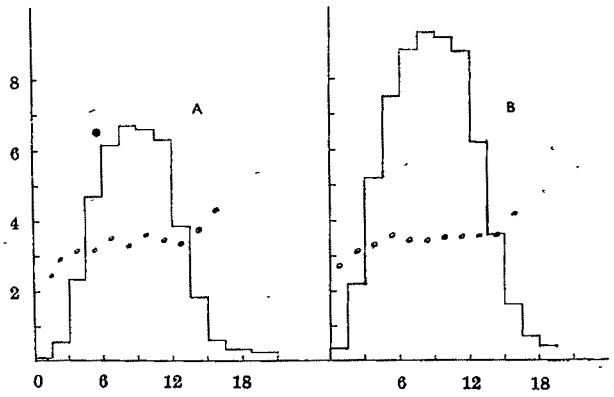

Fig. 3. Retardation chromatography on DEAE-cellulose. Column contained *A*, adsorbed membranes from 4 ml. erythrocytes; *B*, adsorbed iodide extract of membranes from 4 ml. erythrocytes. The sugar added was 6 ml. of the glucose/sorbose mixture described in Fig. 2. Symbols and scale as in Fig. 1.

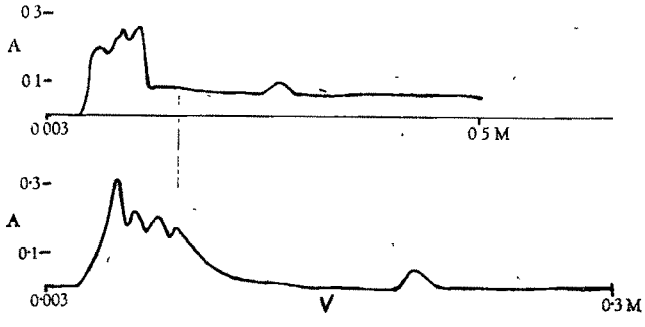

Fig. 4. DEAE-cellulose chromatography of solubilized membranes. A dialysate of the molar sodium iodide extract of the membranes from 7 ml. of erythrocytes was applied to the column, and eluted with a phosphate buffer at *p*H 7·0, a linear gradient to 0·5 M in the first experiment (upper figure) or 0·3 M in the second experiment (lower figure). The maximum specific retardation activity lies in the (compound) second peak of the upper figure and in the third peak of the lower figure (where the resolution appears to be more satisfactory). The ordinate is the absorbance of the effluent solution read at 280 mμ. The abscissa is the molarity of the effluent.

(10^{-4} M) of phloretin, an inhibitor[2] of glucose transport in human erythrocytes (Fig. 1*C*).

These 'Celite' columns have the great advantage that they do not distinguish between glucose and sorbose and do not adsorb phloretin but, in other respects, 'Celite' columns are much more difficult to handle than are the DEAE-cellulose columns used for the remainder of this work. The DEAE-cellulose columns in the absence of membranes or membrane fractions do, in our hands, distinguish between glucose and sorbose (Fig. 2), in that the trailing edge of an emergent plateau gives a clear indication of glucose retardation. Indeed a small peak of radioactivity often emerges at an effluent volume some twice that of the main sugar peak. We can show that this retardation is due to the binding by DEAE-cellulose of a particular form of glucose or of a decomposition product of glucose, in preference to the major form of the glucose, or to sorbose. Little evidence for glucose retardation is, however, found at the leading edge of such plateaux and in the following discussion we shall consider only the leading edges, where the distinction between the behaviour of DEAE-cellulose alone (Fig. 2) and of membranes bound to DEAE-cellulose (Fig. 3) is clear.

By studying the percentage retardation of glucose at different concentrations of glucose, we have been able to demonstrate that the glucose-binding capacity of such columns is saturable and we have obtained an estimate of the dissociation constant for interaction between glucose and the glucose-binding site, on the assumption that this binding is of the simple Michaelis–Menten or Langmuir form. The data from three different experiments at 23° C are collected in Table 1. (We are indebted to Mrs. M. Levine for allowing us to use her data, recorded as the second of these experiments.) The concentration of glucose at the plateau (listed in column 2 of Table 1) must not be used to calculate the effective binding constant for the sugar-site complex, as the real sugar concentration here increases from the value of zero at the leading edge of the sugar front. We have calculated an "equivalent glucose concentration" (recorded in column 3 of Table 1) from the values of the real concentration at different points on the leading edge on the assumption that binding is a saturable function of the glucose concentration. In general, the "equivalent concentration" is between one-half and one-third of the plateau concentration. The data from these three experiments taken together yield a mean value for the Michaelis constant for binding of 18·2 mM with a standard error of ±4·2 mM. The Michaelis constant for the complex formed between glucose and the glucose transport system as determined in kinetic experiments on intact erythrocytes[3] is 11–13 mM at 25° C.

Table 1. Retardation of Glucose as a Function of Glucose Concentration

Experiment	Nominal sugar concentration (mM)	Equivalent concentration (mM)	Glucose retardation (percentage of total glucose added)	Retardation as percentage of value at lowest concentration in the series
4 ml. membranes 0·9 × 27 cm column	2	1	1·9	(100)
	12	5·5	1 1	58
	72	22	0·80	42
Sonicate of 4 ml. membranes 0 8 × 28 cm column	2	1	1·36	(100)
	20	9	0·48	35
	60	20	0 70	51
Iodide extract of 7 ml. membranes 0 8 × 60 cm column	4	2	1·4	(100)
	20	9	0·70	50
	100	26	0·55	39

We have prepared columns from erythrocyte ghosts obtained from cells treated under different conditions with dinitrofluorobenzene (DNFB), an inhibitor of glucose transport[7], and have compared the amount of glucose retardation by such columns with the effectiveness of the residual sugar transport by the inhibited but otherwise intact cells. (We are indebted to Mrs. C. Caygill of this department for the preparation of these DNFB-treated cells and for the permeability assays, performed by measurements of the uptake of sorbose labelled with carbon-14 using procedures described previously)[3]. Table 2 shows that the inhibition of sugar transport and of glucose retardation closely parallel one another. A striking feature of this finding is that the inhibition of glucose retardation also displays the peculiar kinetics of DNFB-inhibition of sugar transport[7]—the rate of inhibition is higher than first order with respect to the DNFB concentration.

Table 2. Inhibition of Sugar Transport in Intact Erythrocytes and of Glucose Retardation by Columns of Erythrocyte Membranes on Treatment with Dinitrofluorobenzene

Concentration of inhibitor DNFB in mM	Time of incubation with DNFB at 25° C (min)	Sorbose permeability (percentage of control)	Glucose retardation (percentage of control)
0 (control)	0	100	100
0·4	20	130	140
4	2	48	58

The cells (control as well as inhibited) were all pre-treated with 0·4 mM DNFB at 4° C for 1 h, a procedure which we have shown to be without effect on sugar transport, but which blocks many DNFB-reacting sites on the cell membrane.

We feel that we are justified in identifying glucose retardation by columns of membranes as a reflexion of a property of the glucose transport system, on the grounds that this retardation is, in parallel with sugar transport, inhibited by phloretin and by DNFB, and saturates with glucose in the same concentration range as does glucose transport in the intact cell. We have, therefore, proceeded with the isolation of the glucose-binding material from erythrocyte membranes.

Our erythrocyte membranes are pink ghosts prepared by washing with distilled water. These ghosts sediment readily at 2,500 r.p.m., in 15 min. Treatment of such a membrane preparation with a 1 M solution of sodium iodide solubilizes the ghosts in that, after dialysis, much of the preparation no longer sediments under these conditions of centrifugation nor in the ultracentrifuge. The material solubilized in sodium iodide, when held on DEAE-cellulose columns at *p*H 7·0 in the presence of 0·003 M sodium phosphate, retains intact its ability to retard glucose in preference to sorbose (Fig. 3). Elution of such a column with a linear gradient of 0·5 M sodium phosphate at *p*H 7·0 yields five major peaks of material absorbing at 254 mμ (and at 280 mμ) (Fig. 4) and, simultaneously, the ability of the column selectively to retard glucose is lost. When the material eluted from the column is, after dialysis, put back on fresh columns of DEAE-cellulose, glucose retardation can once again be demonstrated. The major retardation activity is associated with peak II (60 per cent) while lesser amounts of retarda-

tion are found in peak I (23 per cent) and peak III (17 per cent). Peak IV shows no retardation.

Thus our peak II, a component of the human erythrocyte membrane which is (i) extracted from pink ghosts by molar sodium iodide, (ii) held on to DEAE-cellulose at *p*H 7·0 in 0·003 M phosphate and (iii) eluted at some 0·1 M phosphate, is associated with most of the glucose-binding capacity of erythrocyte membranes. This binding capacity seems to be closely associated with glucose transport. We believe that our peak II material may well be responsible for glucose transport in the intact erythrocyte.

The work described here was supported by a grant from the Nuffield Foundation to Prof. A. R. Birch. One of us (B. B.) holds a Research Fellowship maintained by these funds. We thank the Nuffield Foundation and Prof. Birch for this support and numerous colleagues (in particular, Drs. S. Hunt, S. R. Ayad and A. R. Kolber, and Mrs. M. Levine) for their helpful advice and criticism.

SOLUBILIZATION OF A GLUCOSE-BINDING COMPONENT OF THE RED CELL MEMBRANE

By R. W. BONSALL and DR S. HUNT
Department of Biological Chemistry, University of Manchester

HUMAN red cell membranes are known to contain a system capable of bringing about "facilitated diffusion" of glucose into the cell, presumably mediated by some binding component[1]. Investigations of this system have hitherto been confined, in the absence of techniques which would measure binding of glucose in cell wall extracts, to the intact cell membrane. This article describes the solubilization and assay, by a new technique, of a system which binds glucose in human red cell membranes.

A variety of techniques are available for extraction and disruption of erythrocyte membranes[2,3]. In order to evaluate the validity of these methods in extracting, without damage, active cell wall constituents we have taken as our standard the activity of acetylcholinesterase, an enzyme thought to be an integral component of the erythrocyte membrane itself[4]. On the basis that the acetylcholinesterase activity of the ghosts, when still present after solubilization, is a measure of maintained integrity of other membrane components, we were then able to proceed to studies of glucose binding by the method of retention or retardation analysis.

The technique of retention analysis is based on a method postulated by S. Hunt and W. D. Stein for measurement of binding in general and was subsequently developed by W. D. Stein in this department as an experimental technique. (We are indebted to Dr. Stein for providing us with the practical details for the technique used here.) The basis of this method is the concept of a column composed of binding molecules (either free or held in cell membranes) through which is passing a solution containing both molecules with affinity towards the binding molecules and also molecules with no affinity. Obviously the molecules with affinity will, providing the geometry of the column is correct, eventually lag behind those without affinity. In the present case the column consists of either red cell ghosts or solubilized ghosts supported on some medium (DEAE cellulose) through which is passed a mixture of glucose (with affinity) and sorbose (without affinity). Labelling of the sorbose with carbon-14 and the glucose with tritium permits ready assessment of the lag of glucose behind sorbose.

Retention or retardation analysis is, in essence, the same as any other chromatography in that it involves partition of the separating mixture (glucose and sorbose) between a moving phase (the solution containing the glucose and sorbose) and a stationary phase (the glucose-binding agent). It follows, therefore, that the elution volume of a substance retained by the binding agent is dependent on the equilibrium constant between the free and bound forms. The difference between the elution volume of an interacting molecule and that of a non-interacting molecule will be referred to as the retention volume.

Theoretically the shape of a peak eluted from a column is Gaussian and corresponds to the equation

$$y = \frac{1}{c\sqrt{2}} \cdot e^{-(x-\bar{x})^2/2c^2}$$

where y is the peak height at the elution volume x, $\bar{x}$ is the elution volume at y_{max} and c is a constant which is a function of the peak spread and is dependent on the diffusion rate.

The ratio $y_{retarded}/y_{unretarded}$ for two similar but displaced Gaussian curves plotted against x is an exponential. If the log of this ratio is plotted against x, a straight line results the gradient of which depends on the displacement, that is on the retardation, of one peak relative to the other.

Thus, $y_r/y_0 = e^{(x-x_0)^2-(x-x_r)^2/2c^2}$

Therefore $\log (y_r/y_0) = (x(\bar{x}_r - \bar{x}_0) + \bar{x}_0^2 - \bar{x}_r^2)/k$

and $\log (y_r/y_0) \propto x(\bar{x}_r - \bar{x}_0)/k$

where subscripts 0 and r refer to the unretarded and retarded peaks respectively and where k is a function of c.

To calculate k for a known peak shape it is only necessary to construct a second peak retarded by some predetermined elution volume $(\bar{x}_r - \bar{x}_0)$ and to obtain ratios of y_r to y_0 for a series of values of x. A plot of y_r/y_0 against x then yields a straight line from the gradient of which k may be calculated, knowing $(\bar{x}_r - \bar{x}_0)$. The value of k determined theoretically may then be applied to the determination of $(\bar{x}_r - \bar{x}_0)$ in the real system.

To attain the ideal Gaussian peak shape, in chromatography, the rate of elution must be very slow and there must be only one type of interaction with the stationary phase. At practical elution rates the lower part of the leading edge of the peak is steeper than the ideal; moreover, secondary interactions such as that between DEAE cellulose and glucose cause tailing of the peak. The upper two-thirds of the leading edge do, however, correspond reasonably to the mathematically ideal situation. Thus analysis of this part of the peak in the manner described enables an accurate estimate of retention volume to be made. The analysis can, however, only be assumed to obtain when the amount of spread of the two peaks is the same. For the sorbose–glucose system used here this is assumed to be the case.

Haemoglobin-free erythrocyte ghosts were prepared by a modification of the procedure of Maddy[2]. Washed cells were haemolysed in 0·005 M phosphate buffer at *p*H 8·0 for 1 h followed by washing, on the centrifuge, in 0·01 M phosphate buffer at *p*H 8·0. After standing in the latter buffer at 4° C overnight the ghosts were washed alternately with 0·005 M and 0·01 M phosphate buffers at *p*H 8·0 until white. The white ghosts were finally washed three times in distilled water.

Four separate methods of solubilization or extraction were attempted. The technique of extraction with butanol and water was carried out according to the procedure of Maddy[2], only the aqueous soluble fraction being examined in this instance. Extraction of ghosts with 0·5 M phosphate buffer was performed at *p*H 7·0 and the soluble fraction freed of phosphate by dialysis. Extraction by 1·0 M sodium iodide was carried out according to a procedure developed by Dr. H. Bobinski in this department and we are therefore indebted to him for permission to use this technique before publication. Iodide was removed from extracts by dialysis. Extraction with the detergent 'Triton *X*100' was carried out by mixing equal volumes of ghost suspension, and a 5 per cent v/v aqueous solution of 'Triton *X*100'; clarification of the suspension occurs almost immediately. An exact estimation of the degree of solubilization was not attempted. The following observations might, however, be noted. Whereas, in the solubilization of bovine erythrocytes by butanol, Maddy[2] reports little material remaining at the butanol–water interface, we find a very heavy flocculent white material to be formed. The aqueous extracts were clarified by centrifugation at 20,000*g*. In the case of the 'Triton' extract, centrifugation yielded negligible residue whereas the phosphate extract yielded a considerable solid residue and the iodide extract a fairly considerable residue.

Acetylcholine esterase activity was estimated in ghosts and extracts according to Michel[5]. The aqueous extract resulting from butanol extraction possessed only 3·7 per cent of the original acetylcholine esterase activity of the ghosts while iodide extraction solubilized 8·2 per cent of the activity. Treatment with phosphate failed to extract any acetylcholine esterase activity. The 'Triton' extraction, however, resulted in complete extraction of acetylcholine esterase; moreover, the activity was enhanced, the recovery in the extract being of the order of 130 per cent. On this basis 'Triton' extracts were examined for glucose-binding properties.

Retention analyses were carried out on columns of DEAE cellulose equilibrated with 0·003 M phosphate buffer at *p*H 7·0. In order to attain even distribution of ghosts or solubilized material throughout the column, samples were introduced into the DEAE cellulose before packing the column. After packing, the columns were eluted with 100 ml. of 0·003 M phosphate buffer at *p*H 7·0 followed by careful application to the top of the column of a solution containing tritiated glucose, sorbose labelled with carbon-14, "cold" glucose and "cold" sorbose to a total glucose and sorbose concentration of 2 mM each. Columns were then eluted with 0·003 M *p*H 7·0 phosphate buffer at a rate of 1 ml. per min and fractions of 6 to 10 drops collected after rejecting the first 25 ml. of eluate (hold up volume). Suitable aliquots of each fraction were taken for counting in a Packard liquid scintillation counter. Results were analysed as described. Control columns of DEAE cellulose alone showed no retention of glucose relative to sorbose.

Figs. 1–3 illustrate the results of a typical retention analysis carried out on a 'Triton' solubilized erythrocyte ghost preparation. Fig. 1 shows the eluate plot (or retentiogram) of glucose and sorbose counts versus fraction number while Fig. 2 shows the plot of the ratio of glucose counts to sorbose counts versus fraction number. In addition, Fig. 2 also shows the result of theoretically retarding the glucose effluent curve by two and by four fractions. Fig. 3 indicates the plots of log glucose–sorbose ratio versus fraction number and the plots of log ratio versus fraction number for the theoretical curves. Derivation of $1/k$ from the theoretical curves yields a retention for real glucose curve of 1·36 fractions or 0·205 ml. This value agrees fairly well with the value obtained by observing the displacement at half the peak height on the leading edges of the two curves, that is, approximately 1·25 fractions or 0·188 ml.

In a comparative experiment in which equal volumes of ghost suspension were taken from the same ghost preparation, only one portion solubilized and the whole ghosts and extract then separately subjected to retention analysis and acetylcholine esterase assay, a retention of 0·408 and 0·615 ml. for the ghost preparation and the extract respectively was detected. Acetylcholine esterase activity was enhanced in the extract, in this case by 42 per cent.

The foregoing results thus appear to suggest that treatment of erythrocyte membranes with the detergent

'Triton X100' produces the solubilization of membrane components without loss of biological integrity, the method of retention or retardation analysis permitting identification of the presence of a glucose-binding system both in the whole membranes and the extracts. Work is at present in progress to fractionate the extracts. The system solubilized need not necessarily be the actual glucose transport system. Further investigations would be needed to confirm or deny this. The bovine erythrocyte possesses no such glucose transport system and a comparison, by the methods used here, with human erythrocytes might be illuminating.

HYPERSENSITIVITY INDUCED IN ALBINO MICE BY MELANOCYTE-STIMULATING HORMONE

By DR. ARTHUR SAKAMOTO*

Brookhaven National Laboratory, Medical Research Center, Upton, Long Island, New York

DURING the course of experiments using melanocyte-stimulating hormone (MSH), it was found that albino mice became hyperexcitable after injections of this hormone; that is, they reacted to stimuli with greater force, rapidity and frequency. The change in behaviour induced by MSH was further investigated because such a response might shed light on the physiological significance of this ubiquitous hormone[1].

Mice injected with MSH typically moved in short, fast bursts and were difficult to catch. They struggled more vigorously than control animals during injections and would often attempt to bite. Because of their more frequent and more rapid movements, they could easily be distinguished from controls by the increased noise they made in their cage. If mice injected with MSH were observed without stimulation several hours after injection, their behaviour and movements were similar to those of control mice. If they were stimulated by loud noises, or by tapping or moving their cage, or if attempts were made to catch them, however, their movements would again become rapid and "jerky".

When mice injected with MSH were suspended by their tails, they consistently arched their bodies closer to a horizontal or upright position than did control mice (Fig. 1). At times they climbed up their own tails—a manoeuvre not attempted by control animals.

It was possible to detect hyperexcitability after the fourth to sixth injection of MSH, and the onset of this condition was earlier in younger mice and later in older. The maximum response occurred at 2–3 weeks and it gradually declined over a period of 2 months.

Hyperexcitability was quantified by measuring the increase of motor activity in reaction to stimuli recorded graphically on the motor activity recorder of Easterday and Higinbotham[2]. In this method mice are placed on a 'Styrofoam' platform in contact with four needles attached to gramophone cartridges. The impulses from the cartridges are amplified and recorded.

In the experiments reported here, Swiss albino male mice (*BNL* strain) 5–8 weeks old were randomly divided into groups of from four to seven for each hormone. βMSH, in doses of 0·1–1·0 mg (Armour, sp. act. 2×10^6 U/mg), was generally used. The hormones were mixed with 16 per cent gelatine, and the gelatine solution was used as control material. They were warmed in a water bath at 40° C just before injection, and injected subcutaneously once daily 6 days per week.

Large doses of βMSH were not toxic—the mice injected were vigorous and healthy and gained weight (two groups of mice injected with 0·2 and 1·0 mg for 7 weeks gained 18 per cent of their original weight, compared with controls which gained 25 per cent of their original weight).

After a week or two of injections when hyperexcitability became obvious, one group of mice at a time was placed on the platform of the motor activity recorder[2] for 2–3 min about 15 min after all injections were completed for the day. The process of moving the animals from their own cage to another location plus the previous parenteral injection provided enough stimulation to cause the mice injected with MSH to move about more rapidly and more frequently than the controls. If the mice were tested in the motor activity recorder 2 or 3 h after injection, a stronger stimulus than the mere process of transfer from cage to platform was often necessary to bring about hyperexcitation. Of the various stimuli tried (the alarm of a clock, electric shock, bright lights, etc.) the simplest and most effective in showing the difference between test and control animals seemed to be two light strokes of the rubber eraser of an ordinary pencil beginning from the lower abdomen cephalad to the tip of the nose. Excessive stimuli, such as electric shock, evoked the same response in both test and control animals. Further, when mice were tested individually rather than in groups, it was difficult to obtain consistent results.

The tracings from the motor activity recorder were quantified by summing up the amplitudes of each excursion. Each deflexion represents a burst of vibrations created by a movement of the mouse on the platform.

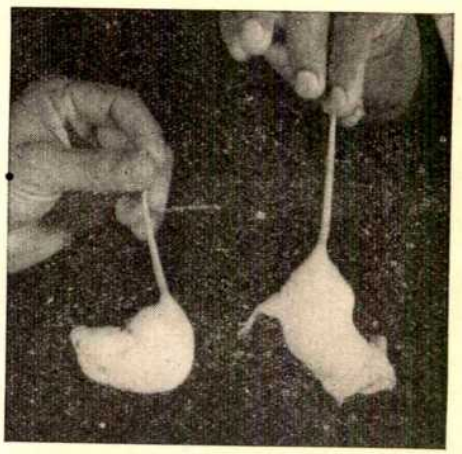

Fig. 1. Albino mice suspended by their tails, showing that the mouse injected with MSH (left) arches its body more closely to horizontal than does the control (right).

* Present address: Veterans Administration Hospital, Northport, New York.

The amplitude of the excursions increased with increase of the loudness of vibrations made by the mouse. Fig. 2 shows the amplitudes of excursions when weights were released from a fixed distance from the platform. The amplitudes are averages of four or five such "drops". The units are arbitrary as the response of the recorder can be varied by a gain control in the motor activity recorder.

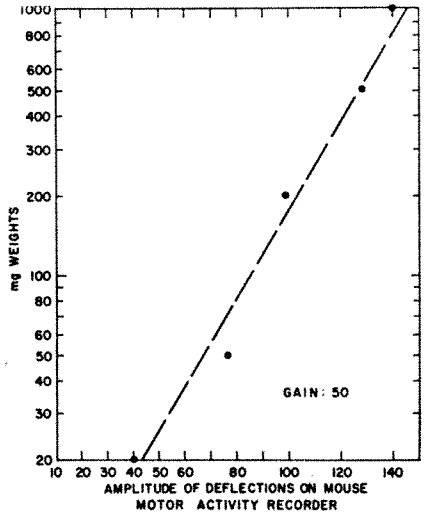

Fig. 2. The response of the motor activity recorder to varying weights dropped 10 cm from surface.

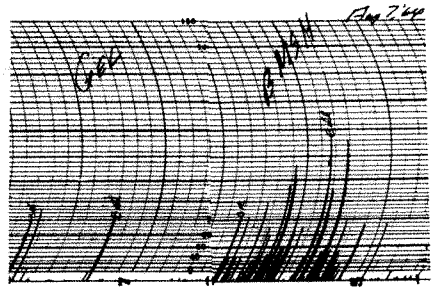

Fig. 3. Graph taken from the motor activity recorder showing increased activity of a group of mice injected with βMSH (right) compared with controls (left).

The increase of motor activity following stimulation of mice injected with βMSH is clearly shown in a tracing taken from the recorder (Fig. 3). A quantitation of such a tracing (Table 1) shows that the degree of hyperexcitability declines after the third week.

We also carried out experiments to find (*a*) whether this hyperexcitability may be due to another well known effect of MSH on the thyroid gland (its "TSH-like" effect)[3], and (*b*) whether the reaction is a result of contamination of the MSH preparation by a polypeptide from the original pituitary preparation.

Question (*a*) was studied by thyroid ablation and by injections of thyroid stimulating hormone (TSH). Two groups of mice were "thyroid ablated" with iodine-131. They were placed on a low iodine diet (whole milk) for 7 days, injected with 200 mc. of $Na^{131}I$, and maintained on the same diet for 10 days more. The "thyroid-lethal" dose was estimated from data presented by Gorbman[4]. One of these two groups was treated with 0·1 mg βMSH and the other with gelatin solution.

Another group was injected with 2·0 mU of TSH—an amount shown to produce more than twice the increase in blood iodine-131 than 0·1 mg βMSH does[3].

The second question, as to whether hyperexcitability may result from a contaminant, was studied using a highly purified αMSH (supplied through the courtesy of Dr. A. V. Schally, sp. act. $1–2 \times 10^7$ U/mg). Small amounts of adrenocorticotropic hormone (ACTH) were tested as its structure is closely related to that of MSH.

In Table 2 the motor activity after stimulation of three groups of mice (those treated with αMSH, βMSH, and βMSH after thyroid ablation) is compared with four groups of mice (those injected with ACTH, TSH, gelatine, and gelatine after thyroid ablation).

Table 1. SUMMARY OF DATA FROM MOUSE MOTOR ACTIVITY RECORDER

Groups	Material injected	Amount per day	Duration	No. of mice	Total activity	Activity per mouse
A	β MSH	0·1 mg	5 weeks	5	2,068	414
	Gelatin	0·05 ml.	5 weeks	5	110	22
B	β MSH	0·1 mg	8 weeks	4	354	88
	Gelatin	0·05 ml.	8 weeks	4	104	26
C	β MSH	0·2 mg	3 weeks	6	6,766	1,127
	β MSH	1·0 mg	3 weeks	6	4,371	725
	Gelatin	0·05 ml.	3 weeks	6	77	13

Average activity per mouse for groups *A*, *B* and *C*:
Mice injected with βMSH; 588 ($t = 2·2$).
Mice injected with gelatin; 20 (P between 0·025 and 0·05).

Table 2. SUMMARY OF DATA FROM MOUSE MOTOR ACTIVITY RECORDER

Groups	Material injected	Amount per day	Duration	No. of mice	Total activity	Activity per mouse
A	β MSH	0·1 mg	1 week	6	510	85·0
	α MSH	0·1 mg	1 week	6	820	136·7
	β MSH and ^{131}I	0·1 mg	1 week	7	640	91·4
B	Gelatin	0·05 ml.	1 week	6	190	31·7
	ACTH	2 U	1 week	6	230	38·2
	TSH	2 mU	1 week	6	200	33·3
	Gelatin and ^{131}I	0·05 ml.	1 week	7	220	31·4

Average activity per mouse:
Group *A*, 104·4 ($t = 5·1$)
Group *B*, 33·7 ($P < 0·005$)

From the results presented in Table 2, it is clear that the hyperexcitability noted was not the result of a "TSH-like" effect of MSH. Also, a highly purified αMSH obtained from a laboratory different from that which supplied the βMSH did produce a state of hyperexcitability. Furthermore, small amounts of the related hormone ACTH were devoid of such activity. It therefore appears likely that the MSH polypeptide is the hormone responsible for this behavioural change.

Recently I noticed that βMSH affects albino rats in a manner entirely different from that reported here for albino mice. It induces drowsiness, hyperpnoea, hypertension, and piloerection. Dyster-Aas and Krakau have reported similar effects in the rabbit, in which MSH produced drowsiness, hyperpnoea, hypotension, and increase of cutaneous temperature[5].

Krivoy, Lane and Kroeger have shown that βMSH "augments excitability" in (*a*) the dorsal root preparation in cats and Lloyd's preparation by increasing the response to submaximal stimulus, and in (*b*) the electric knife fish, by causing a decrease in the frequency of electrical signals emitted, in a manner similar to the response when startled[6]. Krivoy and Guillemin suggest that "one of the possible roles of βMSH in the central nervous system is to maintain and modify the central excitatory state of some neuronal systems' [1]. The increased excitability observed in albino mice could possibly be related to the same group of phenomena.

Further experiments are in progress on the effect of MSH on the behaviour and central nervous system of mammals, to find whether such phenomena are a manifestation of a biological role of this hormone.

IS γ-AMINOBUTYRIC ACID AN INHIBITORY TRANSMITTER?

By PROF. K. KRNJEVIĆ and DR. SUSAN SCHWARTZ*

Wellcome Department of Research in Anaesthesia, McGill University, Montreal

γ-AMINOBUTYRIC acid (GABA) was first identified as a normal constituent of brain tissue in 1950[1,2]. Some years later, GABA was found to have a marked depressant effect on cortical neurones[3], and to be a constituent of Factor I—an extract of brain tissue found to have a strong inhibitory action on certain isolated neurones[4] of Crustacea. The possibility was therefore considered that it might act as a chemical transmitter at synapses, or as a controller of the excitability of neurones. The inhibition of crayfish neurones (and muscle) proved to be particularly significant as it became clear that GABA acts in every respect like the inhibitory transmitter[5–7] of crustacean neurones, and is only found in the inhibitory axons of lobster nerves[8].

The hypothesis that GABA might be the main inhibitory transmitter in the central nervous system (CNS) of mammals was soon discounted, however, because it was considered incompatible with certain experimental observations[9,10]. The most consistent and serious objections were those raised by Curtis and his associates[11–14], who claimed that the action of GABA in the spinal cord differs significantly from that of the inhibitory transmitter. Post-synaptic inhibition of the spinal cells is associated with an increase in membrane potential. But experiments with co-axial pipettes failed to detect any hyperpolarization of motoneurones during the administration of GABA. As there was no evidence that GABA had a hyperpolarizing action in other parts of the CNS, Curtis concluded that GABA could not be the main central inhibitory transmitter[13,14].

On the other hand, more detailed investigations of the effects produced by GABA on cortical cells[15,16] showed a remarkably potent inhibition—more potent, in fact, than the effects of any other substance known to be present in the brain in appreciable amounts. In spite of certain preliminary investigations from which it appeared that GABA had no strong hyperpolarizing action on cortical cells[16], it was therefore concluded that before making a thorough comparison between the effects produced in the cortex by GABA and by post-synaptic inhibition[16,17], the possibility that GABA might be the inhibitory transmitter should not be dismissed. This article reports the results of such a direct comparison.

Our experiments were performed on cats under pentobarbitone anaesthesia. Twin micropipettes were used for intracellular recording and for the extracellular release of GABA; they consisted of conventional single glass micropipettes fixed side by side with dental cement, in such a position that the respective tips were separated by a distance of 20–100μ. One pipette was filled with 3 M potassium chloride or 2 M potassium citrate. Its tip was sufficiently fine (< 1μ) to penetrate at least some cells without excessive injury. The second pipette had a somewhat larger tip (1–2μ) and it was filled with 2 M GABA acidified with hydrochloric acid to *p*H 4·5. The recording electrode was connected to a cathode follower through a saline : silver : silver chloride link and a second cathode follower made contact with muscle on the back of the animal's neck, via a comparable silver : silver chloride electrode. Before further amplification, the outputs of the two cathode followers were fed into a balanced Wheatstone bridge. This bridge allowed short pulses or steady currents to be passed through the intracellular electrode while the membrane potential was being recorded. It was therefore possible to measure changes in cell resistance, or to polarize the cell, while testing the action of GABA. The pipette filled with GABA was connected to a high-impedance polarizing circuit which provided small outward currents (10–100 n.amp) for the iontophoretic release of GABA as a cation. Electrical coupling between the two pipettes was checked regularly, *in situ*. Apart from transients at "on" and "off", artefacts resulting from coupling seldom exceeded a few millivolts.

The twin micropipettes were inserted into the sensorimotor cortex, on either side of the cruciate sulcus. Neuronal inhibition was evoked by cathodal stimulation of the exposed surface of the cortex at a rate of 4–5 sec. The shocks were 1 msec. square waves, at an intensity of 5–20 V. This kind of stimulation has a widespread and prolonged inhibitory effect on neurones throughout all layers of the cortex[18–20]. A single shock causes an inhibitory post-synaptic potential which typically lasts for more than 100 msec.

The cells observed formed two populations: those giving inhibitory or excitatory responses, or firing "spontaneously"; and others which neither fired spikes nor responded to any kind of stimulation. The first type of cells we assumed to be neurones: the second, we suggest, are likely to be glial cells. The "glial" cells yielded significantly higher and more stable membrane potentials than did neurones.

Resistance measurements showed a substantial drop in resistance of the neurones during the initial phase of the inhibitory post-synaptic potential; this can be seen as a diminished pulse immediately after the stimulus artefact in Fig. 1*A*. When GABA was released, there was a marked drop in resting membrane resistance within a few seconds (Fig. 1*B*). At the same time, all inhibitory and excitatory post-synaptic potentials and neuronal discharges (Figs. 1*B*, 2, 3*B* and *C*) were much reduced or abolished. With electrodes filled with potassium nitrate, we recorded hyperpolarizing inhibitory post-synaptic potentials, and GABA regularly had a hyperpolarizing action which occluded the inhibitory

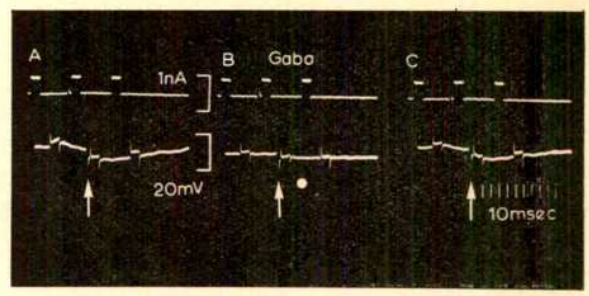

Fig. 1. Intracellular records showing the effect of GABA on the membrane properties of cortical neurones. Upper traces indicate a d.c. reference level and the intensity of outward current pulses delivered through the intracellular electrode for resistance measurements. Lower traces show changes in membrane potential and resistance before and during an inhibitory post-synaptic potential evoked by stimulating the surface of the cortex immediately above the point of recording; arrows indicate the stimulus artefact. The membrane resistance is proportional to the amplitude of the pulses recorded in the lower trace. Downward deflexions are in hyperpolarizing direction. *A*, Control record; *B*, during iontophoretic release of GABA from the extracellular pipette (60 n.amp): note hyperpolarization and fall in resting resistance; *C*, 8 sec after release of GABA was stopped.

* NATO Postdoctoral Fellow.

post-synaptic potentials (Figs. 1*B* and 2). All these effects disappeared soon after the end of the release of GABA (Figs. 1*C*, 2 and 3*D*). If the state of the cell remained satisfactory, the experiment could be repeated several times without any sign of desensitization.

When an inhibitory post-synaptic potential recorded with an electrode filled with potassium citrate was reversed by suitably polarizing the neurone, the action of GABA was also reversed. Furthermore, complete reversal of inhibitory post-synaptic potential was readily obtained when chloride ions were released into the cells (from electrodes filled with potassium chloride); under these conditions GABA also had a depolarizing action, and it even became possible to excite a cell strongly by a steady application of GABA. We did not take records for a sufficiently long time in any one case to test

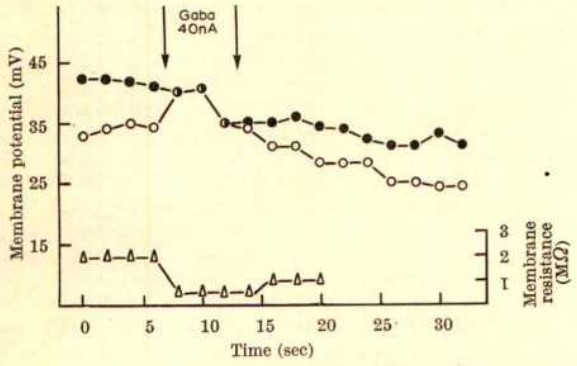

Fig. 2. Graph showing changes in membrane potential and resistance of a neurone produced by an extracellular application of GABA (40 n.amp), indicated by two arrows. ○, Resting potential; ●, potential at peak of inhibitory post-synaptic potential evoked by cortical stimulation; △, resting resistance.

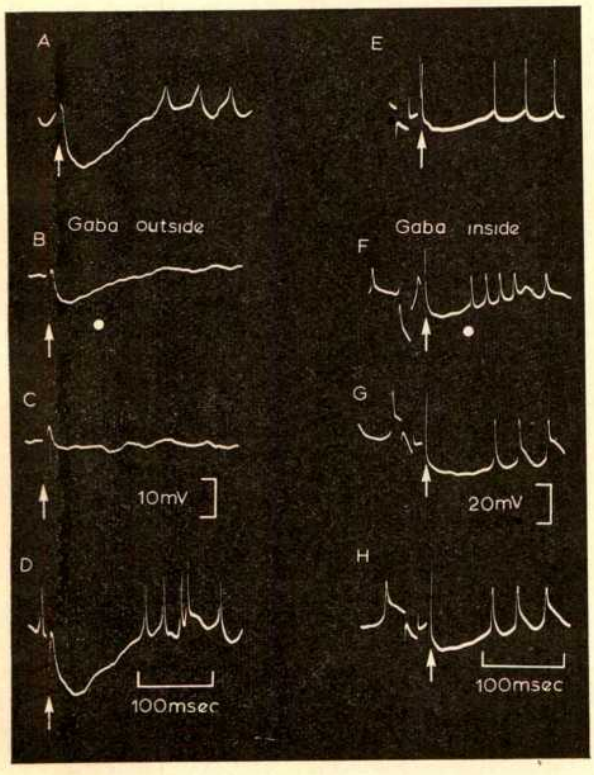

Fig. 3. Intracellular records from two cortical neurones (*A–D*) and (*E–H*), which show that GABA is much more effective when applied outside than inside cells. *A* and *E*, Control traces of injury discharges interrupted by inhibitory post-synaptic potential evoked by single shocks to surface of cortex; *B*, during extracellular release of GABA (40 n.amp); *F*, during intracellular release of GABA (1·2 n.amp); *C* and *G* immediately after iontophoresis of GABA; *D* and *H*, 3–6 sec later.

GABA systematically over a wide range of membrane potentials. The fact that in various cells its action always shifted the membrane potential in the same direction as the inhibitory post-synaptic potential, however, suggests that the two processes must have a similar equilibrium level.

We also released GABA inside cells, by using recording electrodes filled with GABA. Three of these cells were neurones which were firing spontaneously and had clear inhibitory post-synaptic potentials (Fig. 3*E*). Even repeated injections of GABA by currents of 1–3 n.amp, for as long as 45 sec, did not alter greatly their membrane potential, inhibitory post-synaptic potential or rate of discharge (Fig. 3*F* and *G*).

In contrast to the marked and predictable effects of GABA on the membrane potential and conductance of the cortical neurones, the effects produced on the cells in the second population (the glial cells as already defined) were quite different. There was no detectable change in cell conductance, and only a relatively slight, but reversible and repeatable depolarization with large doses of GABA.

Because the action of GABA on cortical neurones is so similar to that of synaptic inhibition, one must seriously consider the possibility that GABA is, in fact, the main inhibitory transmitter in the cortex. It is perhaps worth repeating that the cortex contains very substantial amounts of GABA but relatively little of the other ω-amino-acids (or the corresponding guanidino compounds) which have a comparable depressant action[21]. Weaker depressants, such as noradrenaline, dopamine and 5-hydroxytryptamine[15,22], are found there only in relatively small amounts[23] and there is no histochemical evidence of any important mono-aminergic innervation at the cortical level[24]. Moreover, cortical inhibition is not affected by adrenergic blocking agents[17]. The effects produced in the cortex by acetylcholine and its antagonists suggest that the inhibitory synapses cannot be cholinergic[17].

The rather widespread distribution of free GABA in subcellular fractions (and particularly in the supernatants) of cortical homogenates has been adduced as evidence against the possibility that GABA might be a transmitter[14,25]. The inhibitory effect of suspensions of nerve endings or synaptic vesicles, however, can be accounted for by their GABA content[26]. Like other known transmitters, GABA would probably be distributed throughout the relevant neurones; but only GABA present in the nerve endings is likely to be trapped or bound. As all the evidence suggests that the cell bodies of cortical inhibitory fibres lie mostly within the cortex[20] most of the cortical GABA would not appear in a bound form when the tissue is homogenized.

Despite its relatively high concentration in the cortex, GABA cannot be readily detected in the fluid bathing the surface of the cortex[27]; only under certain special conditions can the release of GABA be demonstrated at all regularly[28]. This observation is not inconsistent with a transmitter function. Clearly, a powerful transmitter could not be allowed to accumulate in the extracellular fluid: in fact, any substance continuously exuding from a tissue in large amounts is extremely unlikely to be a transmitter in the usual sense.

GABA must exert its principal action on the outer surface of the cortical neurones (compare crayfish muscle)[7] as intracellular injections tended to be ineffective. GABA could thus be functionally inactivated by a simple uptake into cells. The uptake of amino-acids, including GABA, by slices of brain is a well known process[29,30], which could take place either in the nerve endings (compare the sympathetic system), or in the perikaryon. Its depolarizing action on "glial" cells, without a corresponding increase in conductance, may indicate that glial cells are concerned in the active transport of GABA. It may not be easy to demonstrate the release of GABA by nerve endings until some means of specifically blocking such an uptake mechanism can be found. It would also be of

great help in the analysis of inhibitory effects in the cortex and elsewhere in the CNS if a specific antagonist for the inhibitory action of GABA were available; so far there has been no convincing evidence that in the cortex one can selectively block either the action of GABA or synaptic inhibition.

In conclusion, it is evident that GABA imitates the action of the cortical inhibitory transmitter at least qualitatively: it usually raises the membrane potential and conductance of cortical neurones, just like the normal inhibitory mechanism at synapses, and when the latter inhibitory effect is artificially reversed, the action of GABA is reversed in a similar way. Hence, in so far as the cortex is concerned, there is no evidence against the hypothesis that GABA is an inhibitory transmitter.

We thank the Wellcome Trust and the Medical Research Council of Canada for their financial assistance.

FACTORS CONTROLLING THE DIFFERENTIATION OF THE HYDATID ORGANISM, *Echinococcus granulosus*, INTO CYSTIC OR STROBILAR STAGES *IN VITRO*

By PROF. J. D. SMYTH, A. B. HOWKINS and MARY BARTON

Department of Zoology, Australian National University, Canberra

IT is generally recognized that the development of *in vitro* culture techniques for parasitic helminths is a fundamental problem in parasitology. In recent years, a number of cestodes have been cultured *in vitro* from the larval stages to maturity or near maturity[1–5].

In vitro culture of the causative organism of hydatid disease, *Echinococcus granulosus*, has presented some very special problems, for not only is the period of maturation relatively long (40 days), but the larval stages (protoscoleces), which are found in a hydatid cyst, are remarkable for being capable of differentiating in two directions. Thus, when a hydatid cyst is eaten by a dog, the freed protoscoleces develop into adult strobilated tapeworms in the duodenum. On the other hand, if a hydatid cyst bursts, while still within the intermediate host (sheep, man, etc.), each of the released protoscoleces is capable of differentiating into a new hydatid cyst should it reach a suitable tissue site. Thus, a protoscolex has the potentialities of developing either into a tapeworm (in an intestinal site) or into a hydatid cyst (in a tissue site)—a degree of heterogeneous morphogenesis unusual for a metazoan organism. This suggests that there are factors present in the intestinal and tissue environments which initiate differentiation in these two directions. Attempts to determine the nature of these factors by *in vitro* experiments have been, to date, largely unsuccessful.

Yamashita *et al.*[7] and Smyth[8] found that, when cultured *in vitro* in a variety of media, protoscoleces of *Echinococcus* differentiated only in a cystic direction, and eventually developed into miniature hydatid cysts with laminated envelopes. This occurred either (*a*) by forming a "posterior bladder" which secreted a laminated envelope (Fig. 1), or (*b*) by becoming vesicular and similarly secreting a laminated envelope (Fig. 1). Webster and Cameron[9], using a succession of complex media, succeeded in obtaining several segmented forms of *E. multilocularis* and *E. granulosus*, but the precise conditions under which this result was obtained were not clarified experimentally or confirmed by further work.

In a series of experiments, extending over a period of some years, we have attempted to initiate the growth of *E. granulosus* in a strobilar direction so that the tapeworm stage could be obtained *in vitro*. On account of the high risk of infection from handling the hydatid organism in infected dogs in the laboratory, it is the *in vitro* culture of this stage which is of special interest and importance. Although a wide range of modified tissue culture techniques were used, as well as techniques which have been used successfully for other cestodes[1], cultures always resulted in growth in a cystic direction as already described. Attempts to alter this pattern of development, by varying the usual physiological conditions of culture (*Eh*, *p*H, pO_2, pCO_2), or the nutritional constituents (amino-acids, vitamins, etc.), were without success.

These consistently negative results led us to speculate that some wholly unsuspected and unusual requirement was missing from the culture conditions provided. Attention was therefore turned to the conditions under which a worm lives while attached to the intestinal mucosa. We have shown[10,11] (*a*) that, in the small intestine of the dog, the worm penetrates deeply between the villi with each sucker, drawing a plug of villus tissue into its cavity, (*b*) that the extended rostellum of the worm normally penetrates a crypt of Lieberkühn, and (*c*) that the rostellar tip contains gland cells which secrete externally. The significance of these observations was not at first clear, but

the failure of *in vitro* methods led us to re-examine them in more detail. This led to the conclusion that the contact of the scolex with the mucosal epithelium was so close that the worm could perhaps be regarded (at least at the early stage in which it consists largely of scolex) as more of a tissue parasite than an intestinal parasite. If this hypothesis were sound, the organism would not only be absorbing nutritive materials from the intestinal contents, but it would also be absorbing directly through its contact with mucosa. In other words, the scolex of *Echinococcus* could be regarded as essentially placental in nature. These speculations were reinforced by investigations of the ultrastructure of the tegument, which showed that the protoplasmic projections termed microtriches were present only on the scolex region of a freshly evaginated protoscolex (Fig. 2) and not on the region posterior to the suckers. This latter region was covered in a dense periodic acid–Schiff positive (PAS-positive) layer beneath which were found what appeared to be undeveloped microtriches. If microtriches are concerned with absorption (and they have been reported from the tegument of a number of cestodes[12,13]) it is likely that absorption can take place initially only from the newly evaginated region.

This led us to speculate that the requirement missing *in vitro* was a solid substrate which could act as a supporting surface and from which, at the same time, nutriment could be obtained directly. We had previously used such a nutritive substrate for the *in vitro* culture of an intestinal trematode[14].

Experiments have shown, in fact, that this hypothesis appears to hold, although a number of basic problems had to be overcome before it could be adequately tested. The chief of these was concerned with obtaining satisfactory evagination of the protoscoleces. Although some evagination takes place without preliminary treatment, the process is greatly accelerated by treatment with enzymes. It is known that pepsin plays some part in evagination[15], but further treatment with pancreatin and trypsin in the presence of bile serves the multiple role of accelerating evagination, stimulating activity and removing cystic debris. Pretreatment with pepsin (0·025 per cent) three times at *p*H 2·0 (20 min) followed by treatment with 0·3 per cent pancreatin (5 N.F.) and 0·1 per cent trypsin (twice) plus 5 per cent dog bile or the equivalent bile salt (for 1–3 h), all in balanced salt solutions, produce almost immediate evagination of more than 90 per cent of protoscoleces. In any one batch of cultures, the degree of evagination appears to be related to the source and freshness of the material and in most cases the percentage falls to about 30–40 after about 3 h.

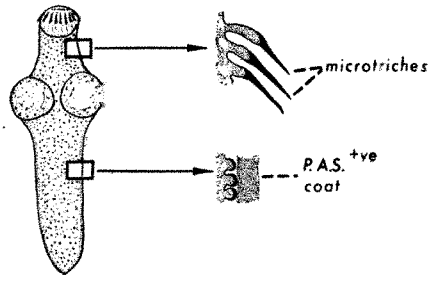

Fig. 2. Ultrastructure of the tegument with anterior and posterior regions of an evaginated protoscolex of *Echinococcus granulosus*. Microtriches only occur in the anterior region.

Once the problem of evagination was essentially overcome, attempts were made to culture the organisms using diphasic media, with liquid and solid phases. The culture system, in screw-top bottles, consisted of a solid base of bovine or canine serum coagulated by heat, into which a series of small holes had been made with a fine glass pipette; alternatively, the surface was roughened. The whole was covered by a liquid phase of 'Parker 199' and 20 per cent hydatid fluid. A gas phase of 8·8 per cent oxygen and 5 per cent carbon dioxide in nitrogen was used. In this diphasic system, a marked change came over the cultures; organisms which were evaginated remained so, became visibly elongated and eventually strobilated. Under the best conditions to date (using bovine serum base covered with 'Parker 199' and 20 per cent hydatid fluid) segmentation has been obtained in 32 days compared with 15 days *in vivo*.

That this growth has resulted from actual placental contact with a suitable substrate and is not merely due to diffusion of soluble materials from the solid base into the liquid phase was shown by the experiment illustrated in Fig. 3. Cultures were set up as follows: *A*, contained a bovine serum base coagulated by heating; *B*, contained the equivalent volume of coagulated serum retained within a cellulose tubing. As a control, culture *C* had no base, but had 10 ml. of serum added to the liquid phase; culture *D* had a non-nutrient agar base instead of serum.

In culture *A*, organisms grew and became segmented as described above. In *B*, although organisms survived for considerable periods, they gradually became abnormal, vesicular, formed posterior bladders (Fig. 1),

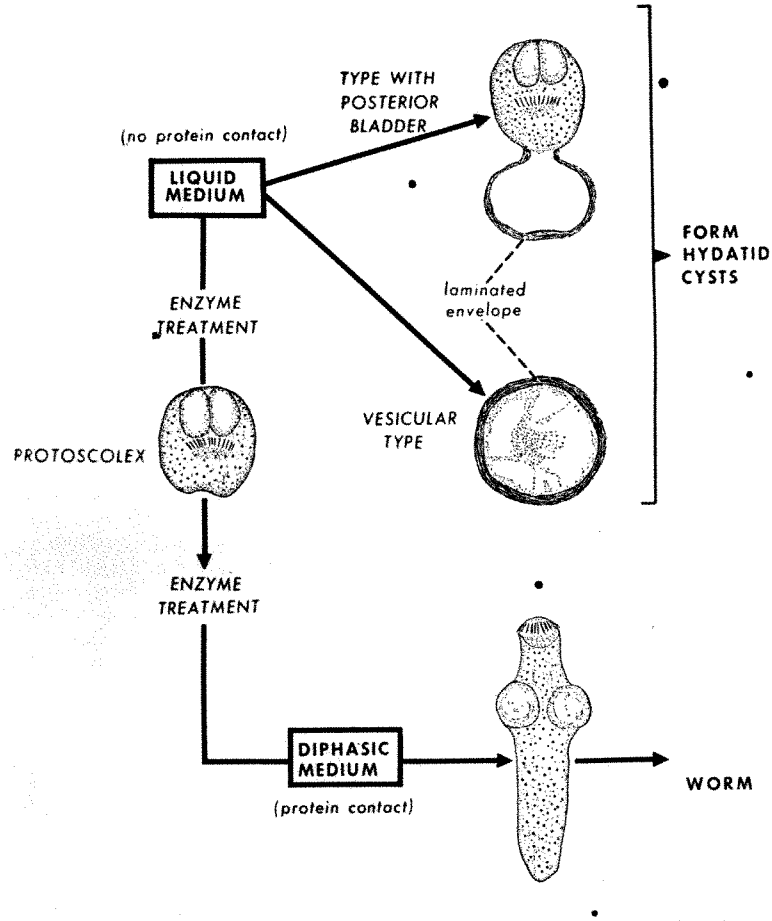

Fig. 1. Pattern of differentiation of the protoscoleces of *Echinococcus granulosus* in liquid (monophasic) and diphasic media: strobilization only occurs in diphasic medium. Unevaginated protoscoleces form miniature hydatid cysts.

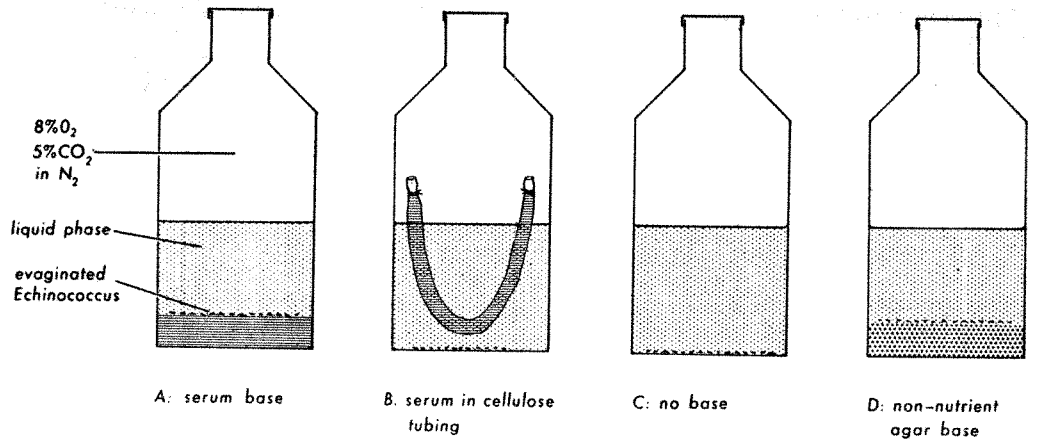

Fig. 3. Various monophasic and diphasic media used for *in vitro* culture of *E. granulosus:* strobilization only occurs in *A*.

or died, as did the organisms in the controls *C* and *D*. This and comparable experiments have been repeated a number of times and, in every case in which a nutritive substrate has not been provided, growth and strobilization have not taken place. That the role of the substrate is truly nutritive and is not merely to provide physical support is shown by the fact that the non-nutrient solid base of agar (culture *D*, Fig. 3) was not effective in supporting growth in a strobilar direction. Contact as such may, of course, be a part of the stimulus necessary for inducing growth in a strobilar direction, but if such a contact stimulus is involved it is clearly not effective in the absence of the appropriate nutriment. In this respect it may be noted that the tip of the rostellum carries a number of delicate hairs, the occurrence of which appears to have escaped previous observation. These structures undoubtedly represent sensory receptors, and their exposure by evagination of the scolex and subsequent contact with a suitable substrate may result in the production of a stimulus necessary for strobilization. This stimulus could perhaps operate through a neuro-secretory mechanism.

The importance of the protein base is further emphasized by observations of the activity of the evaginated protoscoleces during the early phases of cultivations. During this period, in all cultures (even those with bases), there is a decline of activity and the appearance of a remarkable phenomenon, namely the onset of a period of "tetanus"—characterized by the organisms becoming rigid and the suckers ceasing activity. In cultures with bases (A_1 and A_2, Fig. 4), however, organisms slowly regain activity, whereas in those without bases activity further declines until it finally ceases altogether (*B* and *C*, Fig. 4). This result suggests that after a period of contact with the substrate, organisms are able to obtain nutriment from it and utilize it for metabolic activity. We do not yet know precisely how this is done. We have been unable (to date) to detect the occurrence of pinocytosis in the rostellar region, but have some suggestive evidence that the scolex is secreting proteases, digesting the base and absorbing the products at the tegument/base interface. Undoubtedly, the microtriches present on the anterior region play a part initially in establishing close contact with the protein base. Once the organisms begin to grow, further microtriches develop in the posterior region previously covered by the PAS layer.

The failure of unevaginated protoscoleces to develop can be explained by the fact that no microtriches are exposed and intimate contact with the protein substrate cannot take place. The few strobilate worms obtained by Webster and Cameron[9] were undoubtedly obtained as a result of the use of a filter paper support in some of their cultures.

These experiments demonstrate that the conditions required for protoscoleces to differentiate in a strobilar direction *in vitro* are (*a*) evagination of the scolex and (*b*) a nutritive substrate with which intimate contact can be established. Failure to provide both these conditions results in differentiation in the cystic direction. In addition, the usual physiological requirements and conditions (*p*H, *Eh*, gas phase, etc.) must be satisfied within reasonable limits.

At the time of writing, development of *Echinococcus* to a three-proglottid worm *in vitro* has repeatedly been obtained, although the genitalia in such worms are only poorly developed and eggs have not yet been produced. Extensive experimentation may be necessary before appropriate solid and liquid phases, which permit maturation to the egg producing stage *in vitro*, are developed. It is unlikely that the conditions in our experiments are anything approaching optimal, and factors such as gas phase, *p*H, *Eh*, clearly require detailed examination as does the composition of the liquid and solid phases in terms of levels of the usual growth requirements, amino-acids, vitamins, sugars, etc. The *in vitro* system developed should, however, enable quantitative investigations of the relative importance of these factors to be carried out, and perhaps the basis for the strobilar and cystic differentiation at a biochemical or molecular level determined.

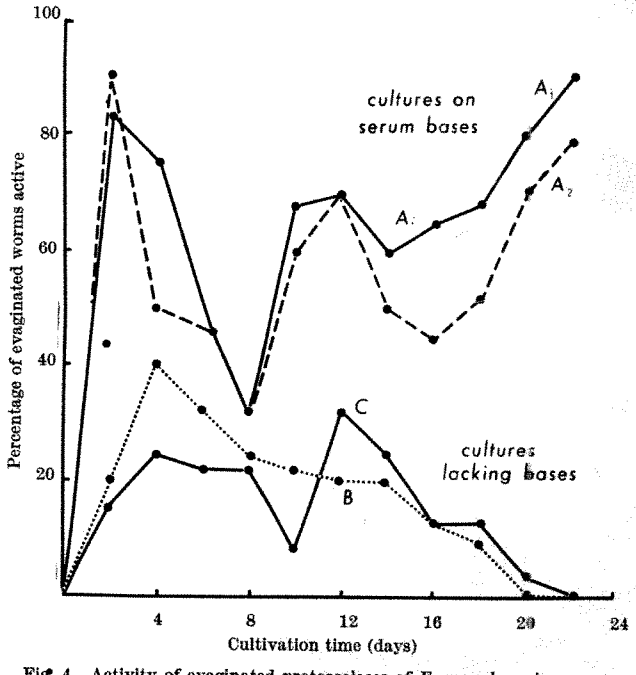

Fig. 4. Activity of evaginated protoscoleces of *E. granulosus* in monophasic and diphasic media. Activity is only maintained in the diphasic cultures A_1 and A_2 (see Fig. 3 and text).

It is interesting to note that Schiller[6] has recently shown that in the case of *Hymenolepis diminuta* a diphasic medium can replace the complex synthetic medium developed by Berntzen[1,2] for the culture of this species. Since, unlike *Echinococcus*, *H. diminuta* can develop in a liquid medium alone, its nutritional demands appear to be substantially simpler than those of *Echinococcus*.

As already mentioned, protoscoleces of *Echinococcus* which fail to evaginate develop in the cystic direction and form miniature hydatid cysts either by the growth of a small posterior bladder or by the swelling up of the protoscolex to become a vesicular form (Fig. 1). The latter appears to be a response to abnormal condition such as a low *p*H (for example 6·5) or mechanical damage to the tegument, although we have not examined this phenomenon in great detail. In both types of growth, a thick laminated envelope (Fig. 1), similar to that found round a hydatid cyst, is secreted which eventually encloses the whole organism.

In summary, then, it has been shown that protoscoleces may be induced to differentiate in either a strobilar or a cystic direction *in vitro* by provision of suitable culture conditions. This culture system is somewhat unusual for a helminth parasite, for differentiation, comparable to that occurring in either the definitive or the intermediate host, is possible.

Apart from the parasitological aspects of these results, the protoscoleces of *Echinococcus* may represent unique biological material. As all the protoscoleces within a hydatid cyst have developed from a single fertilized egg, each has an identical genotype. Moreover, as a single sheep hydatid cyst contains very large numbers of organisms it is possible to obtain perhaps as many as 10^5 organisms with the same genotype. We know of no other metazoan organism which possesses these unusual characteristics, and whose differentiation can be controlled and modified *in vitro* in this way. It would appear to represent an experimental model *par excellence* for experimental investigations in genetics, cell differentiation and morphogenesis.

These experiments have been based on *E. granulosus* but are likely to be used with more success on *Echinococcus multilocularis*, a "species"[10] which matures more rapidly than *E. granulosus*.

We thank the Australian Wool Board, the National Institutes of Health, U.S. Public Health Service and the World Health Organization for financial assistance in support of this work.

OXIDASE ACTIVITY IN ECOTYPIC POPULATIONS OF *Typha latifolia* L.

By S. J. McNAUGHTON

Department of Bacteriology and Botany, Syracuse University, Syracuse, New York

In 1922 Turesson suggested that plant species are differentiated into sub-specific populations which differ in their ecological characteristics according to the habitat they exploit[1]. Since then, genecologists have reported occurrence of morphological[2], phenological[3], and physiological[4] differences between populations adapted to different climates. These investigations provide strong circumstantial evidence for the occurrence of differences in enzyme activity between ecologically distinct populations[5]. This article provides additional evidence for this and indicates that biochemical activities which are dependent on temperature can be influenced by the environment.

Populations of broad leaved cattail (*Typha latifolia* L.), a species which is temperate circumboreal in distribution[6] (predominantly Arctic to 30° S.), were selected from marshes at Beaverton and Redmond, Oregon. Two populations were sampled at each site. Redmond (940 m above sea level) is located in the Deschutes River valley, just east of the Cascade Mountains. Beaverton (60 m above sea level) is in the Willamette River basin, between the Cascades and the Coast Range, and is subject to coastal influence from the Columbia River gorge. Weather reports[7] from stations near the populations sampled show that the climates of the two regions differ substantially (Table 1). The Willamette Valley vegetation is principally grain and truck crops but was originally *Pseudotsuga menziesii* Mirb. (Franco) and *Acer macrophyllum* Pursh[8]. Vegetation at Redmond is *Juniperus occidentalis* Hook. with *Artemisia tridentata* Nutt. at lower altitudes[9].

Rhizomes attached to shoots excised 30 cm above the soil were transplanted to the greenhouse in May and June and experiments were performed with this material in late June and early July and again in late August. The old shoots rarely grow after such transplantation; essentially all growth is from the attached rhizomes which, however, grow only poorly when detached from the old shoot. Mass leaf samples were collected from the natural populations in late August and were iced or refrigerated until experiments could be performed. The maximum storage time was 3 days and previous experiments indicated that no loss in activity occurred during storage for 5 days at 2° C.

Isolation of the chloroplasts was accomplished by a technique modified from standard methods[10]: 20 g of leaves were blended in 80 ml. 0·35 M sodium chloride for 1 min; the slurry was filtered through a double layer of cheesecloth and centrifuged at 1,000*g* for 1 min; the supernatant was centrifuged at 37,000*g* for 10 min; the pellet was suspended in 0·067 M phosphate buffer, *p*H 7·8, to give 0·008 g/ml., and 2·5 ml. of this suspension of chloroplast fragments added to each Warburg vessel. All operations were carried out near 0° C. The departures from standard technique were the longer blending time which was made necessary by the less succulent nature of *Typha* leaves and the higher centrifugation speeds required by the smaller size of the plastids. The preparation was undoubtedly contaminated with mitochondria. All experiments were performed in a dimly lighted room on a Gilson *GRP* 14 respirometer with potassium hydroxide in the centre well of the flasks. The vessels were allowed to equilibrate for 20 min and the rate of uptake of endogenous oxygen measured in two 5 min periods before adding the substrate (this usually approached

zero and was never more than 10 per cent of the rate in the presence of substrate). Substrates and *tris*-hydrochloric acid, buffered to *p*H 7·8, were tipped in from the sidearm to make the suspension 0·008 M. Control flasks lacking plastids were always run but fluctuation in these was negligible. Because of the occurrence of non-enzyme ascorbate oxidation in the presence of cupric ions (ref. 11), rates obtained with boiled plastid preparations (usually about 40 per cent of the enzyme rates) were subtracted from experimental ascorbate sets.

With catechol as a substrate, it was found that the consumption of oxygen at warmer temperatures depended on the place of origin; greater activity occurred in populations from regions with a continental climate (Fig. 1). Activity was stimulated more by temperature in the Redmond plants. The rate of increase of enzyme activity (Q_{10}) over the range of 17°–27° C was 1·4 for maritime and 3·7 for continental plants. It seems probable that several different enzymes, or forms of the same enzyme, are responsible for phenol oxidation and that the enzyme frequently referred to as "polyphenol oxidase" is in fact a group of enzymes rather than a distinct species[12]. Nevertheless, in the populations of *T. latifolia* studied, the ability to oxidize catechol is greater in populations growing in a continental climate, particularly at warm temperatures. This catalytic activity has been related to the possibility of providing protection from attack by micro-organisms[13,14] and also to lignin biosynthesis[15,16], but the precise function of this enzyme has not yet been determined. Because the activity measured is probably the result of that of several enzymes, however, the functions are almost certainly multiple. The data indicate, however, that the activity in the populations of *T. latifolia* investigated correlated with the climate, which therefore suggests that adaptation occurs.

With ascorbic acid as substrate, there were no differences between the natural and greenhouse populations (Fig. 2). Mapson[17] has shown that the activity of ascorbic acid oxidase increases considerably with increased light intensity, and that more of the ascorbate is converted to dehydroascorbate. Once the conditions of darkness are restored, the equilibrium lies in the opposite direction and the quantity of dehydroascorbate declines. Other investigators[18,19] have shown that an NADP–glutathione reductase system links the ascorbate oxidizing system to enzymes oxidizing respiratory substrates with nicotinamide–adenine dinucleotide phosphate. The function of this sytem is not known. The data on *Typha* indicate that activity of ascorbic acid oxidase is not of selective importance in differentiating the four populations sampled.

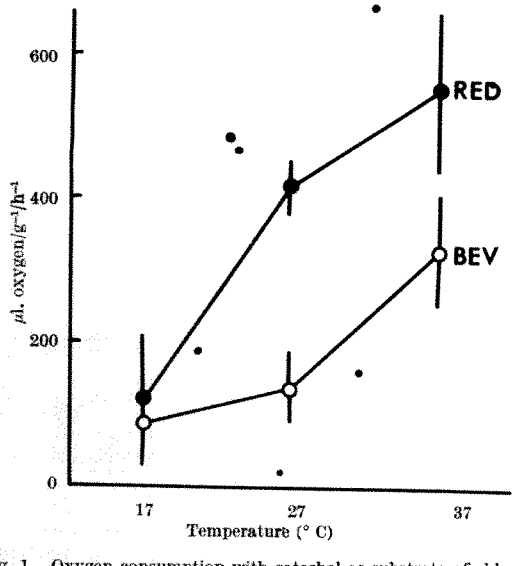

Fig. 1. Oxygen consumption with catechol as substrate of chloroplast fragments from two continental (RED) and two maritime (BEV) populations of *Typha latifolia* L. Points are means of twelve replications, six per population. Vertical bars indicate 95 per cent confidence intervals.

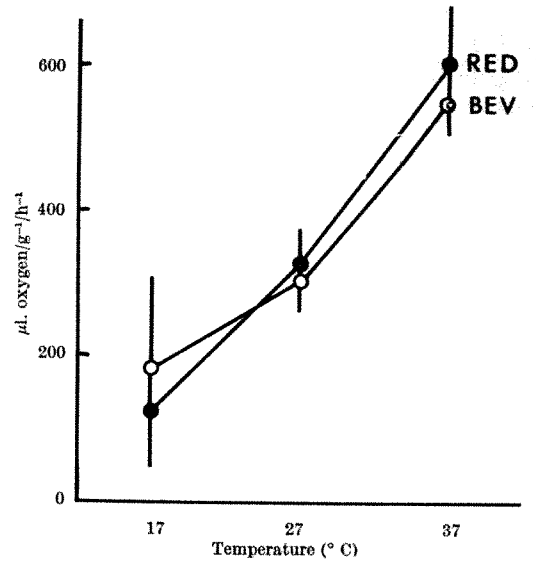

Fig. 2. Oxygen consumption of chloroplast fragments with ascorbic acid as substrate.

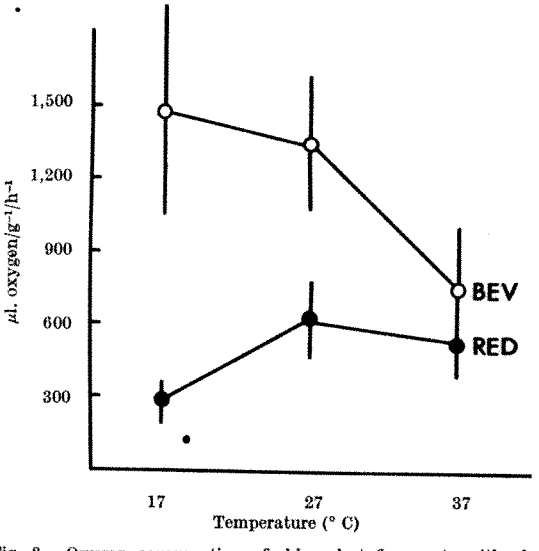

Fig. 3. Oxygen consumption of chloroplast fragments with glycolic acid as substrate.

The most conspicuous enzyme difference found between the populations of *T. latifolia* from different climates was in glycolic acid oxidase activity (Fig. 3). There were pronounced differences in the magnitude and temperature dependence of oxygen consumption with glycolate as a substrate. Populations growing in a maritime climate were much more active at 17° and 27° C. Glycolate oxidation increased with increased temperature in the continental populations while the relationship was an inverse one in the maritime plants. Zelitch[20] has shown that more than half the carbon fixed in photosynthesis may be metabolized by glycolic acid oxidase. This suggests an important adaptive function for this enzyme in assimilatory metabolic pathways. It is known that the Beaverton marsh is most productive in June, August and September. The mean maximum day temperatures during these months (1964) are 21°, 24° and 22° C, respectively. Data concerning the productivity for the Redmond marsh are not available. The frost-free period is only 90 days, however, and average maximum day temperatures during

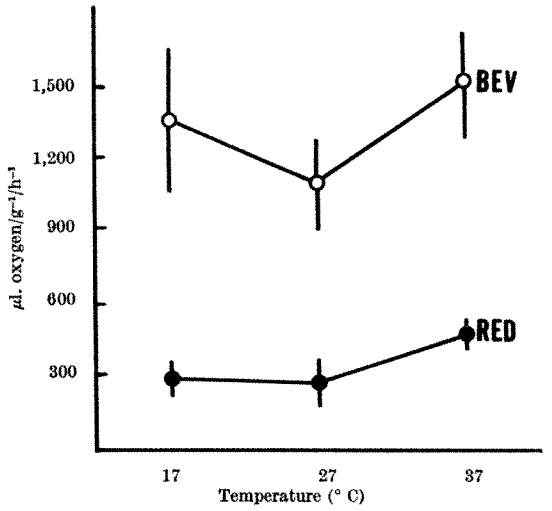

Fig. 4. Oxygen consumption of chloroplast fragments from greenhouse-grown plants with glycolic acid as substrate.

these months are 23° (June), 30° (July) and 27° (August). It seems clear from the data available that the dependence on temperature of glycolic acid oxidase activity in natural populations of *T. latifolia* is related to the daytime temperatures at the native site. If, as Zelitch's recent data indicate[21,22], glycolic acid is an early and important product of carbon fixation by photosynthesis, the ecological importance of this temperature dependence in integrating assimilatory pathways with temperature climate is considerable.

In early studies of plants from the natural populations transplanted into the greenhouse, the dependence on temperature of glycolic oxidase activity was similar to that of natural populations[5]. After 3 months in the greenhouse, however, the dependence on temperature had shifted (Fig. 4). Oxidase activity in all populations was relatively independent of temperature, but with slightly greater rates at 37° C. The maritime populations were still much more active in glycolate oxidation, but temperature dependence was similar in plants from different climates. For Beaverton plants at 37° C, a comparison of the enzyme activity of plants growing in their natural habitat and those grown in the greenhouse gave a t value of 65·3—a highly significant difference ($P \ll 0{\cdot}001$ with $d.f. = 10$). Glycolic acid oxidase activity in Redmond plants was significantly different at 27° C, depending on the growing conditions ($t = 37$ with $d.f. = 10$; $P \ll 0{\cdot}001$). In view of the similarity of the activities at 17° and 37° C, however, it is doubtful whether this is a significant difference in any practical sense. The greenhouse conditions did not resemble the temperature climate of either native site, although the maximum day temperatures (about 38° C) were closest to those at Redmond. As can be seen in Table 1, the frequency of days approaching this temperature is much greater at Redmond. There were 4·5 times as many days at 32° C, or warmer, at the continental site compared with the maritime site.

Table 1. WEATHER DATA FROM TWO OREGON SITES DURING THE PERIOD WHEN MINIMUM TEMPERATURES WERE GREATER THAN −2° C AT REDMOND

Location	Month (1964) June	July	August
Beaverton (Hillsboro)			
Avg. temp. (° C)	15	18	17
Avg. maximum	21	25	24
Avg. minimum	8	11	9
No. days max. ⩾32	0	1	3
No. days min. ⩽0	0	0	0
Redmond (Redmond Airport)			
Avg. temp.	14	18	16
Avg. maximum	23	30	27
Avg. minimum	4	6	4
No. days max. ⩾32	2	10	6
No. days min. ⩽0	5	2	3

This is probably reflected in the negligible modification of the temperature curve in the plants from Redmond compared with those from Beaverton. Recent studies of photosynthetic and respiratory rates in reciprocal transplants have shown that temperature dependence may be altered by climate[23–25]. Björkman *et al.*[26,27] have shown that photosynthetic activity can be dramatically altered by growing ecotypes under different conditions.

Enzymatically distinct races have been known since Mitchell and Houlahan's work on *Neurospora*[28]. The most intensively studied multiform enzyme is the lactic dehydrogenase system[29]. As many as fifteen electrophoretically distinguishable isoenzymes, all presumably formed by different tetrameric combination of three polypeptide chains, have been discovered[30]. Dorn[31,32] has shown that there are three mutants of *Aspergillus nidulans* which produce active phosphatases when grown at 35° C and partially or wholly inactive phosphatases when grown at 25° C. He has proposed that the various isoenzymes are produced by different combinations of distinct protein monomers. Glycolic acid oxidase is a tetramer in its most active form[33]. It is attractive to envisage a combination of various monomers producing various forms of the enzyme in the *T. latifolia* ecotypes under the control of different environmental conditions.

The data presented here indicate that populations of *T. latifolia* from climatically distinct sites are enzymatically distinct. The results also indicate that activity may be regulated by environmental conditions. There is no reason to suppose that the differences in catechol oxidation in populations from different sites would not disappear if they were grown under the same conditions. Similarly, populations might differ substantially in ascorbic acid oxidase activity when grown under the same conditions even though activity was identical in the native populations. The data are indicative, not definitive.

The investigation reported here was done while I was a faculty member of Portland State College, Portland, Oregon. It was supported by grants from Tektronix Foundation and Portland State College. The technical assistance of Mrs. Leta Burnham is gratefully acknowledged.

NEW ASPECTS OF VISUAL PERCEPTION THRESHOLDS

By GEORGE A. HAY

University of Leeds, Department of Medical Physics, The General Infirmary, Leeds 1

THE statistical hypothesis advanced by Rose[1,2], and independently formulated by de Vries[3] and Pirenne[4], to account for visual contrast and acuity thresholds in conventionally illuminated scenes, was extended to X-ray images by Sturm and Morgan[5], and further elaborated by Coltman[6] and by others. This extension has been tacitly assumed, though with some reason, to apply to all visual images in which random fluctuations of luminance tend to obscure the regular patterns (so called "noisy" images).

The conventional image of common experience and the noisy image differ in that only the latter exhibits marked spatial and temporal correlations between the emission of light photons; the former does not appear to be noisy, although stochastic processes in the eye must certainly result in a noisy pattern of visual stimuli from the retina. Albrecht[7] has therefore rightly remarked that the validity of a common theoretical approach to perceptibility in both types of image is by no means obvious. Although there seems to be no experimental evidence in support of this equivalence of treatment, the necessary computational facilities which man has acquired by evolutionary development for dealing with the conventional visual image appear to be equally effective for the frankly noisy image. There is no protracted learning process involved in the perception of the grainy photograph, the half-tone reproduction, the noisy television image (X-ray or conventional), the *pointilliste* painting, etc., suggesting that the same computational mechanism is used for both types of image.

The essence of the Rose theory is that the perception of image detail is a sampling process in which the fluctuations in the image at that point in the system where the event flux density is smallest are integrated over the size of the detail and over the so-called storage or integration time of the system. If then the detail contrast, against its background, is greater by a certain factor k (the threshold signal-to-noise ratio) than the root mean square fluctuation so observed, the detail will be perceived. Clearly the effect of noise on detail perceptibility on this hypothesis is less for larger details, for longer storage times and for larger event flux densities.

Despite its usefulness, many criticisms of the Rose hypothesis are possible; some of these have recently been voiced by Morgan, who has proposed[8] an alternative model of visual perception. Morgan has raised two main objections to the Rose theory.

First, at a given level of event flux density the measured perceptibility of both large and small detail falls below the value predicted from the theory, a value which holds good for medium-size detail. Rose recognized this fact and attributed it correctly, but unspecifically, to "local limitations" in the eye. Morgan has elaborated this idea in the light of later developments and has described it in terms of light diffusion for small detail and of the level-correcting feed-back mechanisms in the eye for large detail. Both effects can be represented generally by the modulation transfer function (assuming the system to be linear over small amplitude excursions).

Second, although in the noisy image Rose assumes the eye to integrate the noise over the whole area of an image detail, nevertheless finer noise within that detail is still clearly visible and might therefore be reasonably assumed to interfere with the detail perceptibility. By way of analogy, Morgan points out that the noise amplitude in the output of an electrical transmission system is a function not of the frequency spectrum of the signals passing through it but of the physical bandwidth of the system itself. He therefore supposes that in an image system the effective noise amplitude is constant for a given event flux density and independent of the size of the detail; it is to be calculated from the input noise and the overall modulation transfer function, by way of the concept of noise-equivalent bandwidth. This type of hypothesis, based on a physically realizable noise level, is conceptually more plausible and satisfying than the Rose model in which the effective noise must be assumed to change from instant to instant as the attention of the observer turns to detail of varying size. Its introduction seems, however, to leave the following important points unresolved.

First, the calculation of the noise amplitude from available data may not be simple or even possible. If the spatial bandwidth limitations are predominantly external to the eye, there is in principle no difficulty, as the diffusion characteristics of a physical system may in general be determined as accurately as desired. If the properties of the eye significantly limit the system bandwidth, however, adequate diffusion data may not be available. In the limiting case of the conventional visual image, when the diffusion limitations are solely those of the eye, to calculate noise amplitude it is necessary to know the overall modulation transfer function of the visual system, including the optical components and the retina, but dissociated from any noise limitations. So far as is known, no separation of diffusion and noise processes in the eye has ever been made, and it is my belief that no valid information about the overall modulation transfer function of the eye exists. The reciprocal perceptibility thresholds for sinusoidal details commonly referred to as "sine-wave response", etc. (for example, Schade[9]), must necessarily include a visual noise component and therefore may not properly be used in the calculation of noise-equivalent bandwidths.

Second, Morgan asserts that the perceptibility differences between details of different size arise solely from diffusion and similar processes and not at all from spatial noise integration. No experimental evidence is offered in support of this proposition. I believe, however, that such experimental data as are available appear to be more consistent with the suggestion that the effect of noise on detail perceptibility is area-dependent. As only one example, Fig. 1 shows the results of subjective measurements of disk perceptibility in an X-ray image intensifying system, carried out by Hay, Clarke and Marquerinck and reported by Marquerinck and Recourt[10]. The viewing conditions were such that the diffusion limitations were effectively those of the physical system and were approximately known: the noise limitations were predominantly of X-ray quantum origin, as interpreted by the visual mechanisms of the observer.

The relative noise contribution to perceptibility, calculated from all the experimental data and normalized to a single value of event flux density, is shown in Fig. 1 as a function of detail size. Shown also are the theoretical noise contributions calculated from both the Rose and the Morgan models. (The upper limit to the "Rose" noise is set by the spatial bandwidth of the intensifier system: clearly the noise cannot possibly exceed this value, however small the image detail.) Similar evidence is reported

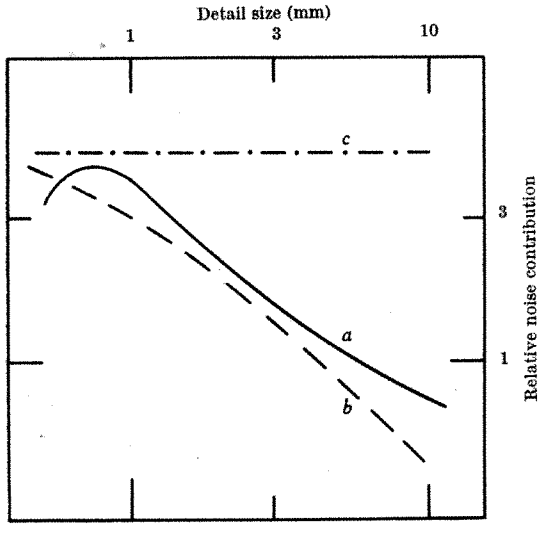

Fig. 1. Relative noise contributions to the perceptibility of circular detail. (*a*) Calculated from experimental data using an X-ray image intensifier television system; (*b*) calculated from the Rose theory; (*c*) calculated from the Morgan theory.

elsewhere, for example, for sinusoidal image detail in measurements by Coltman and Anderson[11]. It must be emphasized, however, that because of the complexity of the processes involved, quite different interpretations are possible for the data so far available. Clearly there is a great need for a new series of experimental studies performed with careful attention to all the relevant disturbing factors.

Third, the temporal characteristics of the visual system are expressed by Rose in the form of an integration time having the often quoted but poorly substantiated value of 0·2 sec; this in calculation yields plausible values for k of 2–5 depending on the nature of the image. Morgan, on the other hand, makes use of Kelly's measurements[12] of the temporal frequency response of the eye, corresponding to much smaller integration times from 0·02 to 0·07 sec; he calculates far less plausible values for k of 0·1 to 0·2. If k has indeed this order of magnitude then it necessarily loses its significance as a threshold signal-to-noise ratio, that is, as a ratio based on a statistical confidence level: it could be suggested that the wrong signal is being compared with the wrong noise. The conclusion seems inescapable that the visual system is at the same time capable of high-speed response as well as effectively long integration time.

The evidence outlined here reveals not only a remarkable symmetry between the spatial and temporal aspects of visual system behaviour but also a hitherto unformulated duality in frequency response, whether spatial or temporal. It suggests to me the possibility of a third type of hypothesis to account for visual perceptive thresholds. Three broad conclusions can be drawn from the evidence, of which two at least have not, so far as I am aware, been previously enunciated.

First, the spatio-temporal symmetry suggests that one might reasonably look for stochastic limitations to temporal response. Further analysis of Kelly's results[12], as well as of similar measurements at lower values of retinal illumination, is clearly desirable.

Second, the combination of good spatial and temporal high frequency response with low frequency "integration" is most satisfactorily accounted for by the assumption of a receptor of good spatial and temporal resolution, together with a computer which does not integrate and therefore destroy the fine detail from the receptor, but examines and analyses its pattern according to the needs of the moment. For example, in the temporal domain it becomes possible to reconcile Kelly's results[12] with the traditional 0·2 sec or thereabouts of the Rose theory by supposing that Kelly's data refer to the receptor (as is indeed most likely) and that the computer is normally effective over longer periods of the order of a second. This latter period has been referred to by previous authors (for example, Albrecht[7]) as a "short term memory"; it may well be identical, in mechanism as well as in magnitude, with that called by the psychologists "the observed present", which from quite different types of experiment is found to have a value between 0·2 and 1·0 sec. I find it difficult to imagine how any of these computational processes can occur in the retina, because as a result of rapid saccadic movements the co-ordinates of the input image relative to the retina must change many times in the longer computational period. It seems essential to postulate that these processes occur within a stable framework of reference relative to the mental presentation and this can surely be only central.

Third, we must look for a model to represent the type of analysis performed by the computer on the basic high frequency data from the receptor; this model must preserve the fine detail and yet permit its assessment in larger domains. I believe that in the spatial domain at least the meagre experimental evidence so far available, as well as objections of the kind raised by Morgan, can be accounted for by the adoption of a hypothesis of visual perception thresholds based on the Wiener or power spectrum of the noise in relation to the Fourier transform of the relevant image detail—the noise amplitude being determined in principle on the basis of Morgan's model.

There is virtually no experimental evidence from which such a hypothesis can be elaborated, but if it were assumed, in very general terms, that the perceptibility of image detail of a given linear dimension were disturbed only by noise of spatial frequency corresponding to a wavelength greater than that dimension, an effective noise dependence on detail size similar to that predicted by the Rose theory (with Morgan's modifications to account for diffusion processes) would be obtained. The important difference is that the idea of integration, with its implication of the destruction of fine-grain information, is avoided. Analogous behaviour has been observed in the aural system by Wegel and Lane[13], who have found that a tone of given frequency is well obscured by masking tones of frequency lower than its own but far less effectively by higher frequencies. Whether or not such a mechanism is operative visually in the temporal domain can at present be only a matter of conjecture.

The truth of this new hypothesis cannot be verified from existing experimental data because in almost every case the noise has been of the kind known as "white"; its Wiener spectrum has been uniform from zero to the upper frequency limit of the system. However, one isolated piece of supporting evidence is reported by Coltman and Anderson[11], who found that a reduction in noise bandwidth from 5 Mc/s to 600 kc/s (a noise amplitude decrease of 2·8) caused an improvement in the perceptibility of a 170 kc/s sinusoidal detail of only 25 per cent. Moreover, this small change could well have been due to the disappearance of low frequency noise intermodulation products resulting from the non-linearity of the display monitor.

LETTERS TO THE EDITOR

ASTRONOMY

Observations on Stellar Extinction obtained in the *Gemini* 9 Space Flight

LINK[1] has suggested that there is a high absorbing layer in the Earth's atmosphere. This layer, presumably dust, was suggested in order to explain the anomaly in the size of the Earth's shadow during eclipses. Some support for the suggestion came from measurements of stellar extinction from Mont Blanc[2]. The height of the layer has been estimated as 100–150 km above the surface and it is presumed to have a vertical optical depth of 0·025–0·05. The purpose of this communication is to show that on the basis of stellar extinction measurements made in the *Gemini* 9 flight, no layer at an altitude above 80 km exists with a vertical optical depth of more than 0·0015. Either Link's layer does not exist at all or it is at a lower altitude than 80 km.

Table 1

1 Star	2 Magnitude $\frac{B+V}{2}$	3 Log_{10} brightness Frame 3	4 Log_{10} brightness Frame 2 normalized to Frame 3	5 Average of columns 3 and 4
α C Ma	−1·4	4·36	4·29	4·32
α C Mi	+0·56	3·47	3·58	3·53
ε C Ma	1·39	3·14	3·21	3·17
β C Ma	1·84	3·04	3·00	
δ C Ma	2·17	3·00	2·93	2·96
η C Ma	2·58	2·88	2·78	2·83
0^2 *C Ma*	2·98	2·65	2·58	2·61
ω C Ma	3·4	2·40	2·50	2·45

The extinction experiment was performed with two negatives of the airglow viewed in profile from above. These negatives were taken with a special camera designed for dim light photography in manned space flights. The 30 sec exposures were taken by astronauts Cernan and Stafford on June 4 during the *Gemini* 9 flight. In the first photographs (Frame 2) all the bright stars of Canis Majoris are above the airglow layer. In the second photograph (Frame 3), the star β *C Ma* is in the airglow layer. The experiment consists of comparing the brightness of β *C Ma* when it is above and when it is in the airglow layer. The height of the tangent ray to β *C Ma* in Frame 3 is about 80 km. The extinction produced in a thin layer viewed in profile is seventy times the vertical extinction. (The ratio of the tangent path to the vertical path is $\sqrt{(8R)}/y$, where R is the radius of the Earth, and y is the layer thickness or the scale height. For $y = 10$ km, the ratio is 70.) The brightness of the airglow layer viewed in profile from above is, of course, increased by approximately the same factor.

Fig. 1. Wide angle photograph of the sky, the airglow layer viewed in profile and the moonlit Earth obtained in *Gemini* 9 on June 4, 1966. The star β *C Ma* is in the airglow layer. *α C Mi* is left of centre in the picture. The obscuration in the lower left is due to the spacecraft window.

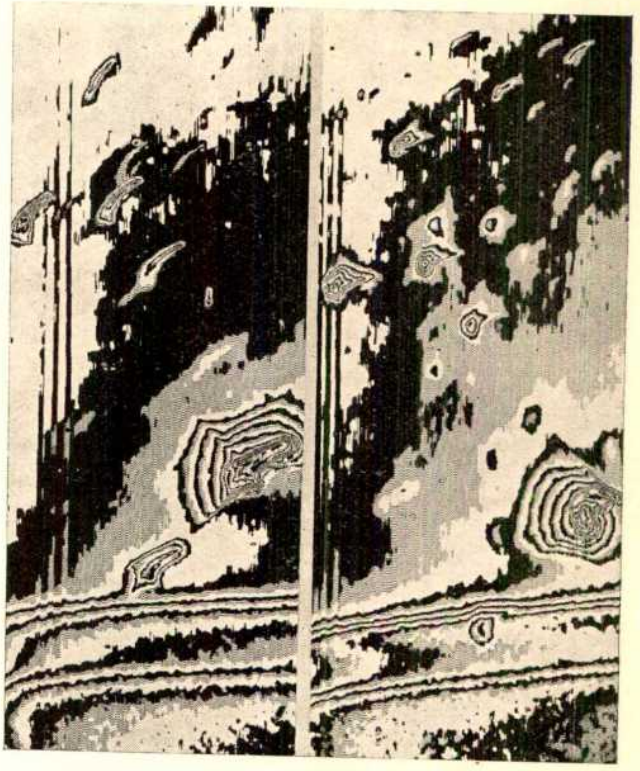

Fig. 2. Isodensity tracings of the portions of Frame 2 and Frame 3 which contain the constellation Canis Majoris. In Frame 3 right hand tracing β *C Ma* is in the airglow layer.

Fig. 1 shows the complete field of view of Frame 3. The field is 130° by 50° and the constellation Canis Majoris is at the left with the star β *C Ma* in the airglow layer. The star Procyon is just left of the centre of the picture.

Fig. 2 shows an isodensitrace of the portions of Frame 2 and Frame 3 which include Canis Majoris. Seven stars including β *C Ma* in Canis Majoris and *α C Mi* were accurately measured with a densitometer in Frame 2 and Frame 3. The calibration of the film was obtained from a step wedge exposure on the same film. The magnitude scale was determined by using all the stars except β *C Ma* in both frames. Table 1 shows the pertinent data, including the known magnitudes of the stars involved. Because of the wide spectral range of the film ('Tri *X*') the magnitudes used are the average of *B* and *V* magnitudes.

In Fig. 3 the experimentally determined values in column 5 of Table 1 are plotted against the magnitudes in column 2. The two values for β *C Ma* are shown with respect to this calibration. No extinction is detectable. Also shown in Fig. 3 is the position expected for β *C Ma* in Frame 3 if the vertical optical depth of the layer were 0·025, as previously proposed. This is clearly ruled

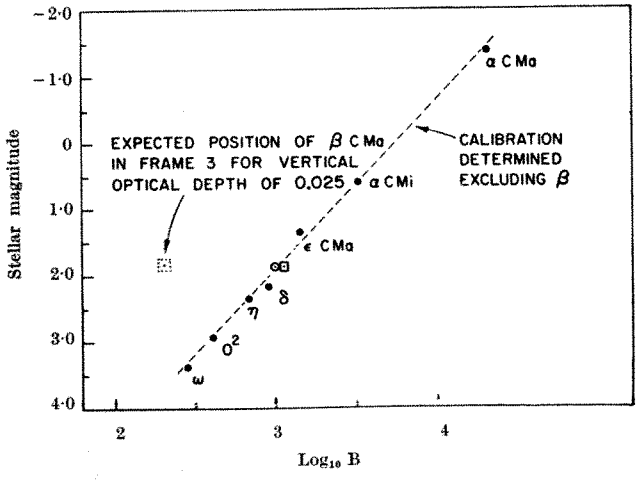

Fig. 3. Plot of the measured brightness of the stars in Canis Majoris and *α C Mi* establishing the film calibration. The values obtained for *β C Ma* in Frame 2 and Frame 3 are also shown and there is no measurable extinction in either case. The predicted value of the measurement in Frame 3 is shown for the vertical optical depth of 0·025. □, *β C Ma* Frame 3; ○, *β C Ma* Frame 2.

out by the experiment. For a pure Rayleigh scattering atmosphere the vertical optical depth above 80 km is of the order of only 10^{-5} and our experiment, although ruling out the dust layer, sets an upper limit of $1{\cdot}5 \times 10^{-3}$, corresponding to our measurement of extinction in Frame 3 of magnitude $0 \pm 0{\cdot}1$.

We acknowledge the excellent work of astronauts Cernan and Stafford in carrying out the experiment. The backup crew astronauts Lovell and Aldren were very helpful. We also thank Dr. Jocelyn Gill, John Lintott, W. F. Huch and Fred Gillett.

PHYSICS

Proposed Search for Antimatter among Hydrogen-like Atoms in the Ambiplasma

H. Alfvén and O. Klein have developed[1,2] an appealing idea in which antimatter plays an important part in cosmology. N. A. Vlasov[3] has suggested an optical method for observing hydrogen-like atoms in an ambiplasma consisting of protons, anti-protons, electrons and positrons.

We have made some calculations relating to this question in which we include the positive and negative muon in the ambiplasma together with the four particles in Alfvén's model[2]. Radiation from positronium (e–$\bar{e}$), protonium (p–$\bar{p}$) or muonium (μ^+–e, or μ^-–$\bar{e}$), if observed in the centre of our galaxy, or in one of the quasi-stellar radio sources, would provide significant support for the Alfvén–Klein cosmology. Vlasov has suggested that our own galaxy might consist of an arm and an anti-arm and that the centre of the galaxy would be a logical place to search for an ambiplasma. The immense amount of radiant energy which apparently comes from quasars makes it plausible to assume that a significant mechanism is matter–antimatter annihilation. (The possibility that pair annihilation is the source of energy in quasars has recently been discussed by A. G. Ekspong, N. K. Yamdagni and B. Bonnevier[4].) This is the reason why we believe that the quasars may be ambiplasmas, that is contain significant admixtures of matter and antimatter.

Table 1. Wavelengths in Ångströms for Several Hydrogen-like Atoms

		Positronium	Protonium	Muonium	Hydrogen
Lyman	α	2430·9	1·3234	1220·9	1215·7

Series limit		45563	24·815	22892	22794

In Table 1 we list some wavelengths from the "Lyman", "Balmer", "Paschen", "Brackett", and "Pfund" series of positronium, protonium, muonium and hydrogen. These are calculated from the Bohr theory formula

$$E_n = -\frac{\mu c^2 \alpha^2}{2n^2} \qquad (1)$$

with accurate values[5] used for the reduced mass μ in each case.

The wavelengths for positronium are almost exactly double those for hydrogen and span the ultra-violet, visible and near infra-red portions of the spectrum. The wavelengths for protonium are in the X-ray region. It is necessary to consider much higher values of the principal quantum number n to reach wavelengths for this atom in the ultra-violet. The $n_i = 14$ to $n_f = 13$ transition in protonium has a wavelength $\lambda = 1217{\cdot}8$ Å which is close to the Lyman-α line in hydrogen. The wavelengths for muonium differ from the corresponding values for hydrogen by just a few Ångströms.

If only hydrogen-like spectra from a quasar were to be observed it would be possible to confuse positronium with hydrogen. It could be said, for example, that the $1{\cdot}13122\mu$ line came from positronium in a quasar with $Z = \Delta\lambda/\lambda_0$ equal to two (no red-shift) or from hydrogen in the same quasar but with a Z number equal to 3. The ambiguity can be resolved by positive identification of spectral lines from other atoms, so that there is no appreciable uncertainty in the Z number. Or one could look, with radio telescopes, for the wavelengths associated with the hyperfine splitting of the ground state of these various atoms. These are well known[6] and well understood[7] for positronium, muonium and hydrogen and are listed in Table 2.

Table 2. Ground State Hyperfine Split Frequencies and Wavelengths for Several Hydrogen-like Atoms

Positronium	Muonium	Hydrogen
$\nu = 2{\cdot}0337 \times 10^5$ Mc/s	$\nu = 4{,}463$ Mc/s	$\nu = 1{,}420$ Mc/s
$\lambda = 0{\cdot}147$ cm	$\lambda = 6{\cdot}72$ cm	$\lambda = 21$ cm

It is natural to enquire whether or not a matter–antimatter hydrogen-like atom will suffer annihilation or

decay before radiation occurs. We have found that protonium in the $n = 2$ state will annihilate before the Lyman-α radiation takes place, using the approach of Bethe and Hamilton[8]. Consequently, we do not believe that the 1·32 Å line of protonium can be observed. In all other cases the annihilation or decay lifetime is long compared with the radiative lifetime.

N. A. Vlasov has estimated that there is a very small flux—0·0054 photons/cm²/sec/steradian at the top of our atmosphere—due to hydrogen-like atoms like protonium. This means the detection problem can be solved only by using large apertures and long exposure times. Vlasov's estimate may well be pessimistic in view of the observations of Giacconi *et al.*[9], who report a soft X-ray flux of 5 photons/cm²/sec¹/steradian from a source near the galactic centre. We believe this search is well worthwhile. Positive identification of an ambiplasma source of positronium, protonium, or muonium radiation would clearly open up new and exciting fields of spectroscopy and enrichen observational astronomy.

We are grateful to Dr. Frederick R. West for his encouragement and comments.

PLANETARY SCIENCE

Implications of the *Mariner* IV Photography of Mars

LEIGHTON *et al.*[1] and Loomis[2] have recently provided brief assessments of various aspects of the *Mariner* IV photographs of Mars. Their conclusions imply an almost universal acceptance at the present time of the impact theory of lunar cratering. Loomis states "little disagreement remains that the Moon's craters were formed by hypervelocity impact rather than volcanism". I would suggest, however, that the facts do not justify this generalization. There is, on the contrary, a wide body of international opinion favouring endogenous—volcanic or quasi-volcanic—causes for the development of the large lunar craters, and I myself hold such views[3,4].

The principal objection to the volcanic theory is posed by the question "Where have all the meteorites gone?" But this objection is no more insurmountable than those which have been ranged against impact theory[3,4]. The truth is that there are valid objections to both theories, and the controversy is far from being resolved—contrary to Loomis's statement. Gold[5] refers to the volcanic theory being abandoned "because a large amount of the detail could not be accommodated into it". His arguments involve the assumption that the cratering is explosive, and that volcanism involves immense lava outpourings. Neither is necessary. I have demonstrated that there is a good case for the alternate theory in the case of the Moon[3,4], and that there is much detail irreconcilable with impact theory. I shall endeavour to show that the same applies to the martian cratering.

Certain modifications of the impact theory have become popular, particularly since the successful *Ranger* project. Some modifications of the "all-out" impact theory were needed, and two have been suggested. The first involves a clear-cut separation of the large lunar craters into impact explosion craters (for example, Tycho and Copernicus) and caldera craters of volcanic origin (for example, Alphonsus and Ptolemeus). The second assumes considerable secondary volcanic modification of initial impact explosion craters. Neither modification of the impact theory seems to have been taken beyond a vague statement, and it is doubtful if either would stand up to a rigorous analysis of the detailed relationships between craters and linear (tectonic) structures, and of the integral structure of the craters. To emphasize this point, in the case of the first modification I would refer the reader to a photograph published by Moore[6], showing the craters Azarchel, Alphonsus and Ptolemeus. Can it be doubted that these three craters are broadly congenetic? Yet a comparison between Azarchel and Copernicus will reveal remarkable similarity. Both show high, terraced walls; depressed floor; a little disrupted outline; median sector graben structure corresponding to a ridging of the central peak. There is a complete gradation between lunar crater types, and no clear-cut separation into contrasting genetic types can be substantiated. The second modification of the impact theory cannot seriously be maintained because the rays clearly overprint everything else around the large rayed craters and this is fatal to any theory of secondary volcanic modification. Another answer will surely have to be found to explain the anomaly of caldera features in rayed craters such as Copernicus.

Leighton *et al.*[1] conclude that the martian craters, like those of the Moon, resemble impact craters on Earth, but this conclusion would be difficult to justify by detailed analysis. I believe that lunar craters do not closely resemble terrestrial impact explosion craters, but do closely resemble terrestrial volcano-tectonic craters[3]—calderas and surface cauldrons. Which particular terrestrial impact explosion craters are the lunar craters supposed to resemble? Leighton *et al.* have produced good statistical evidence for the congenesis of lunar and martian craters, but by no accepted standard of scientific evaluation could this be considered to be evidence for anything more. The unresolved controversy concerning the formation of craters has simply been extended to Mars by the *Mariner* IV probe. I do not doubt that the barren, cratered surface revealed by both these small planetary bodies reflects a shared fundamental cause: but I believe that what we are seeing is the surface reflexion of a primitive phase of quasi-volcanic activity (such as has been suggested by Fish, Goles and Anders in another context[7]), and that these surfaces have never progressed beyond this primitive state, lacking the more complicated internal and surface processes which have affected the Earth.

The eleventh frame of the *Mariner* photographs (Figs. 1 and 2) shows a focal bright spot in the crater in the upper right-hand corner. Without doubt this is a central peak structure, such as has been recognized in other frames, and suggests that the phenomenon responsible for crater formation was endogenous rather than impact explosion. Such a structure has never been satisfactorily explained in terms of impact in the case of lunar craters: chance "bull's eye" strikes by other meteorites, rebound and isostatic adjustment are all untenable[3]. Of considerable significance are the perfectly formed scalloped facets in the walls of the crater shown near the top of the frame, left of centre. Previously, I had recognized a restricted development of such scalloped facets in the walls of lunar craters (Clavius and Schiller, ref. 3), but I treated this

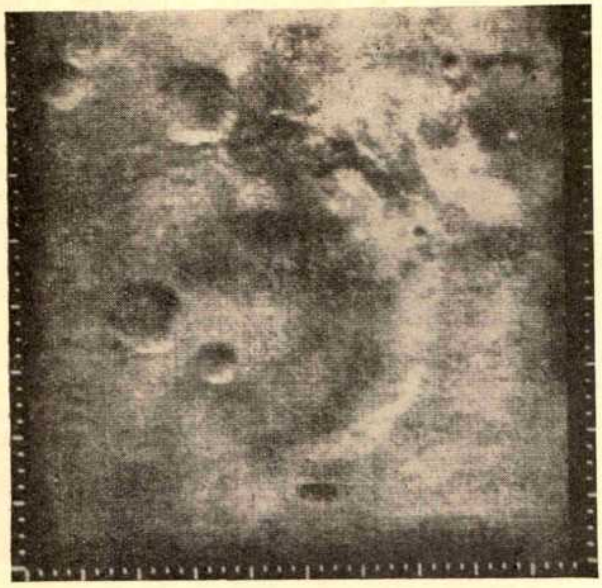

Fig. 1. *Mariner* IV Frame 11 (by permission of the National Aeronautics and Space Administration). East—West 270 miles; North—South 240 miles.

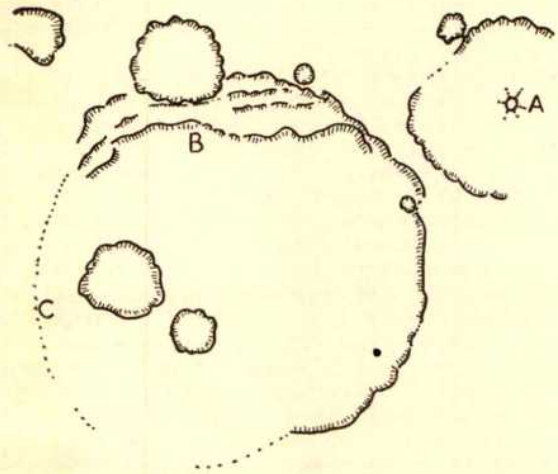

Fig. 2. Tracing of Fig. 1, in which *A* represents the bright spot at the crater focus, *B*, the large scale step-faulted zone of the largest crater, and *C*, the section of wall of the largest crater which is either obscured or not developed.

evidence with some reserve. The martian scalloping, however, is so perfect that it must be regarded as important evidence.

Many terrestrial subsidence calderas of volcano–tectonic origin show scalloped facets in their walls[8], and among the better known examples are Krakatau, Aso, Crater Lake, Santorin and Menengai[8,9]. While the exact origin of this phenomenon is debatable, such a structure has not been found developed to any significant degree in any crater produced by eviscerating explosion. My inference[3] of a subsidence origin for the Trou au Natron crater, Tibesti, was based entirely on this feature—contrary to an opposing interpretation. (Recently, in a personal communication, Prof. H. Tazieff has confirmed this view.) I therefore take pronounced scalloping of crater walls to be a valid indication of volcano–tectonic subsidence.

Scalloping is also evident in the walls of the largest of all the known martian craters, and in the two smaller craters sited within it (Figs. 1 and 2). (Since this communication was first prepared, Fielder[10] has commented on this scalloping.) Not only is simple scalloping evident in the walls of the largest crater, but also giant scalloped steps, which can only reflect step-faulting on an immense scale. Scalloping is also evident in the walls of the crater showing the bright focal spot already mentioned.

Scalloping seems to be emphasized in the case of the martian craters, and not very conspicuous in the case of the lunar craters. The walls of martian craters tend to be less complicated by linear fractures and thus exhibit more circular outlines. Such divergences in cratering style from the surface of one planetary body to that of another are to be expected with endogenous cratering—eruptive processes are very flexible. It may be questioned, however, whether such marked disparity is likely to develop between craters on two separate planetary surfaces by the agency of the much less flexible process of impact explosion. But then it is difficult to see how scalloped facets could be developed in the walls of impact explosion craters at all!

Loomis[2] refers to the obscuration of a section of the walls of the large crater shown in Fig. 1. Obscuration by superimposed volcanics is also possible—this has actually occurred in the case of the outer caldera of Suswa volcano, Kenya[11]. I prefer, however, yet another possible alternative explanation—that the ring fracture was simply incompletely developed in the first place. Terrestrial caldera walls, and annular fractures in ring-complexes are by no means always entire, and most calderas show unequal displacement downwards of the floor. This large crater is, I believe, a surface cauldron of subsidence.

Theory of some Quiet Magnetospheric Phenomena related to the Geomagnetic Tail

THIS is an outline of a theory which correlates four quiet aeronomic phenomena—(1) the ionized plasma in the geomagnetic field, particularly the tail; (2) the maintenance of the polar F region in winter; (3) type A red polar cap aurora and (4) some aspects of the scattering of solar Lyman alpha radiation (L_α) into the night sky.

Briefly, the theory is that a very small fraction (generally < 1 per cent) of the solar wind plasma impinging on to the geomagnetic field diffuses into it at times of magnetic quiet. The plasma helps to form the geomagnetic tail. In the outer geomagnetic field (B) the plasma cools and heat is conducted away along B to the polar ionosphere. The cooled plasma contributes to the gravitational diffusive equilibrium distribution along B and thus to the polar F region ionosphere. Sufficient heat is given to the F region electrons of the polar ionosphere to generate red auroral glow over the polar caps by thermal excitation of atomic oxygen. In a steady state, the capture of proton–electron pairs from the solar wind is balanced by the ejection of hydrogen atoms from the outer atmosphere of the Earth. This is achieved by charge exchange between protons moving faster than escape velocity and hydrogen atoms. The escaping hydrogen atoms provide interplanetary centres for scattering of solar L_α into the night sky.

The physical quantities used in what follows to illustrate the theory mostly apply to conditions at sunspot minimum and to magnetically quiet times.

The plasma in the outer geomagnetic field consists of a thermal part comprising electrons and protons of energy 5–7 eV and density ~ 5–20 cm^{-3}, and at least two non-thermal parts comprising electrons at 22 eV, and protons at 350 eV, respectively, both at a density of ~ 1–2 cm^{-3}. (The actual numbers are taken from the work of Sagalyn and Smiddy[1].) It is supposed that at least the non-thermal parts diffuse into the geomagnetic field from the solar wind. This assumption is necessary for the part of the theory concerned with the maintenance of the F region, but is not essential for the theory of the red arcs as such or of the aspects of L_a. Non-thermal plasma has also been observed in the outer geomagnetic field by Gringauz *et al.*[2] and Serbu[3]. The energy density of the plasma is in the range 6–14×10^{-10} ergs cm^{-3}. This is the same as in a magnetic field of strength 12–19×10^{-5} gauss. It is therefore of the correct magnitude to contribute significantly to the formation of the observed geomagnetic tail[4].

The polar region is considered to be connected to the geomagnetic tail[4]. In the cooling of the plasma in this tail, the cooled particles contribute to the thermal electron content of the tube of force and fall into the polar atmosphere where they contribute ionization to the F region. The rate at which the tail provides this ionization is

$$\mathcal{J}_{(\max)} = \sum_c n'_c\,(t'_{sc})^{-1}\,B_I\,B_T^{-1}\,L \text{ cm}^{-2}\text{ sec}^{-1} \qquad (1)$$

where n'_c represents the density of a component (c) of non-thermal plasma, t'_{sc} the slowing down time of this component in the thermal plasma, B_I the geomagnetic field at polar cap, B_T the magnetic field in tail, and L the characteristic length of geomagnetic tail.

Consider the maximum contribution to $\mathcal{J}$ by non-thermal electrons. Put $n'_c = 1$–2 cm^{-3}, $t'_{sc} \approx 5 \times 10^5\ n_e^{-1}$ sec, where n_e, the thermal electron density, is 5–20 cm^{-3}, $B_I \approx 0{\cdot}6$ gauss, B_T is 10–30×10^{-5} gauss, $L \approx 30$ Earth radii (R_E) (ref. 4). It is found that

$$7{\cdot}5 \times 10^7 \lesssim \mathcal{J} \lesssim 1{\cdot}5 \times 10^9 \text{ cm}^{-2}\text{ sec}^{-1} \qquad (2)$$

These fluxes are large and it can be shown theoretically[5] that a substantial polar F region can be maintained by them. In particular, assuming a recombination coefficient of about 5×10^{-8} sec^{-1} at 300 km, a maximum electron density of $0{\cdot}25$–5×10^5 cm^{-3} can be sustained at altitudes of 300–400 km. The upper limit of the flux ($\mathcal{J}$) may be lowered somewhat by consideration of the next section.

The high red polar cap aurora can be attributed partly to dissociative recombination of F region electrons and partly to thermal excitation of atomic oxygen by F region electrons. The latter is the same hypothesis as was used earlier for the stable auroral red arc which is reported in middle latitudes during geomagnetic storms[6]. If the red glow at wavelengths of 6300 and 6364 Å resulted entirely from thermal excitation by F region electrons, the ratio of the intensities $I(6300)/I(5577)$ would be very large and $\gtrsim 50$. If the red resulted entirely from recombination, then $I(6300)/I(5577) \approx 4$. Although the ratio is frequently very large[7,8], sometimes it is small[8]. When the index of local magnetic disturbance (K) is zero, $I(5577)$ is not increased[7] above its value at middle latitudes where it is predominantly influenced by some photochemical process at the height of the lowest E region. Photometric measurements show that on one occasion in a polar cap arc $I(6300) \approx 1{,}000\ R$ (where $R = 10^6$ photons cm^{-2} vertical column sec^{-1}) while $I(5577) \lesssim 100\ R$ (ref. 8). On the basis of recombination, the latter intensity puts an upper limit of about 5×10^8 cm^{-2} sec^{-1} on $\mathcal{J}$. This limit would be decreased if allowance were made for generation of some light at a wave-length of 5577 Å—in this case in the E region by some photochemical process. The considerations applied to existing observations suggest that 10^8 cm^{-2} sec^{-1} is a reasonable order of magnitude estimate of the average value of $\mathcal{J}$ but that it may extend over the values given in relation (2).

We shall now assume that the red polar cap glow is due dominantly to thermal excitation by F region electrons. It should be noted, however, that the arcs near the auroral zone are considered to be caused predominantly by corpuscular bombardment by electrons of energy 1–10 keV and only partly by the thermal excitation. This discussion is intended to account for the $K = 0$ type of regime found by Sanford[7] (see his Fig. 8) in which green arcs at the auroral zone apparently do not exist.

The height integrated cooling rate (Φ) of the electrons in the red polar aurora[7,8] can be found by the theory given elsewhere[6]. Knowing the intensity of the aurora, the electron temperature can be found and thus also Φ. I have found that Φ is matched by the integrated cooling rate of non-thermal particles in the tail which is

$$F = \sum_c n'_c\,E'_c\,(t'_{sc})^{-1}\,B_I\,B_T^{-1}\,L \text{ ergs cm}^{-2}\text{ sec}^{-1} \qquad (3)$$

where E'_c is a representative energy of a non-thermal component (c). Again non-thermal electrons contribute most to F and we find, using the parameters following equation (1),

$$1 \times 10^{-2} \lesssim F \lesssim 3 \times 10^{-1} \text{ ergs cm}^{-2}\text{ sec}^{-1}$$

These values of F span those of Φ. Heat conduction is invoked to transport the heat from the geomagnetic tail to the polar ionosphere.

Although the accumulation of hydrogen at rates given by relation (2) usually represents far less than 1 per cent of the solar wind flux impacting on the geomagnetic field, it represents a significant rate of accumulation for the Earth. Integrated over both polar caps the fluxes are from $2{\cdot}3 \times 10^{25}$ to $4{\cdot}6 \times 10^{26}$ sec^{-1}. Averaged over the Earth, these fluxes become 5×10^6—1×10^8 cm^{-2} sec^{-1}. On their own these fluxes would change the amount of hydrogen in the atmosphere above 100 km by a factor 2 in 10^5–10^6 sec. This is unacceptable. Given that the hydrogen does not combine with oxygen and descend into the oceans, an equal amount of it must escape from the Earth. This can be achieved by charge exchange of magnetospheric plasma with hydrogen atoms in the outer atmosphere. The protons in the outer atmosphere are relatively energetic, and have energies of from 1 eV to 5 eV (refs. 1 and 9). If these protons could only be made neutral by charge exchange they would have sufficient energy to escape. The rate of charge exchange is given by

$$\mathcal{J}(\text{H}^+)\,n(\text{H})\,V\sigma(\text{H}^+ \text{ in H}) \qquad (4)$$

where $\mathcal{J}(\text{H}^+)$ is the flux of H^+, $\sigma(\text{H}^+ \text{ in H})$ the charge exchange cross-section of H^+ in H, $n(\text{H})$ the density of hydrogen atoms, V the volume of space in which charge exchange takes place. Between 2 R_E and 6 R_E altitude, the flux of protons is 10^9–10^{10} cm^{-2} sec^{-1} (ref. 1), $\sigma = 5 \times 10^{-15}$ cm^{-2} (ref. 10), $V \approx 2 \times 10^{29}$ cm^3. A flux of 5×10^{26} sec^{-1} hydrogen atoms out of the gravitational field would require $n(\text{H}) \approx 50$–500 cm^{-3}. Johnson[11] considers that this is the concentration of hydrogen atoms which does exist at sunspot minimum between 2 R_E and 6 R_E, although his argument does not take into account the charge exchange process considered here. The hydrogen escaping from the Earth consists of an amount approximately equal to the capture rate of proton–electron pairs from the solar wind together with the rate of thermal escape. Outside the shadow of the Earth these hydrogen atoms can scatter solar L_a into the night sky. The flux required to account for a significant background of intensity of night L_a is, for example, on one model[12] of the order of 10^8 cm^{-2} sec^{-1}. Charge exchange appears capable of accounting for fluxes of this order of magnitude. Moreover, about 15 per cent of the L_a of the night sky requires interplanetary hydrogen atoms with

energy in excess of about 1 eV (ref. 13) for its explanation. Clearly, these hydrogen atoms may come from the geomagnetic source suggested here, although an alternative has been suggested[14].

The theory is compatible with and constrained by sunspot minimum observations of geomagnetic plasma, red aurora, and electron densities in the polar cap F region, and night L_a. Although the four phenomena are consistent on an order of magnitude basis, the theory calls for better measurements of the parameters involved. There will be further tests of it when measurements appropriate to sunspot maximum conditions and geomagnetic quiet are available.

This research was carried out with a grant from the National Science Foundation.

Temperature Conditions of Salt Dome Intrusions

IN discussing the effect of temperature on salt dome intrusions, Dr. W. C. Gussow[1] quoted the example of salt domes in Iran, and implied not only that raised temperatures are necessary for inception of salt (halite) intrusion at depth, but that they must also be involved in the movement of salt glaciers at the surface.

Temperatures of the order required are well attested at depth by the kind of data quoted, and also by alteration of exotic blocks of igneous and other rocks in the salt in Iran, and by metasomatism and pneumatolytic action elsewhere, as in Arctic Canada[2,3]. O'Brien[4] believes movement to be begun by igneous intrusion, but this hypothesis has not been accepted as generally applicable[5,6]. Once large salt bodies have started moving, however, they remain mobile at shallow depths where temperatures are demonstrably far lower than the 200° C which Gussow regards as the limit for flow, and their movement can be traced by stratigraphical anomalies in the rocks through which they are forced. There is ample evidence of shallow movement of plugs during sedimentation, and of their occasional temporary emergence at the surface. Recent work has emphasized that the upper part of a plug is not intruded as an inert piston, but that it changes its shape in response to varying stresses while still moving through relatively shallow overburden[7].

The active surface salt plugs and salt glaciers of Iran, however, demonstrate most clearly that salt flow occurs at nearly normal temperatures. The climate of southern Iran is arid but nevertheless has a measurable rainfall, and there are numerous examples to show that if intrusion ceases the dome begins to dissolve, and eventually becomes a thickly detritus-cloaked mountain, or even an empty crater[6,8,9]. There has never been any doubt that salt mountains such as Kuh-i-Namak, near Bushire, owe their elevation (in that case 4,000 ft. above the adjacent plain level) to salt extrusion continuing to the present day. There is no thick mantle of detritus; the salt flanks are precipitous and salt avalanches are recorded. But this salt is not hot, nor is that of the salt glaciers, contrary to Gussow's implication. The glaciers are related to the modern topography and may show surface flow lines similar to those of ice glaciers. They demonstrably waste by solution so that like melting ice tongues) they attenuate distally and terminate as thin salt layers sandwiched between "moraines" of insoluble matter. Solution, soil creep and rainwash as well as glacier movement are continually active in moving the salt and its clastic content downhill; it is only by the continuing feed from the active dome above that their precipitous unstable slopes are maintained. All this takes place at temperatures which in summer may reach 46° C, but which are unlikely to be significantly higher.

Whether solid flow or the development of shear planes is the dominant element in salt movement has not been established, but it is abundantly clear that movement does take place at the temperatures occurring both at shallow depths and at the surface in tropical climates.

Possible Relationships between Continental and Oceanic Basalt and Kimberlite

BASALTIC rocks conform to two standard compositions—alkali-basalt or tholeiitic basalt. Both types of magma occur in continental as well as in oceanic areas[1], but tholeiitic basalts are much more abundant than alkali-basalts. For example, the volcanoes of Hawaii were shown to consist largely of tholeiitic basalts with only a very thin cap of alkali-basaltic rocks[1]. The same holds for the volcanic rocks of the Mid-Atlantic Ridge[2]. In continental areas the amounts of alkali-basaltic rocks are likewise very small in comparison with tholeiitic rocks.

Most authors agree that the origin of basaltic magmas must be attributed to some process of differential melting of peridotitic rocks in the upper mantle. To reach the required temperature, convection currents in the mantle are invoked by several authors[3]. The origin of alkalic and tholeiitic basalts is controversial. Yoder and Tilley's experiments[4] indicate that at pressures of more than 19 kbars, corresponding to a depth of more than 60 km, crystallization of basaltic magma produces a "high-pressure" mineralogy, that is pyrope and omphacite instead of plagioclase and augite. Settling of garnet, observed in some of their experiments, would yield a residual liquid enriched in alkalis. At depths greater than 60 km, gravitational separation of pyrope crystals from a tholeiitic basalt magma might thus produce residual magmas of alkali-basaltic compositions. Similar ideas have been expressed by Evans[5] and Holmes and Harwood[6].

As a source of basaltic magmas, Yoder and Tilley suggest widespread occurrence of garnet peridotite in the upper mantle. A more likely hypothesis, in my opinion, has recently been put forward by De Roever[7], based on

ideas of Bernal[8], and experimental work by Ringwood[9–13]. According to Ringwood, it is plausible that at very high pressures, equivalent to depths exceeding 1,000 km, forsteritic olivine will no longer be stable and will transform into a magnesium and silicon-rich spinel of higher density. This cubic "olivine" would be capable of dissolving considerable quantities of foreign elements in solid solution in its crystal lattice, for example, chromium, aluminium, calcium, sodium and volatiles. De Roever suggested that basaltic magma might originate as the fluid by-product of the decay of this spinel into forsteritic olivine, enstatite, chrome-diopside and chrome-spinel in the rising parts of convection cells in the mantle. Squeezing out and coalescence of the interstitial magma droplets formed in this way would produce magma pockets in the mantle that would, under favourable conditions, give rise to basaltic volcanism. It is possible that this magma might be of tholeiitic composition.

There is a similarity, in the type of basaltic volcanism observed in continental shield areas such as those of northern Siberia and southern Africa, and in the oceanic areas of Hawaii and the Mid-Atlantic Ridge. This re-resemblance may well indicate a similar origin of basalt volcanics in both environments. In continental shield areas as well as in oceanic areas, the volcanism of alkali-basaltic type is preceded by a long period of volcanism of tholeiitic basalts. The tholeiitic type of volcanism is characterized by a quiet and fairly continuous outpouring or intrusion of very large quantities of uniform tholeiitic basalts and, to a lesser extent, of tholeiitic differentiates. In the volcanic area of Hawaii, the initial tholeiitic basalt volcanism is gradually decreasing, and changing into a volcanism of alkali-basaltic type. This is of explosive, discontinuous and much less uniform character, comprising true alkali-basalts, melilite basalts, nepheline basalts, etc. The alkali-basaltic rocks are also characterized by peridotitic and occasionally eclogitic xenoliths. Many authors have argued that these xenoliths represent parts of the upper mantle[14–23]. So far as I am aware, peridotitic or eclogitic upper mantle xenoliths are absent in tholeiitic basalts. This may be attributed to the non-explosive character of the tholeiitic basalt volcanism, making transport of xenoliths out of the mantle impossible.

In the continental shield areas of southern Africa and northern Siberia, there is a similar early period of tholeiitic volcanism which is devoid of peridotitic and eclogitic xenoliths, and which is followed by alkali-basalt volcanism. Here, however, there is a very long period between the end of the tholeiitic volcanism and the beginning of a peculiar type of alkali-basalt volcanism. For example, in southern Africa the intrusion of the tholeiitic Karroo dolerites ceases in Lower Jurassic time, whereas it is not before Upper Cretaceous time that new volcanism starts: the highly explosive kimberlite volcanism. Similar relations are found in the shield area of northern Siberia. In this area, there is a gap from Upper Trias to Lower Cretaceous time between the end of the outpouring of the tholeiitic trapbasalts and the beginning of kimberlite volcanism.

Explosive kimberlite volcanism is an initial, extremely gas-rich phase of alkali-basalt volcanism, comparable with Maar-type volcanism[24,25], in which the alkali-basaltic magma is obviously obscured by large quantities of upper-mantle xenoliths and fragments of the crust[26,27]. Both types of xenoliths are often disintegrated into loose crystals. Most xenoliths are of peridotitic composition. As in the oceanic alkali-basalts, eclogitic xenoliths are much less abundant. According to several authors[26,27], melilite basalt is the magmatic component.

The possible genetic connexion between kimberlite volcanism and an older period of tholeiitic basalt volcanism had been put forward as early as 1920 by Du Toit[28], and seems to be accepted by many Russian authors[29,30]. As was stated by Du Toit: "It may even be suggested that this younger eruptive phase has been derived from the ultrabasic differentiate from the dolerite magma still remaining in the subcrustal reservoir . . . ."

After the short kimberlite phase, the alkali-basalt volcanism seems to have acquired a less gas-rich and less explosive character. The amounts of xenocrysts and xenoliths decrease and the nature of the magmatic component becomes more conspicuous: melilite basalts, nepheline basalts, etc. These rocks also form pipes and dykes, possibly by the expulsion of older kimberlite fillings[31]. Apparently, after the explosive opening of escape ways for the magma from the upper mantle to the surface, a more quiet outpouring of magma can take place. In many Maar-type volcanoes of the kimberlite phase, however, volcanism ceases, except for post-volcanic action causing calcification, serpentinization, etc.

The origin of tholeiitic basalt is thought to be connected with the rising convection currents in the mantle. In the areas where rising currents approach the Earth's surface, strong tensile stresses and heat-flow will affect the crust and upper mantle, giving favourable conditions for the magma to reach the surface.

If a genetic connexion between alkali-basalt volcanism and the older tholeiitic basalt volcanism is accepted (in shield areas tholeiitic basalt volcanism being very much older), it is plausible that, at the termination of a convective mantle current, pockets of tholeiitic magma remain in the upper mantle. These magma pockets cool slowly and this is especially so under continental shield areas because of the higher production of radiogenic heat in the overlying crustal material. At depths greater than 60 km they consolidate to form high-pressure minerals. Variations in temperature, pressure, form and volume of the magma reservoirs may cause alkali restmelts of widely varying compositions to develop and also possibly carbonatitic magmas. Excessive vapour pressures may build up in the reservoirs of consolidating magma. Under continental shield areas, this may give rise under favourable conditions—for instance, renewed movements in the mantle yielding deep fault zones from the upper mantle through the crust—to explosive ejection of the rest magmas, that is kimberlite volcanism. These explosions cause fragments of crust and upper mantle to be ejected with the magma. It seems feasible that the most forceful explosions and very rapid transport of mantle material through the crust cause diamonds to be brought to the surface, "frozen" in the high-pressure carbon modification.

Oceanic regions will require a much shorter period than continental shield areas for the upper mantle to cool after the termination of a convection current. Consequently, differentiation of tholeiitic magma portions in the upper mantle into residual melts of alkali-basaltic compositions should be a much more rapid process. Escape of alkali-basaltic magma through the relatively thin crust is also much easier. Explosions of the kimberlitic type apparently do not occur under these conditions, and transport of upper-mantle xenoliths by the outpouring magmas is also relatively rare. Diamonds evidently do not survive a relatively slow ascent to the surface in a hot magma.

If the conditions favourable for escape of the magma to the surface do not occur, the magma pockets in the upper mantle will finally consolidate to form eclogitic rocks or, at a depth less than about 60 km, gabbroic rocks. Only relatively small masses of eclogitic rock should therefore be present in a mainly peridotitic upper mantle. This is in accordance with the relative rarity in alkali-basalts of eclogitic xenoliths, compared with peridotitic xenoliths. Similarly, only relatively thin lenses and bands of eclogitic compositions are present in alpine-type peridotite masses, which may be considered to represent the best samples available from the Earth's upper mantle.

I thank Dr. H. N. A. Priem for helpful suggestions and discussions and for critically reading the manuscript. This work forms part of the research programme of the "Stichting voor Isotopen-Geologisch Onderzoek", sup-

ported by the Netherlands Organization for the Advancement of Pure Research (Z.W.O.).

Low Spin Ferrous Iron in the Iron Silicate Deerite

AGRELL[1] recently found a group of new minerals occurring in ferruginous cherts metamorphosed under conditions of the glaucophane–lawsonite schist facies. This metamorphic environment is characterized by a combination of pressures near 10 kbar and temperatures in the range 200°–300° C. The partial pressure of water must be high. High-pressure phases such as jadeite, lawsonite, omphacite and aragonite are found in related rocks. Deerite, one of the new minerals, is essentially a hydrated ferrous–ferric silicate. The mineral is almost opaque to visible radiation and this property suggested that the magnetic behaviour might be of interest.

Deerite was separated from a sample from the type locality, Laytonville, California. The chemical analysis is listed below in Table 1. The formula is appproximately $Fe^{2}_{13}Fe^{3}_{7}Si_{13}O_{44}(OH)_{11}$ with minor substitution of titanium and aluminium for ferric iron and manganese for ferrous iron.

The inverse magnetic susceptibility is shown as a function of temperature in the range 80°–300° K in Fig. 1. The susceptibility is independent of field strength between 2,500 and 6,500 G over the temperature range studied. But the marked deviation from Curie–Weiss law behaviour suggests that ferromagnetism might be observed at lower temperatures. It is hard to suggest an alternative explanation for the temperature dependence of the susceptibility but some field dependence would be expected at lower temperatures if the system is ferromagnetic.

The observed susceptibility per formula unit (that is, 20 iron atoms), corrected for diamagnetic components, is $147{,}700 \times 10^{-6}$ c.g.s. units at 295° K. Expected susceptibilities for various configurations are summarized in Table 2 and no high spin arrangement will account for the observed susceptibility.

Table 1

Chemical analysis		Formula based on 55 oxygen atoms	
SiO_2	32·95	Si	13·02
TiO_2	0·19	Ti	0·06
Al_2O_3	0·19	Al	0·09
Fe_2O_3	22·81	Fe^3	6·78
FeO	35·24	Fe^2	11·64
MnO	4·00	Mn	1·34
MgO	0·08	Mg	0·05
CaO	0·15	Ca	0·06
Na_2O	—	OH	10·87
K_2O	—	O	44·13
H_2O^+	4·12		
H_2O^-	0·10		
Total	99·79		

Table 2

Configuration	$10^6 \times$ Susceptibility at 295° K		
	Fe^3	Fe^2	Formula unit
High spin, octahedral	14,700	10,200	235,500
Low spin, octahedral	2,250	0	15,750
High spin, tetrahedral	14,700	11,000	245,900

As there is no evidence for antiferromagnetic behaviour, it may be concluded that some of the ions present are in a low spin configuration. It has been suggested[2] that ferrous ions will assume a low spin configuration at lower ligand field strength than ferric ions. This assumption would suggest that of the thirteen ferrous ions about four are in the high spin configuration, perhaps due to a distribution between octahedral and tetrahedral sites. This must be considered an approximation and further refinement would require knowledge of the crystal structure. It seems certain that a range of sites for the M^2 cations will be found in the structure.

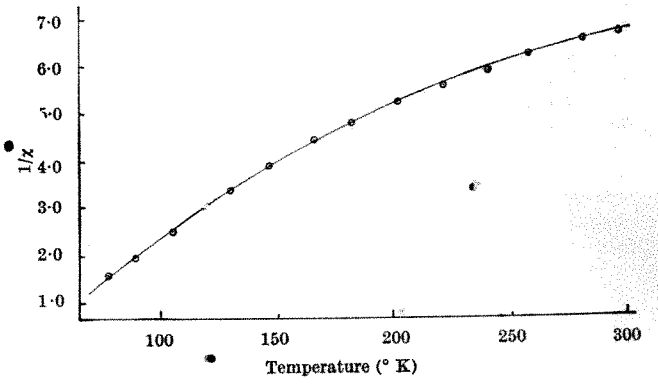

Fig. 1. Temperature dependence of inverse susceptibility of deerite. Units shown correspond to observed pull on the sample.

Deerite is a moderately dense substance in the sense that reactions between silicates and oxides leading to deerite indicate a large negative volume change. This would be expected on the basis of a small low spin ferrous ion. It is also possible that π interaction is enhanced with shorter bond distances and may account partly for the anomalous optical properties. The magnetic properties show that low spin ferrous iron in oxygen co-ordination does not require extreme pressures and leaves little doubt that olivine or spinel phases in the mantle of the Earth will contain iron in this diamagnetic state as previously suggested[3].

ENGINEERING

Effect of Polymer Additives on Boundary Layer Separation and Drag of Submerged Bodies

THIS communication describes a simple experiment which demonstrates that in some circumstances the use of polymer additives can increase drag owing to a change in the position of boundary layer separation which results in a change of wake size and thus form drag.

Recently, there has been considerable interest in the turbulence damping properties of certain long chain polymers when dissolved in water. It has been found that very small traces in solution can reduce turbulent friction by a very significant amount and drag reductions of more than 50 per cent are possible by the addition of just a few parts per million by weight of the polymer[1,2].

The large drag reduction produced by these visco-elastic polymer solutions is being considered for practical application in many fields. The effect has already been made use of in certain aspects of oil field technology and experiments are at present being carried out with the view of using it in marine technology[3] in the testing of ship models[4].

If we consider flow around a submerged surface, flow separation is likely in a region of adverse pressure gradient and the point of separation will depend on whether the boundary layer is laminar or turbulent—the separation point being nearer to the leading edge with a laminar boundary layer.

For this experiment a concrete sphere 7·75 in. in diameter was dropped into a 'Perspex' sided tank which contained either water or dilute poly (ethylene oxide) solution ('Polyox' *W.S.R.* 301), and the wake pattern was recorded by high speed ciné photography. A comparison of the drag coefficients has also been obtained by analysis of the film record.

The sphere was first made hydrodynamically smooth by careful rubbing down and painting and was then dropped into water from a suitable height so that the average Reynolds number was just below the critical value ($\rho Vd/\mu < 2 \times 10^5$). The wake is shown in Fig. 1, which indicates a laminar boundary layer with characteristic early separation.

The front of the sphere was then roughened by glueing on a patch of sand, and the sphere was again dropped into the water from the same height. Fig. 2 shows the wake pattern from this test which exhibits a much later separation point caused by the turbulent boundary layer. The drag coefficient was about half the value found from the previous test. These results are well known and are described in any standard fluid dynamics text[5].

For the third test the roughened sphere was dropped into a solution of 'Polyox' (60 parts per million by weight). Fig. 3 shows that the polymer additive has suppressed turbulence in the boundary layer and caused the separation point to move forward again with a resulting increase in form drag. The drag coefficient was about the same as for the first test.

It is therefore seen from this rather basic experiment that although polymer addition can significantly reduce skin friction, the effect can in certain circumstances be more than offset by an increase in form drag caused by a change in the separation point and wake size.

The effect was anticipated by Gadd[6] and could lead to difficulties with tests of ship models in polymer solution.

Particle Migration in Cone-plate Viscometry of Suspensions

VISCOMETERS with a cone and plate configuration are often used for viscosity measurements on non-Newtonian fluids, and for suspensions provided that a particle cone truncated near its open end is used. In the latter case it has been assumed that radial motion of particles occurs too slowly to affect the accuracy of the measurements involved.

Recently, however, while investigating the behaviour of suspensions of spherical particles in certain non-Newtonian fluids using a cone and plate viscometer, rapid radial migration of the suspended solids was observed at low cone speeds (up to 40 r.p.m. corresponding to a shear rate of 184 sec^{-1}). Significant migration was observed after shearing for only 5 min whereas centrifugal

Fig. 2.

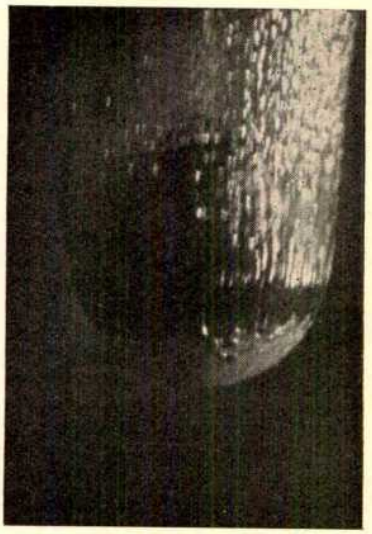

Fig. 3.

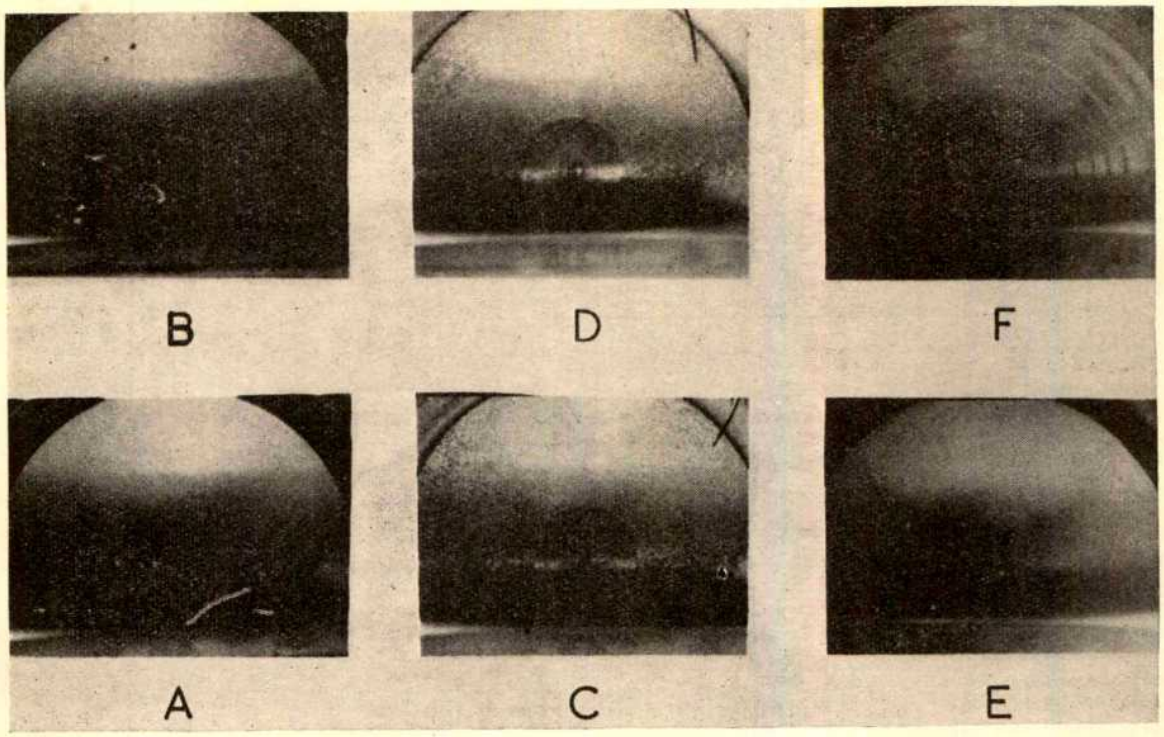

Fig. 1. Suspensions of 'Kallodoc' in: *A* and *B*, a Newtonian fluid, 'Rheoplex 200', before and after shearing for 30 min. *C* and *D*, in a non-Newtonian fluid with only small normal stress effects, 3 per cent sodium-carboxy-methyl cellulose in water, before and after shearing for 30 min. *E* and *F*, in a non-Newtonian fluid producing large normal stress effects, a 10 per cent solution of poly-iso-butylene in 'Tetralin', before and after shearing for only 5 min.

forces would require many hours to produce comparable effects.

The apparatus used was a Ferranti-Shirley cone and plate viscometer with a particle cone 2 cm in radius and of 0·0228 radians gap angle. The instrument was modified to accept a glass prism in place of the lower instrument plate so that observations of the distribution of particles were possible during shearing.

Fig. 1 shows the comparative effects of shearing suspensions of 'Kallodoc' spheres, about 100μ diameter, in three media at 138 sec^{-1}. The extended periods of shearing produced only minimal effects on the distribution of particles present in the control experiments, while in the poly-iso-butylene a marked clearance of the cone area is apparent.

Numerous tests[2] on the poly-iso-butylene solution indicated certain general features of the phenomenon. First the particles, initially at a uniform concentration of 9 per cent by volume, fell into distinct circular rings of high particle density (~25 per cent by volume) within seconds of the start of the shearing motion. Second, the whole particle population (whether free or in the rings) migrated towards the outer edge of the cone at a rate which increased with the rate of shear resulting in complete clearance of the cone area within 20 min at 30 r.p.m. (134 sec^{-1}). Finally, in control experiments using 'Rheoplex' and sodium-carboxy-methyl-cellulose no appreciable clearance resulted during long periods of shearing (up to 60 min), thus directly eliminating centrifugal effects, or non-linearity of the flow curve, as a primary cause of this phenomenon.

A theory for the overall radial migration of the particles has been developed in terms of the effect on a single particle of the normal stress gradient $\left(\frac{\partial p_{33}}{\partial T}\right)$ present in a cone and plate system during the shearing of a normal stress producing material such as poly-iso-butylene solution[3]. This approach led to a successful prediction of the overall clearance time and its dependence on the rate of shear; however, the mode of formation of the rings remains obscure, and is not accounted for by the present theory.

The effect of the migration of particles was to produce a fall in the measured value of the apparent viscosity of the suspension by up to 10 per cent of its initial value, in the first moments of shearing at a constant rate of shear. The pure solutions used as the liquid phases in this work did not exhibit any such change of apparent viscosity with time of shearing and the entire effect resulted from particle motion.

Many materials with complex rheological properties show a similar drop in apparent viscosity (at a constant rate of shear) during the first moments of shearing. For this reason, in work which involves suspensions and cone and plate measuring systems it is essential to distinguish between changes in apparent viscosity resulting from transient effects in the base fluid and a re-distribution of the suspended solids.

THE SOLID STATE

Direct Solution of Organic Crystal Structures from Molecular Packing Considerations

A LARGE body of information on bond lengths and angles, and on intra- and inter-molecular contact distances has been amassed. Because of this, and because high speed computers are now available, the solution of crystal structures without diffraction data (except for the

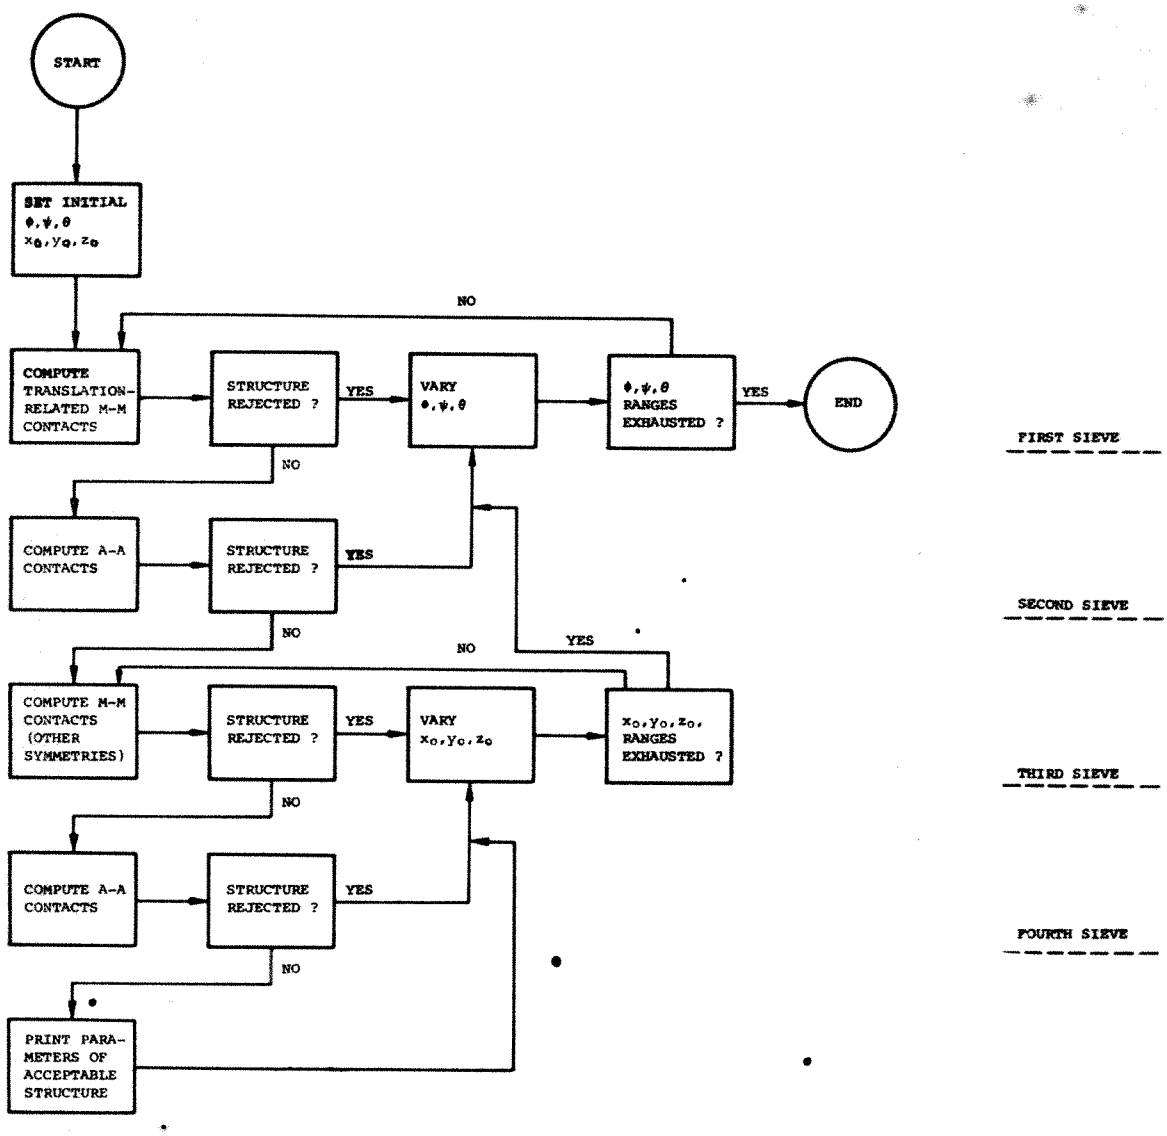

Fig. 1.

crystallographic constants of the unit cell) is an interesting challenge[1]. We wish to report some experience with a FORTRAN computer programme (SEARCH) currently being developed[2,3] which has successfully tackled this task in several instances.

We define the model of the generating unit (which as, for example, in centrosymmetrically paired carboxylic acids need not be identical with the asymmetric unit of the unit cell) by specifying its atomic co-ordinates in an orthogonal molecular system, M_i, preferably the system defined by the three principal axes of inertia of equally weighted atoms. The crystal structure is now defined by (*a*) the orientation of M_i with respect to the unit cell edges, (*b*) the position in fractional co-ordinates (x_0,y_0,z_0) of the origin of M_i in the unit cell, and (*c*) the space group symmetry elements operating on the generating unit. The orientation of the M_i system in the unit cell may be conveniently defined by the use of three Eulerian angles (φ,ψ,θ) specifying the rotation of M_i with respect to another, auxiliary, orthogonal system L_i fixed in the unit cell.

By stepwise variation of the six parameters $(x_0,y_0,z_0, \varphi,\psi,\theta)$ and by applying the symmetry operations on the generating unit we derive a set of trial structures. An acceptable solution is defined as a structure that involves no inter-atomic contact shorter than a preset minimum.

In order to reduce computations to reasonable dimensions, a sieving procedure was adopted which handles the entire molecule, rather than the atoms, as the fundamental unit for contact calculations; the molecules are treated as rectangular parallelopipeds or ellipsoids. For an initial orientation, the molecule-to-molecule contacts are computed between the generating unit and its translation-related neighbours in order of successive proximity to the former up to a preset radial distance determined by the dimensions of the unit. These distances depend solely on the orientation of the unit and not on the position (x_0,y_0,z_0) of its origin. An orientation is rejected if the interpenetration of the units for that orientation is deeper than a preset minimum. Rejection bypasses the scan of the (x_0,y_0,z_0) parameters; if the orientation has passed this first coarse sieve, actual interatomic contacts are computed for atoms of translation-related units. An interatomic contact shorter than a preset value leads to rejection and to stepped changes of the angular settings. If the orientation has passed this second sieve, molecular contacts across other elements of symmetry are computed. Because these contacts are dependent on (x_0,y_0,z_0) a scan with stepped changes in these co-ordinates is executed. (Obvious restrictions by symmetry elements on space occupancy reduce the volume of the unit cell to be scanned.) If no position of

‡ Limited precession around the normal to the very strongly reflecting (201) plane.
§ After least-squares refinement.

the molecular centre survives this sieve the orientation of the generation unit is changed, and the programme repeats the cycle described. Alternatively, all interatomic contacts are computed. The parameters of a structure model, resulting from this final sieve, with contacts not less than the preset minima, are printed.

The flowchart of the programme is shown in Fig. 1. The input consists of: (1) unit-cell information (cell constants, symmetry operations; definition of the auxiliary co-ordinate system L_t); (2) information on the generating unit (co-ordinates of all atoms, including hydrogens, in the inertial system; dimensions of the molecular envelope; (3) contact information (maximum molecular penetration; minimum interatomic distances); (4) parameter information (intervals and ranges to be varied, the latter determined by the symmetries of the generating unit and of the unit cell[3]). Minimum interatomic distances are given for pairs of atoms rather than computed as sums of individual atomic radii so as to allow for contacts not necessarily of the van der Waals type, such as polar (hydrogen) or ionic bonding. The values to be used as preset contact minima are correlated with the degree of uncertainty in the assumed molecular model and with the size of intervals in the search parameters. Restrictions on molecular orientation other than those mentioned so far have been used in compounds crystallizing in unit cells having short axes (4 Å) or showing outstandingly heavy reflexions.

We have found experimentally that 80 per cent van der Waals radii, and steps of 9° in φ,ψ,θ, and of 0·4 Å in (x_0,y_0,z_0), yield a limited number of solutions, including the correct crystal structure, within reasonable time on the *GOLEM* computer of the Department of Applied Mathematics of this Institute.

Table 1 lists the structures that have been solved *ab initio* by this technique. We have not given the number of spurious solutions nor the computing times required for each of these structures as these change with the procedure adopted and with the continued improvements now being made; of the two cinnamic-acid structures the β-methyl derivative gave one correct and one spurious solution, and the *o*-methoxy acid only the correct solution, both in a matter of 60 min. The individual structure analyses will be reported elsewhere.

We have developed this programme for several fields of applications: first, in our studies[4] of the topochemical control of organic solid-state reactions we required information on the molecular packing arrangement and the contact geometry of functional groups. Second, in order to be able to vary and thus to control this contact geometry we are analysing the crystal structure types of organic molecules having common functional groups (for example, $-CO_2H$, $-CONH_2$, $-CN$, $-NO_2$). Third, we are investigating in a related study the problem of limited polymorphism within chemically related molecular types[5], for example, $Ar(CH:CH)_n.CO_2H$ (where Ar = phenyl substituted by halogen, alkyl, alkoxyl, nitro, groups; n = 0,1). These problems can be attacked by structure analyses accurate enough to supply packing data to within 0·02 Å; because we consider that limited diffraction data are adequate for this purpose particularly when, as in our situation, collection of (photographic) data is the decisively limiting factor, a programme based on molecular rather than diffraction data seemed to us a desirable addendum to existing crystallographic techniques.

In a further extension of the procedure outlined we intend to discard fixed contact distances and to introduce interatomic potential energy functions[6,7].

We thank Drs. Bart, Coppens, Hirshfeld, Leiserowitz, and Shmueh for intensity data of some of the structures listed, and for suggestions concerning the molecular configuration of the input models. We are grateful to Prof. C. L. Pekeris and members of the Computing Laboratory of the Applied Mathematics Department of this Institute for time on the *CDC* 1604 *A* and the *GOLEM* computers.

F values were derived from observed intensities. The signs of the values of allevardite were assigned from the probable structure (ref. 1).

of 60–120 atm. for 2–3 h. The mean heating rate was about 2° C per min. The autoclave was then allowed to cool in air at a mean cooling rate of 0·5° C per min. When the material in the crucibles had cooled to room temperature it was immediately washed with distilled water in order to remove any water-soluble materials. The residue was examined by X-ray crystallography and other mineralogical techniques.

As a result of these examinations, it was evident that various kinds of complex clay minerals had been formed together with alunite. These included minerals with interplanar spacings of 30, 25, 15, 9 and 7 Å. This communication is concerned with the 25 Å mineral.

Usually, the 25 Å mineral was formed together with the 15 Å mineral and alunite, and was the main component when aluminium sulphate and magnesium carbonate were used in the proportions 0·5 : 0·08.

The following properties are noteworthy: (*a*) The long spacing was particularly sensitive to the surrounding humidity. In cold dry weather there is a 23–25 Å reflexion which is relatively weak compared with the second order reflexion. In wet warm weather a strong 25–27 Å reflexion is apparent. When the spacing was 25 Å, a complete series of orders of this reflexion could also be observed as shown in Table 2. (*b*) Treatment of this sample with ethylene glycol resulted in the 25 Å and 12·5 Å reflexions being replaced by weak reflexions at 27 Å and 13 Å, and an extremely strong 17 Å reflexion became apparent. (*c*) Treatment with 1 N potassium chloride led to the 25 Å and its second order reflexions being almost entirely replaced by a 10 Å reflexion. (*d*) The chemical composition of this sample is as shown in Table 1 (2). Subtracting the chemical composition of alunite the following formula for the 25 Å mineral was obtained:

$$(Mg_{0\cdot57}Ca_{0\cdot25}(Na,K)_{0\cdot24})(Al_{3\cdot65}Fe_{0\cdot18}Mg_{0\cdot17})(Si_{6\cdot28}Al_{1\cdot72})O_{20}(OH)_4$$

(*e*) The electron micrograph of this sample showed that the original shape and size of the parent mica flakes were still well preserved and gave a hexagonal pattern by electron diffraction. Patches of alunite were also present.

These data indicate that although the 25 Å mineral is similar geometrically it is quite different dynamically from the regular mixed-layer mineral of the 15 Å and 10 Å layers because both of these are expandable.

Table 2 shows *F*-values which were derived from intensities by the factor $(1 + \cos^2 2\theta)/\sin 2\theta$, which is a valid procedure because the specimen was formed on a slide glass at the optimum orientation. These *F*-values are close to those of allevadite[1], which has been shown to be identical to rectorite[2].

When potassium alum ($KAl(SO_4),12H_2O$) (0·025 g–0·1 g) was added to the sample together with aluminium sulphate and magnesium carbonate, the X-ray behaviour of the 25 Å mineral approached that of the natural regular mixed-layer mineral, mica-montmorillonite. This suggests that potassium ions inhibit the expansion of the 10 Å layers.

Similar results were obtained when flakes of muscovite or phlogopite (1 *M* type) were used as the starting materials. It would seem that magnesium carbonate plays an important part in providing favourable conditions for the formation of 15 Å, 25 Å and 30 Å minerals from the dioctahedral micas. These minerals were successfully formed, however, from phlogopite even without magnesium carbonate. The use of magnesium oxide or magnesium sulphate instead of magnesium carbonate did not provide conditions favourable for the formation of the 25 Å mineral from the dioctahedral micas.

CHEMISTRY

Structural Changes in Poly-β-benzyl-L-aspartate

DIFFERENTIAL thermal analysis has been applied over a wide field in the study of thermally induced structural changes in polymers[1]. This communication reports the application of this technique to an investigation of such changes in poly-β-benzyl-L-aspartate. It is generally recognized that polypeptides can form crystalline, helical structures in the solid state, in particular the α-helix of Pauling, Corey and Branson[2]. The stability of such a helix depends on a number of factors, in particular the nature of the side-chain[3], and the degree of polymerization of the molecule[4]. Of particular interest is poly-β-benzyl-L-aspartate, which adopts a relatively unstable left-handed α-helical conformation in the solid state, at room temperature. It has been suggested that the preferential formation of the helix with this anomalous sense results either from steric interference between the side-chain and the main-chain atoms[5,6], or from the competitive hydrogen bonding between the ester carbonyl groups of the side-chain and the amide groups of the main-chain[7], which precludes the formation of the more common right-handed helix. In this investigation, changes in the heat-energy of the polymer when heated at a constant rate were followed by differential thermal analysis and were correlated with structural changes, characterized by X-ray diffraction and infra-red spectroscopic methods.

The sample used was obtained from Yeda Research and Development Co., Rehovoth, Israel, and had a molecular weight of about 5,000 (lot *AS*10). The thermogram obtained using a DuPont 900 differential thermal analyser is shown in Fig 1. The double exothermic peak at about 100° C, and the endotherm at about 180° C divide the thermogram into three regions, *A*, *B* and *C*. Neither peak is observed on cooling from *B* or *C*, or on reheating the polymer from room temperature.

The X-ray diffraction powder photograph of the unheated polymer can be identified from its three clearly defined rings; but after heating to the temperature of the exotherm the pattern changes and many more reflexions become obvious. This diagram is further replaced by one with two sharp rings as soon as the temperature of the endotherm is exceeded. The many spacings exhibited by the sample after it had been heated to temperatures between those of the two peaks could be indexed on a tetragonal cell, with $a = b = 13{\cdot}8$ Å, $c = 5{\cdot}42$ Å, and we

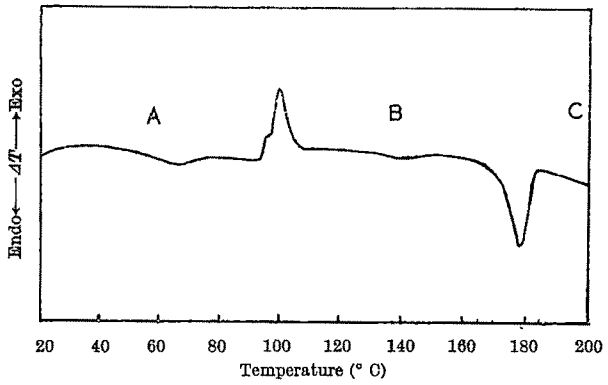

Fig. 1. Thermogram of poly-β-benzyl-L-aspartate. Heating rate 10° C/min. Sample *in vacuo*.

associate this pattern with the ω-helical conformation of the polymer. This value for the axial repeat is greater than that found by Bradbury *et al.*[6]; it is, however, not so high as that observed in the ω-form of poly-S-benzyl-thio-L-cysteine[8].

Corroborative evidence for the existence of the intermediate ω-helical state was obtained from the infra-red spectra (using the potassium bromide disk technique) of samples which had been heated to temperatures in the regions *A*, *B* and *C*. The specimens gave strong absorption bands at the frequencies indicated in Table 1. From these results it seems that the exotherm results from the transition of the polymer from the α- to the ω-helical conformation, with subsequent crystallization on a tetragonal lattice. The appearance of a sharp band at 1,639 cm^{-1} in samples heated above the temperature of the endotherm suggests that this is associated with the conversion to the cross-β conformation[4], with the formation of inter-chain hydrogen bonds.

Table 1. INFRA-RED ABSORPTION FREQUENCIES (cm^{-1})

Region	Ester C=O	Amide I	Amide II	Aromatic C—C
A	1,739	1,664	1,549	1,501
B	1,733	1,669 1,677	1,539	1,502
C	1,726	1,639 1,703 (weak)	1,528	1,501

Differential thermal analysis would thus seem to be a promising technique for the investigation of the relative stabilities and heats of transition of polypeptide structures in the solid state. Results so far seem to indicate that the stability is highly dependent on the crystallinity and the molecular weight of the sample.

We thank the Wool Textile Research Council for financial support during the course of this investigation.

Detection of Thorium-234/Protactinium-234*m* in Sediments from the Ribble Estuary, Lancashire, England

SAMPLES of silt and sand are collected regularly from the estuary of the River Ribble as part of the programme of environmental monitoring conducted by the Ministry of Agriculture, Fisheries and Food to measure the distribution of radioactivity discharged into the Irish Sea. This discharge occurs from the United Kingdom Atomic Energy Authority's factories at Windscale (in Cumberland), and Springfields (in Lancashire).

Gamma spectrometric analyses of the dried samples collected in October 1965 showed γ-photons at 1·47 MeV from naturally occurring potassium-40, and at 0·51, 0·62, and 0·75 MeV from ruthenium/rhodium-106 and zirconium/niobium-95 from the Windscale factory discharges. A further γ-photon at 1·00 MeV was detected in some of these samples, notably in the sample collected near the mouth of the Springfields factory effluent pipeline, as shown in Fig. 1. Although ruthenium-106 emits a γ-photon at 1·06 MeV, the abundance of the emissions at 1·00 MeV exceeded those expected from ruthenium-106 alone, and the presence of protactinium-234*m*, which emits γ-photons with energies of 0·76 and 1·00 MeV, was suspected; this isotope is part of the uranium $(4n+2)$ series

$$^{238}U \xrightarrow[4.5\times10^{9}\text{ years}]{\alpha} {}^{234}Th \xrightarrow[24\cdot1\text{ days}]{\beta} {}^{234m}Pa \xrightarrow[1\cdot18\text{ min}]{\beta} {}^{234}U \xrightarrow[2\cdot5\times10^{5}\text{ years}]{\alpha} \text{etc.}$$

(Branch to ^{234}Pa)

Confirmation of the presence of protactinium-234*m* was obtained in two ways: first by comparison of the γ-spectrum obtained from the sample with that of a standard of pure uranium (in equilibrium with thorium-234 and protactinium-234*m*) distributed on sodium phosphate; and secondly by a chemical separation of thorium from the sample. This separation involved leaching the ignited silt with 5 M nitric acid and passing the acid extract through 'Dowex 1' anion exchange column in the nitrate form. After thorough washing with 5 M nitric acid to remove uranium and other metals, the thorium was eluted with 0·2 M nitric acid[1,3]. The γ-spectrum of this eluate contained the two peaks corresponding to γ-photons at 0·76 and 1·00 MeV from protactinium-234*m* and was identical with a γ-spectrum of thorium-234 separated from pure uranium (Fig. 2); the decay of this eluate was followed and the half life was found to be 25·3 days,

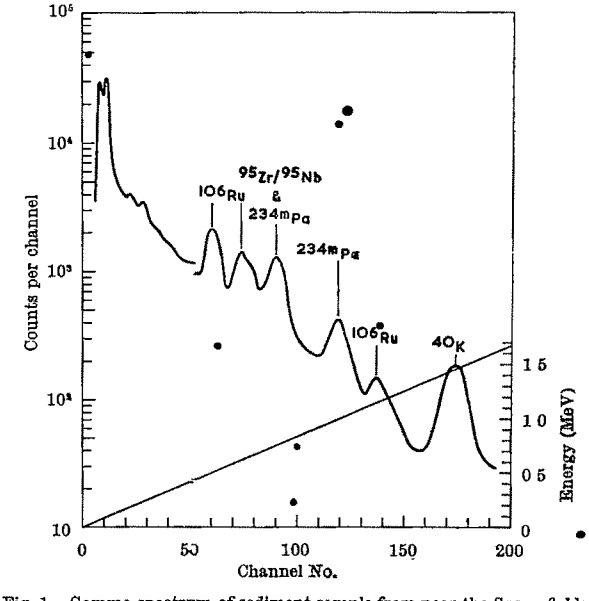

Fig. 1. Gamma spectrum of sediment sample from near the Springfields effluent pipeline.

Table 1

	Yards upstream of effluent pipeline					Yards downstream of effluent pipeline			
	12,500 (Samlesbury)	3,000	1,000	550	Effluent pipeline	100	1,000	5,500	12,000
Thorium-234 pCi/g dry	>300	700	1,280	680	1,450	>300	>300	>300	>300
Ruthenium-106 pCi/g dry	>1	39	57	28	20	12	32	52	41

confirming the presence of thorium-234 (half life 24·1 days).

The decay of the 1·00 MeV γ-photon in the original sample was also followed and the measured half life was about 28 days. The protactinium-234*m* in the sediments is therefore associated with thorium-234 and not with uranium-238.

Sediments which contain naturally occurring uranium normally emit γ-photons characteristic of the whole of the $(4n+2)$ series and additionally uranium-235. The γ-spectrum of such a sample, from the River Ribble above the tidal limit at Samlesbury, is shown in Fig. 3. In addition to photopeaks from fall-out nuclide γ-emission (cerium/praseodymium-144, antimony-125 and ruthenium/rhodium-106) and potassium-40, peaks corresponding to γ-photons with energies of 0·185 MeV from uranium-235, 0·242, 0·295 and 0·342 MeV from lead-214, and 0·610 MeV and other higher energies from bismuth-214 can be seen. These γ-photons are only just discernible in the Ribble estuary sediments where protactinium-234*m* occurs, so

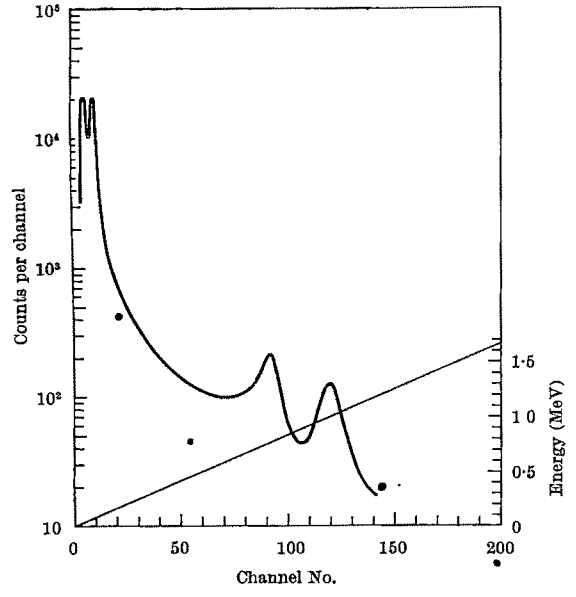

Fig. 2. Gamma spectrum of thorium extract.

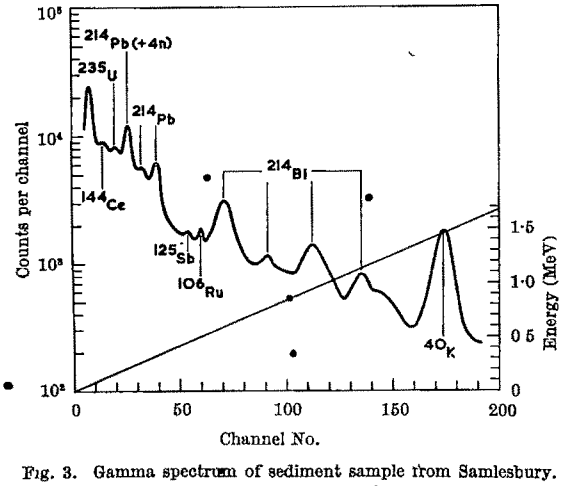

Fig. 3. Gamma spectrum of sediment sample from Samlesbury.

the thorium-234 in these samples is not associated with radium-226 and its daughters.

The probable source of the thorium-234 is the Springfields factory, where it arises as a result of uranium purification by a solvent extraction process and is subsequently discharged in the effluent in accordance with authorizations issued by this Ministry and the Ministry of Housing and Local Government.

Comparison of the count rates obtained from the samples with those from standards indicated the levels of thorium-234 and ruthenium-106 in the silts at the time of collection (Table 1).

Although ruthenium-106 occurs throughout the estuary, in this survey thorium-234 has been detected only between the Springfields factory pipeline and the upper tidal limit. This distribution may be due to the heavy dredging of the estuary; levels of radioactivity are of course affected by the dredging history of an area, and a later survey (carried out in March 1966) indicated the presence of thorium-234 downstream of the pipeline mouth. All these activity concentrations are considerably less than those which could result in a significant radiation dose to people or to marine organisms.

I wish to thank Mr. C. Barker and Mr. J. Robson for collecting the samples, and Mr. B. Harvey for carrying out the chemical separations.

Effect of Excess Energy on the Reactivity of Methylene

ALTHOUGH earlier work had suggested that the species methylene, CH_2, could participate in "insertion" reactions into C—H and C—Cl bonds[1,2], it has recently been shown that in the gas phase reaction of methylene with methyl chloride the course of reaction is best described by a radical abstraction–recombination mechanism[3,4]. It was shown that both ethane and dichloroethane appeared at rates at least as great as the rate at which ethyl chloride (the true "insertion" product) was formed in the reaction. The electronic state of the methylene may, however, determine the reaction path, and there is some evidence that it is excited singlet methylene which undergoes the insertion reaction[5,6]. Methylene is most conveniently prepared by the photolysis of ketene[7] or diazomethane[8], and the proportion of triplet (ground state) and singlet methylene formed depends on the precursor and the wave-length of the radiation used for photolysis[9,10], more singlet being formed at shorter wavelengths. We wished to investigate the effect of change of excess energy in methylene on the course of reaction, and we present here preliminary results.

Ketene was used as the source of methylene, and was prepared as previously described[3]. Ultra-violet radiation was derived from a 125 W *MB/D* high pressure mercury vapour lamp, and was incident on a quartz reaction cell maintained at 25° C. The wavelength region 2500–3400 Å was isolated by means of a chance *OX*7–nickel sulphate solution filter, while the region 3000–3650 Å was obtained by use of a glass filter (the optical absorption of ketene[11]

Table 1. RELATIVE RATES OF FORMATION OF ETHANE AND ETHYL CHLORIDE AT VARIOUS TOTAL PRESSURES

Total pressure (cm of mercury)	$\lambda = 2500$–3400 Å $d[C_2H_6]/d[C_2H_5Cl]$	$\lambda = 3000$–3800 Å $d[C_2H_6]/d[C_2H_5Cl]$
2·6	5 0	2·4
7·8	3·0	1·7
10 4	2 8	1·8
13·0	2 0	1·1
26·0	1·1	0·9
52 0	1 1	0·8

defined the longer wavelength limit). A reaction mixture of 5 parts ketene to 8 parts methyl chloride at various total pressures was photolysed in each wavelength region. The products formed were analysed by vapour phase chromatography.

Since ethane can be formed only by a radical mechanism, while ethyl chloride could be formed by insertion (although we believe it is not), the relative rates of formation of these two products are of significance. Table 1 shows the function $d[C_2H_6]/d[C_2H_5Cl]$ at a number of different total pressures in the two wavelength regions. Ethylene, dichloroethane and vinyl chloride, together with smaller amounts of methane and dichloromethane, were detected in addition to ethane and ethyl chloride. Experiments were carried out with the light intensity reduced by a factor of nine: the relative rates of ethane and ethyl chloride formation were unaffected. Thus the wavelength used for the photolysis does alter the product distribution, and the effect cannot be ascribed to differing absorbed intensities in the two spectral regions. It is seen that the rate of formation of ethyl chloride never exceeds significantly that of ethane, and that the ratio $d[C_2H_6]/d[C_2H_5Cl]$ is in general higher in the shorter wavelength region. Such a result is in direct contrast with that expected on the basis of the insertion theory, since singlet methylene—the species believed to insert[5,6]—is formed preferentially at shorter wavelengths[9,10].

A satisfactory interpretation of the results may be made in terms of the radical abstraction theory, if the exothermic (about 90 kcal/mole) recombination of methyl and CH_2Cl radicals produces a "hot" molecule of ethyl chloride which may either be quenched, or undergo a unimolecular decomposition to ethylene and hydrochloric acid (a process which requires about 55 kcal/mole). The only decomposition for ethane is the direct dissociation to two methyl radicals, a process not thought to be important under our experimental conditions. Setser gives a review of these processes[4]. Thus, for the formation of ethylene, ethane and ethyl chloride, our simplified reaction scheme (omitting abstraction reactions of the radicals) is

$$CH_2CO + h\nu \rightarrow CH_2 + CO \quad (1)$$

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad (2)$$

$$CH_2 + CH_3Cl \rightarrow CH_2Cl + CH_3 \quad (3)$$

$$2CH_3 \rightarrow C_2H_6 \quad (4)$$

$$CH_3 + CH_2Cl \rightarrow C_2H_5Cl^* \quad (5)$$

$$C_2H_5Cl^* + M \rightarrow C_2H_5Cl \quad (6)$$

$$C_2H_5Cl^* \rightarrow C_2H_4 + HCl \quad (7)$$

The recombination of two CH_2Cl radicals gives rise similarly to "hot" dichloroethane which may be quenched, or decompose giving hydrochloric acid and vinyl chloride (observed product).

It is apparent that the rate of decomposition of $C_2H_5Cl^*$ in (7) depends on the wavelength used to photolyse the ketene, and this suggests that the excess energy carried by the methylene is transferred to the methyl or chloromethyl radicals. At least at the lowest pressures used by us, the radicals cannot become "thermalized" before recombination, as otherwise the wavelength of photolysis would not affect the $d[C_2H_6]/d[C_2H_5Cl]$ ratio; however, at the higher pressures the radicals may reach thermal equilibrium before they recombine. The excess energy of the methylene which is carried over to $C_2H_5Cl^*$ may be in the form of the electronic excitation known to occur, but it may equally well be that vibrational or translational excitation is important in the present connexion. The experimental data do not permit us to reach a conclusion about the mode of excitation. The effect of total pressure on the ratio is also easily understood: increase in pressure leads to greater stabilization of $C_2H_5Cl^*$ in (6). The ratio should, therefore, tend to a limiting value dependent on the rate constants, k_4, k_5 of (4) and (5) (our limiting ratio of ~ 1 suggests that if $[CH_3] \sim [CH_2Cl]$, then $k_4 = 2k_5$).

The hypothesis that $C_2H_5Cl^*$ needs to be quenched may be tested by adding an "inert" gas under conditions where $C_2H_5Cl^*$ would otherwise decompose to a considerable extent. We made up to 1 atm. with nitrogen or carbon dioxide a reaction mixture at a total pressure of 2·6 cm of mercury, and photolysed it by light of the shorter wave-length region. The ratio $d[C_2H_6]/d[C_2H_5Cl]$ dropped from 5·0 without the gas to 1·9 with nitrogen and 1·4 with carbon dioxide, which is entirely consistent with the mechanism proposed.

Thermochemical Data Storage for Inorganic Compounds

THE method proposed by Alcock[1] as a means of correcting an approximate free-energy change calculated from the simple two-term equation

$$(\Delta G^\circ_T)_{\text{approx.}} = \Delta H^\circ_{298} - T\Delta S^\circ_{298}$$

leads to a system of thermochemical data storage which possesses many advantages over the free-energy function and polynomial methods. This "free-energy deviation" does not, however, allow for transformations or changes in state of reactants and products, whereas in many processes the standard free-energy change would be required for examples such as

$$M_{(l)} + O_{2(g)} = MO_{2(l)} \quad (1)$$

$$M_{(c)} + 2Cl_{2(g)} = MCl_{4(g)} \quad (2)$$

to provide the basis for calculating equilibrium activities in solution and equilibrium partial pressures in a vapour phase. It is immediately apparent that the heat and entropy changes associated with such transformations must be taken into account and for reaction (1), where it is assumed that the solid state represents the normal equilibrium form of the metal and its oxide at 298° K, an approximate free-energy change is given by

$$(\Delta G^\circ_T)_{\text{approx.}} = \Delta H^\circ_{298} - \Delta H_{f,M} + \Delta H_{f,MO_2} - T(\Delta S^\circ_{298} - \Delta S_{f,M} + \Delta S_{f,MO_2})$$

For many purposes this approximate free-energy change is sufficient, but in the terms in which it is written it

cannot be combined with one or more free-energy deviation functions to give a true value for the change in free-energy.

To demonstrate this, consider the reaction

$$M_{(l)} + O_{2(g)} = MO_{2(c)} \quad (3)$$

at a temperature T °K > T_1° K, the melting point of the metal M. The true change in free-energy is given by

$$\Delta G^\circ_T = \Delta H^\circ_{298} - \Delta H_{f,M} + \int_{298}^{T_1} \Delta Cp_1 dT + \int_{T_1}^{T} \Delta Cp_2 dT$$

$$- T\left[\Delta S^\circ_{298} - \Delta S_{f,M} + \int_{298}^{T_1} \frac{\Delta Cp_1}{T} dT + \int_{T_1}^{T} \frac{\Delta Cp_2}{T} dT\right]$$

where ΔCp_1 and ΔCp_2 are the heat capacity equations appropriate to the temperature ranges 298 – T_1° K and T_1 – T° K.

Writing

$$\int_{T_1}^{T} X dT \quad \text{as} \quad \int_{298}^{T} X dT - \int_{298}^{T_1} X dT$$

we have

$$\Delta G^\circ_T = \Delta H^\circ_{298} - T\Delta S^\circ_{298} - \Delta H_{f,M} + T\Delta S_{f,M}$$

$$+ \left\{\int_{298}^{T} \Delta Cp_2 dT - T\int_{298}^{T} \frac{\Delta Cp_2}{T} dT\right\}$$

$$- \left\{\int_{298}^{T_1} (\Delta Cp_2 - \Delta Cp_1)\, dT - T_1 \int_{298}^{T_1} \frac{(\Delta Cp_2 - \Delta Cp_1)}{T} dT\right\}$$

$$+ (T - T_1) \int_{298}^{T_1} \frac{(\Delta Cp_2 - \Delta Cp_1)}{T} dT$$

The terms in braces are Alcock's free-energy deviations and

$$\Delta G^\circ_T = \Delta H^\circ_{298} - \Delta H_{f,M} - T(\Delta S^\circ_{298} - \Delta S_{f,M}) + \Delta(G.D.F.)_T$$

$$- \delta(G.D.F.)_T + (T - T_1) \int_{298}^{T_1} \frac{\delta Cp}{T} dT$$

where $(G.D.F.)_T$ stands for the free energy deviation function and is to be calculated for reaction (3) at T° K, and $\delta(G.D.F.)_{T_1}$ stands for the similar function for the melting of the metal, with

$$\delta Cp = (\Delta Cp_2 - \Delta Cp_1) = Cp_{M(l)} - Cp_{M(c)}$$

It can be shown that for each transformation or change of state between 298° K and T° K in the reactants and products the additional terms

$$\left(\pm \Delta H_t \pm T\Delta S_t \pm \delta(G.D.F.)_{T_t} \pm (T - T_t) \int_{298}^{T_t} \frac{\delta Cp}{T} dT\right)$$

are required. In general, for i transformations or changes in state

$$\Delta G^\circ_T = \Delta H^\circ_{298} - T\Delta S^\circ_{298} + \Delta(G.D.F.)_T$$

$$+ \sum_i \left(\pm \Delta H_t \pm T\Delta S_t \pm \delta(G.D.F.)_{T_t} \pm (T - T_t) \int_{298}^{T_t} \frac{\delta Cp}{T} dT\right)$$

where the immediately accessible approximate free-energy change is given by

$$(\Delta G^\circ_T)_{\text{approx.}} = \Delta H^\circ_{298} - T\Delta S^\circ_{298} + \sum_i (\pm \Delta H_t \pm T\Delta S_t)$$

As a result of this extended treatment, the particular value of the free-energy deviation as the difference between a true and an approximate free-energy change is lost. By referring the transformation data to 298° K, that is

$$\Delta H_{t,298} = \Delta H_{t,T_t} - \int_{298}^{T_t} \delta Cp\, dT;$$

$$\Delta S_{t,298} = \Delta S_{t,T_t} - \int_{298}^{T_t} \frac{\delta Cp}{T} dT$$

a second approximate free-energy change is obtained as

$$(\Delta G^\circ_T)_{\text{approx 2}} = \Delta H^\circ_{298} - T\Delta S^\circ_{298} + \sum_i (\pm \Delta H_{t,298} \pm T\Delta S_{t,298})$$

which differs from the true free-energy change only by

$$\int_{298}^{T} \Delta Cp\, dT - T \int_{298}^{T} \frac{\Delta Cp}{T} dT$$

where ΔCp is the difference in heat capacities for the states of the reactants and products appropriate to the temperature T °K. This is the required free-energy deviation and thus

$$\Delta G^\circ_T = (\Delta G^\circ_T)_{\text{approx.2}} + \Delta(G.D.F.)_T$$

In this expression the change in free energy is now in the form proposed by Alcock, and is rigorously applicable to all processes irrespective of the states of the reactants and products. It is obvious that for many purposes the first approximate value for the free-energy change suffices, while the correction of this by means of the free-energy deviation function will satisfy most of the remaining requirements. The calculation of true changes in free energy requires the tabulation of heats and entropies of transformation and changes in state for the temperature 298° K. It is noted that heats of evaporation and sublimation at 298° K are already tabulated in a compilation[2] of thermochemical data which enjoys a large following, and it is suggested that an extension of the tables to include 298° K values for all such processes would facilitate and encourage the use of Alcock's free-energy deviation function.

Reactions of the Hydroxyl Radical in the Radiolysis of Aqueous Solutions of Di-ethyl Acetal

IT has recently been suggested[1] that the decomposition of aqueous solutions of di-ethyl acetal induced by radiation is due to hydrolysis, catalysed by hydronium ions formed in the spurs in the primary radiolytic process.

$$H_2O \rightarrow H_2O^+ + e^- \quad (1)$$

$$e^- + nH_2O \rightarrow e^-_{aq} \quad (2)$$

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH \quad (3)$$

As the result of our experiments on the reaction between hydroxyl radicals produced by the photolysis of hydrogen peroxide, and acetal, we have come to the conclusion that this reaction may account for at least a part of the decomposition observed in the radiolysis.

$$OH + CH_3CH(OC_2H_5)_2 \xrightarrow{k_4} CH_3CHO + C_2H_5OH + \text{other products} \quad (4)$$

The experiments were carried out as follows: solutions of acetal (10^{-2} M) and hydrogen peroxide (10^{-1} M) in neutral water (phosphate buffer) were irradiated with a low pressure mercury lamp, virtually monochromatic with respect to the 2537 Å component. The intensity of the 2537 Å light was determined by the uranyl oxalate actinometer as modified by Pitts *et al.*[2] and was $1{\cdot}1 \times 10^{19}$ quanta l./sec.

At the concentrations used virtually all the light is absorbed by the hydrogen peroxide for which an extinction coefficient of 20 l./mole/cm was found, in agreement with other determinations[3]. The extinction coefficient

* All at pH 7 except where otherwise stated.

for acetal at 2537 Å was found to be less than 0·6 l./mole/cm.

After irradiation the products were determined by gas chromatography on a 1 m 'Carbowax 400' column operated at 138° C. The main products of the photolysis were found to be ethanol and acetaldehyde together with a small amount of what has tentatively been identified as di-ethyl ether. For short irradiations the concentration of these products increases linearly with irradiation time while that of acetal decreases linearly with approximately 1 mole each of ethanol and acetaldehyde formed for each mole of acetal destroyed.

Other reactions leading to the same products were also observed. First, even at pH 7, a small amount of hydrolysis took place and, second, reaction between acetal and hydrogen peroxide was found. Direct photolytic decomposition of acetal at this wavelength was not observed in peroxide free solutions. The results of these and the other experiments are summarized in Table 1.

As the irradiation time is increased beyond 1 min the yields of the products tend to fall off, indicating competition with acetal for hydroxyl radicals. The ethanol concentration reaches a maximum of $4{\cdot}5 \times 10^{-3}$ moles/l. after 6 min of irradiation while for acetaldehyde this maximum is $6{\cdot}2 \times 10^{-3}$ moles/l. after 15 min. This is qualitatively in accord with the reaction rate constants of hydroxyl with ethanol and acetaldehyde in aqueous solution which have been determined[4] as $1{\cdot}2 \times 10^{9}$ l./mole/sec and 7×10^{8} l./mole/sec respectively.

The fact that ethanol competes with acetal for hydroxyl radicals introduces a complication as the product of this reaction in the presence of oxygen is also acetaldehyde[5]. The mechanism is probably the following:

$$OH + C_2H_5OH \rightarrow C_2H_4OH + H_2O \quad (5)$$

$$C_2H_4OH + O_2 \rightarrow C_2H_4(OH)O_2\cdot \quad (6)$$

$$2C_2H_4(OH)O_2\cdot \rightarrow O_2 + H_2O_2 + 2CH_3CHO \quad (7)$$

In confirmation of this we have photolysed aqueous solutions of ethanol and hydrogen peroxide and found that one mole of acetaldehyde is formed for each mole of ethanol destroyed. That the reaction is due to hydroxyl radicals and not to direct decomposition was shown by irradiating a peroxide free solution, which did not decompose.

The problem which now arises is whether acetaldehyde is a primary product of the reaction of hydroxyl and acetal or is formed by the secondary attack of hydroxyl on ethanol. We believe that at low doses it is a primary product. First, its dose-yield curve when corrected for thermal contributions is linear and passes through the origin with no indication of an induction period. Second, it has been found that the addition of chloride ion (10^{-1} M) has no effect on the rate of formation of acetaldehyde. Chloride ions react with hydroxyl radicals in competition with ethanol to yield chlorine atoms which appear to be unreactive toward ethanol[6]. Thus if attack on ethanol were responsible for acetaldehyde formation, the addition of chloride would be expected to suppress the rate of this reaction. The fact that no competition between chloride and acetal is apparent can be explained if it is assumed that chlorine atoms react with acetal to produce the same radical, a precursor of ethanol and acetaldehyde, as that produced by the hydroxyl radical

$$CH_3CH(OC_2H_5) + Cl \text{ or } OH \rightarrow R\cdot \leftarrow \text{Products} \quad (8)$$

So far, we have only considered the reaction of hydroxyl radicals produced by the primary decomposition of hydrogen peroxide

$$H_2O_2 \rightarrow 2\ OH \quad (9)$$

These radicals will, however, react with the peroxide in competition with (4), and the possibility thus exists that the effects we have observed may be due to reactions of the peroxy radical

$$OH + H_2O_2 \rightarrow H_2O + HO_2 \ (k_{10} = 4{\cdot}5 \times 10^{7} \text{ l./mole/sec}) \quad (10)$$

$$HO_2 + \text{Acetal} \rightarrow \text{Products} \quad (11)$$

Without a determination of k_4 it is not possible to assess the importance of (10), but if (10) and (11) are responsible for acetaldehyde production in these experiments then it is likely that reaction (11) is the source of this product in the radiolysis experiments. The latter were carried out in the presence of air so that the reducing radicals will react according to (12) and (13) to form the peroxy radical or its basic counterpart

$$H + O_2 \rightarrow HO_2 \ (k_{12} = 2{\cdot}6 \times 10^{10} \text{ l./mole/sec}) \quad (12)$$

$$e^-_{aq} + O_2 \rightarrow O_2^- \ (k_{13} = 2{\cdot}2 \times 10^{10} \text{ l./mole/sec}) \quad (13)$$

In conclusion we can state that the present work strongly indicates that in the radiolysis of aqueous acetal the formation of acetaldehyde is partly due to reaction between acetal and either the hydroxyl or the peroxy radical. Because of the effects of competition on the part of the products the present work is not extensive enough to ascertain whether this is the only effect or whether hydrolysis induced by radiation and catalysed by acid contributes to the formation of the products. A detailed investigation of the problem is being made with the emphasis on photolysis at low doses, on the effect of hydroxyl scavengers on the radiolysis and on methods for the determination of the rate constant of reaction (4). These results will be communicated at a later date.

Rapid and Specific Effects of Bromine on the System Keratin/Formic Acid

FORMIC acid interacts strongly with many fibrous proteins, polypeptides and polyamides; it produces either complete dissolution or considerable swelling together with a marked contraction of the fibre resulting from melting of the crystalline material[1]. Fibres of α-keratin, however, show considerable radial swelling (about 50–60 per cent) in concentrated formic acid, but virtually no change of length. The swelling will tend to lengthen the fibre while the melting of α-helices will tend to contract it, but the major cause for the constant length must be

sought in the stability of a residual proportion of the crystallites which have been shown by X-ray measurements to remain in the α form in 98 per cent formic acid[2]. This residual stability has been shown to persist even in dilute solutions of the helix-forming protein extracted from wool[3].

In the absence of mechanical stress, the melting-point of the crystallites in a normal α-keratin (for example, wool or hair) in water[4,5] is above 100° C. Partial melting at least can, however, be induced below 100° C, either by stretching combined with heat treatment[5,6] or by immersion in a suitable medium such as lithium bromide solution[7,8]. At room temperature, the contraction obtainable in 8 M lithium bromide is only about 10 per cent, but at 100° C contractions up to about 50 per cent can be achieved in times of the order of an hour. Very small amounts of bromine can strongly inhibit the contraction produced in lithium bromide and this has been attributed[7] to the action of the tribromide ion $(Br_3)^-$ on keratin.

The influence of small amounts of bromine on the interaction of wool with formic acid has now been investigated, with surprising results. In contrast to the behaviour in formic acid alone, rapid elongation is produced. This shows that the constraint of the residual α-helical keratin has been overcome. This could be the result of a direct attack of the bromine on the tyrosine residues, a conclusion indicated by model experiments[9] and supported by the amino-acid analyses below. As the tyrosine residues occur at regularly repeating distances along the helix[10], there will be a tendency for relatively short segments of crystalline order to survive the treatment, which would account for the phenomena described here.

In a typical experiment, a Corriedale wool fibre was immersed in 98 per cent formic acid. A slight initial contraction was observed, after about 10 sec, followed by a lengthwise swelling. Equilibrium was reached with the fibre about 1 per cent longer than its original length. A force-extension measurement revealed a substantially linear relationship up to about 15 per cent extension, with a Young's modulus of about 7×10^8 dynes/cm^2. After washing out the formic acid with water, the original length and Young's modulus (about $1{\cdot}8 \times 10^{10}$ dynes/cm^2) were largely restored.

The same procedure was then carried out with 98 per cent formic acid containing about 0·1 per cent w/v bromine. There was a small initial contraction (as in the absence of bromine) but then a rapid lengthening of the fibre, reaching an apparent equilibrium at a length about 40 per cent greater than the original. This apparent equilibrium was reached in about 20 sec and no further change was observed in the following 5 min. In this swollen condition the fibre could be extended to a length 90 per cent greater than the original without breaking: the modulus in the early stages of the extension was very low, certainly less than 10^6 dynes/cm^2.

When the fibre was transferred from the bromine/formic acid mixture to water at 20° C, it contracted spontaneously from 40 per cent above to 30 per cent below the original length. In this process it became white and opaque. The contracted length was not altered by immersing the fibre in water at 20° C for 16 h or by heating it in water at 52° C for 1 h. Further contraction did, however, take place, in boiling water, reaching a value of 38 per cent after 1 h. It would appear that some remaining crystalline segments melted in water between 52° and 100° C.

The contracted fibre, in water, was still soft (Young's modulus approximately 4×10^8 dynes/cm^2) and highly extensible with a breaking extension of about 120 per cent of the contracted length or 80 per cent referred to the initial length (extension rate approximately 15 per cent/min). Under these conditions, such high extensibility is not shown by fibres contracted in other media such as lithium bromide[7].

Table 1. CHANGES IN THE AMINO-ACID COMPOSITION OF WOOL INDUCED BY IMMERSION IN FORMIC ACID/BROMINE SOLUTION

Residue	Concentrations in μmole/g Before treatment	After treatment	Change
Lysine	205	252	+47
1/2-Cystine	901	800	−31
Cysteic acid	16	86	
Tyrosine	275	12	−263
3-Bromo tyrosine	—	178	+178
Phenylalanine	214	168	−46

Further physico-chemical investigations of these phenomena are in progress, but amino-acid analysis of the treated wool has already indicated that a very specific mechanism is involved. Most residues showed only an insignificant change (about 5 per cent) from the control, but marked alteration was shown by the residues listed in Table 1. Lysine increased and the groups containing sulphur decreased, although if half-cystine and cysteic acid are taken together, the total loss of these is only about 3 per cent. In contrast the tyrosine has been almost entirely eliminated, and this is presumably the main point of attack by the bromine (which is present here in the molecular and not the ionized form (Br_3^-) as in lithium bromide). About two-thirds of the tyrosine has been isolated as the mono-brominated derivative, and a separate experiment showed that 3 : 5 di-bromotyrosine appeared at the location of the lysine peak on the amino-acid analyser, thus accounting for the apparently anomalous increase in lysine. Altogether, then, about 80 per cent of the original tyrosine has been isolated as bromo-derivatives, 15 per cent has apparently been destroyed or otherwise modified, and 5 per cent is left intact.

We thank Mr. A. S. Inglis of the C.S.I.R.O. Division of Protein Chemistry for the amino-acid analysis.

Spontaneous Bubbling at Porous Hydrophobic Membranes

IT has been observed that when a hydrophobic membrane permeable to gases is present at the interface between water and a dry gas, the gas passes through the membrane and is released in the liquid as bubbles. The interesting feature of this process is that it proceeds without the need to raise the pressure of the gas and will even operate against a positive hydrostatic head of liquid. Indeed, substantial static pressures are developed in the water chamber when escape of the gas is prevented on the liquid side of the membrane. The membrane used in these experiments was a 7-mil thick, extruded tetrafluoroethylene (TFE) film which, in the course of preparation, was never subjected to temperatures above 300° C. The morphology and pore size of the film have not as yet been determined.

The tests were performed with disks of the TFE membranes 1 in. in diameter mounted in various orientations. With the membrane oriented vertically or horizontally (with the liquid phase uppermost), buoyancy forces remove

the gas. If, however, the membrane is orientated horizontally with the gas phase uppermost, bubbles collect beneath the membrane and displace the water. This does not arrest further transport of the gas, which indicates that physical contact between the membrane and the liquid phase is not necessary for the process.

When the water temperature was 70° C, the hydrostatic head 1 in., and the gas delivered at 1 in. water pressure at 25° C, the approximate gas flow rates for hydrogen, nitrogen, oxygen and air were found to be 8·0, 1·6, 1·4 and 1·6 ml. cm^{-2} min^{-1}, respectively. These flow rates increased to 26·0, 5·2, 5·0, and 5·2 ml. cm^{-2} min^{-1}, respectively, when the water temperature was raised to 90° C.

A total head of water of 2·0 lb./in.² gauge was necessary to arrest the transport of hydrogen across the membrane at 70° C. Similarly, to arrest the passage of air, minimum water heads of 0·6, 1·6, 2·3 and 3·0 lb./in.² gauge were required at water temperatures of 70°, 80°, 85° and 90° C, respectively.

It has been shown that this phenomenon results from interdiffusion of water vapour and gas through the porous membrane, with the partial pressure gradients of the respective gases through the pores providing the driving force for the process. The translation of this familiar process into the unusual effects described is possible because of the impermeability of the hydrophobic membrane to liquid water either by direct permeation or by condensation. The liquid water thus acts as a displaceable barrier to gas transport and, at the same time, is the source of water vapour. So far as we know, the TFE membranes are unique in providing a separator with the combination of physical and chemical inertness, porosity, and high hydrophobicity necessary to give rise to the observed effects.

Separate measurements have been made of the interdiffusion of water vapour and gas across the membrane in the absence of the liquid phase. These experiments were carried out at 70° C under conditions of zero differential total pressure and with the partial pressure gradients of the two components across the membrane essentially constant. Anhydrous calcium sulphate was used as a drying agent in the gas chamber and was placed close to the membrane. In the water vapour chamber, also close to the membrane, there was a glass wool wick partly immersed in a pool of water. The increase in weight of the drying agent was taken as a measure of the quantity of water vapour transported across the membrane while the gas transported in the opposite direction was collected over water in a gas burette. Tests were performed with air, carbon dioxide, carbon monoxide, helium, hydrogen, oxygen and methane. The following relationship was found to hold within experimental error:

$$\frac{\text{flux water}}{\text{flux gas}} = \sqrt{\frac{\text{Mol. wt. gas}}{\text{Mol. wt. water}}}$$

This result agrees with the findings of other investigators who have used a variety of membranes and various sets of interdiffusing (non-condensable) gases. The relationship holds both for Knudsen effusion and for diffusion, and has been given a theoretical interpretation by Evans *et al.*[1]. As well as the flux ratio relationship we found that the flux of water and gas is an inverse function of the molecular weight of the gas.

Less satisfactory agreement with the theoretical relationship was obtained in the experiments with liquid water. The possibility that this may be related to the kinetics of bubble release is now being investigated.

BIOCHEMISTRY

Periodic Cross-banding in Amyloid Filaments

THE presence of a fibrous component in amyloid first detected in 1959 by the electron microscopic studies of Cohen and Calkins[1] has been confirmed by all subsequent observers. The fibrillar structure of amyloid, its physicochemical properties and its exclusive occurrence in the extra-cellular portion of the connective tissue suggested that amyloid is a variant of one of the normal fibrous proteins[2,3]. We believe that the following observations are pertinent to this hypothesis.

Tissues obtained by biopsy or at necropsy from cases of familial Mediterranean fever, multiple myeloma, idiopathic primary amyloidosis and experimental leishmaniasis-induced amyloidosis in hamsters were fixed in glutaraldehyde–osmium tetroxide, embedded in 'Vestopal', contrasted with uranyl acetate–lead and examined under a Siemens Elmiskop I electron microscope.

Examination of native amyloid from these sources showed that it is made up of filamentous structures which are present only in the connective tissue ground substance. Filaments as long as 1μ and ranging in thickness from 40 Å to 140 Å were measured. Organization beyond the filament stage was never noted. At high resolutions it sometimes seemed as if the filament were composed of two strands twisted around one another[2,4].

In primary enlargements of ×30,000 or more, a clear cross-striation of alternating 30 Å dark and 25 Å bright bands was sometimes observed with a 55 Å periodicity. The grouping of bands such as occurs in ripe collagen was not apparent (Fig. 1).

Fig. 1. Cross-banding in amyloid deposits in familial Mediterranean fever. Arrow indicates filaments which appear to be composed of two strands (×120,000).

The periodic cross-banding is of considerable significance to an understanding of the ultrastructure of amyloid. Indications of this have been recorded in the past as beading; Gueft and Ghidoni reported "an irregular granular periodicity . . . of approximately 40 Å"; Shirahama and Cohen found "a regular beading which measured approximately 100 Å" in isolated amyloid filaments[4]. Recently, these indications were strengthened by the observations of Hashimoto *et al.* in a study of lichen amyloidosis[5]. In areas where amyloid and collagen were intimately intermingled, these authors found thin amyloid filaments which showed irregular 150–250 Å beading and thicker fibrils with regularly spaced cross-banding of about 150–250 Å. Boere *et al.* reported 40 Å cross-striation in isolated and negatively stained primary and secondary amyloid[6].

The properties of amyloid cited here, together with its intermingling with collagen and reticulin within a common matrix[7], and the occurrence of secreting fibroblasts and

fibrocytes as the only active elements in amyloid-laden tissues[5,8] seem to suggest that amyloid may be related to the collagen family. It is significant that collagen does not always possess 640 Å periodicity and under certain conditions a variety of periodicities occur[9,10]—for example, embryonal and young collagen show predominantly shorter periodicities, ranging from 70 Å to 210 Å (ref. 11). Proline and hydroxyproline are apparently absent from amyloid, and for this reason similarities in structure which seem to link it with collagen require careful examination before they are accepted as an indication of a family relationship.

This study was supported in part by a grant from the U.S. Public Health Service through the National Institutes of Health, Bethesda.

Purification and Characterization of Ribonuclease from Unfertilized Eggs of the Sea Urchin, *Psammechinus miliaris*

KNOWLEDGE about the various types of RNA involved in the biosynthesis of proteins has increased greatly over the past few years. Little is known, however, about the part played by the various ribonucleases (RNases) known to be present in most cells, in the metabolism of the RNA. There has been much speculation on this topic, but few attempts have been made to investigate the physiological action of these substances. This is largely because few of the many RNases identified have been isolated and purified sufficiently to allow them to be characterized. The purification of RNase has great interest at present because of its possible use in the structural analysis of RNA molecules.

Sea urchin eggs have long been intensively used in investigations of maturation, fertilization and early cell differentiation processes which have a marked effect on the metabolism of ribosomal RNA[1–3]. Investigations of the RNase content of eggs of the sea urchin, *Psammechinus miliaris*, were therefore undertaken in this laboratory. Although minute traces of RNase activity in sea urchin eggs have been reported[4] no attempt has so far been made to isolate and characterize the enzymes. This communication reports the isolation and purification of an RNase from mature, unfertilized eggs of *Psammechinus miliaris*.

A homogenate of lyophilized sea urchin eggs was extracted with chloroform to remove lipid material. After extraction, the aqueous phase was lyophilized and redissolved in water. The active part of the fraction was precipitated at *p*H 3·5 by fractionation with ammonium sulphate. 90 per cent of the activity was obtained in the fraction between 45 and 75 per cent saturation. Gel filtration on a column of 'Sephadex *G*-100' increased the specific activity (activity/$A_{280\ m\mu}$) of the preparation to about 1,000 times that of the homogenate. The enzyme solution was concentrated using an '*SE*-Sephadex *C*-50' column, and the final purification was accomplished by chromatography on a column of '*CM*-Sephadex *C*-50', which was eluted with a sodium chloride gradient in 0·1 M ammonium acetate buffer, *p*H 4·8 (Fig. 1). This step of the purification resulted in an enzyme preparation with a specific activity about 10,000 times higher than that of the homogenate. Purified yeast RNA was used as a substrate in the assays[5] of the phosphodiesterase (DEase) activity, and synthetical nucleoside 2′,3′-phosphates were used as substrates in the assays[6] of the cyclic phosphatase (CPase) activity. The activity was related to standard curves prepared using crystalline bovine ribonuclease (Armour). Because of the small amount of activity present in the egg material (75 μg RNase/g lyophilized eggs) special care had to be taken to ensure high yields in each step of the purification. The overall yield in the purification was about 50 per cent.

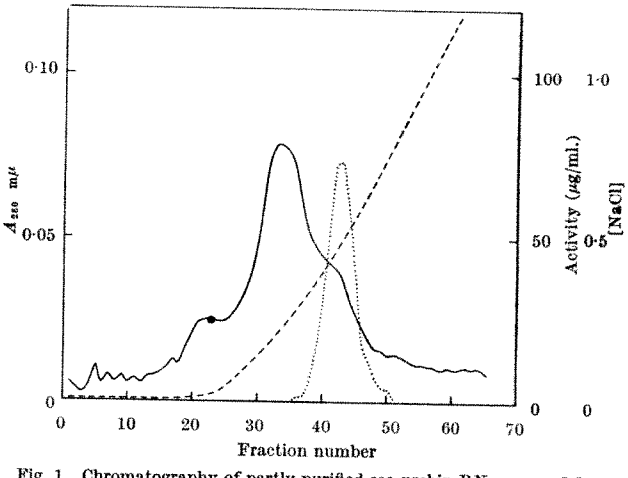

Fig. 1. Chromatography of partly purified sea urchin RNase on a 0·5 × 60 cm column of '*CM*-Sephadex *C*-50'. The load used was 220 μg of RNase in 1·2 ml. solution obtained from the '*SE*-Sephadex' step. Initial buffer: 0·1 M sodium acetate, *p*H 4·8 (– – –) sodium chloride. Flow rate 3·6 ml./h. 0·6 ml. per fraction. (——) A_{280}. (. . .) Activity.

Investigations of the specificity of this purified preparation showed that the sea urchin RNase hydrolysed RNA to both purine and pyrimidine cyclic riboside 2′,3′-phosphates. The purine cyclic riboside 2′,3′-phosphates were hydrolysed at a considerably slower rate to their corresponding dihydrogen phosphates of the 3′ isomer form. The enzyme lacked CPase activity against the pyrimidine cyclic riboside 2′,3′-phosphates, and in this respect it was similar in its specificity to tobacco leaf RNase[7] and pea leaf RNase[8]. The curve of *p*H against activity for the RNase showed an optimal *p*H of 5·4. Investigations of the heat stability at different values of *p*H revealed that the activity had higher stability in the acid region of the *p*H range, but the stability in general was found to be rather low. On the other hand, when the purified enzyme was kept at −20° C during a period of over a year, little or no loss of activity was observed. Determinations of the molecular weight of this RNase using a column of 'Sephadex *G*-100' and reference substances with known molecular weights gave a molecular weight of 32,000–35,000 for the enzyme.

During the investigation, two other separate enzymes were isolated from the egg homogenate. One showed an acid *p*H optimum while the other had its optimum *p*H at about 7. Both the enzymes showed high CPase activity but completely lacked DEase activity, and thus probably a complementary function to the RNase.

Change in Ribonuclease Concentrations in L-Asparaginase-treated Lymphosarcomata

BROOME[1,2] suggested that L-asparaginase is responsible for the antilymphoma activity of guinea-pig serum[3]. We confirmed the hypothesis[4] and furthermore presented[5] evidence that extracts of *Escherichia coli B* contain an asparaginase which also has high antilymphoma activity. This communication presents evidence that the regression of lymphosarcoma 6*C3HED* induced by L-asparaginase is preceded by an increase in the alkaline ribonuclease of the post-mitochondrial cell fraction of the tumour, while the acid ribonuclease of that fraction is increased later during the regression.

Asparaginase assays were performed as previously described[5]. Purification of asparaginase is shown in Table 1. The enzyme was extracted from lyophilized *E. coli B* cells by sonication of the suspended bacteria (10 per cent w/v) for 30 min. The sonicate was centrifuged at 30,000*g* for 30 min. After precipitation of the nucleic acids by 1·0 M manganese chloride (0·05 × volume), the supernatant was subjected to fractionation using ammonium sulphate. The 55–100 per cent saturated fraction which contained the asparaginase was dialysed until no ammonia could be detected in the dialysate with Nessler's reagent, and applied to a hydroxylapatite column (2·0 × 23 cm). The column was washed with disodium hydrogen phosphate and the enzyme was eluted with dipotassium hydrogen phosphate, both buffers being 0·1 M with a *p*H of 8·6. Tubes containing most of the enzyme activity were pooled and purified either by additional hydroxylapatite chromatography or by column electrophoresis. Better purification was usually achieved by electrophoresis.

The effect of the enzyme on the growth of the tumours is shown in Fig. 1. The *BW* 5147 and the resistant strain of 6*C3HED* continued to grow while the sensitive strain of 6*C3HED* progressively decreased in size. The resistant tumours of animals which were treated with the buffer only grew at the same rate as those of the animals which were treated with asparaginase.

Animals bearing a tumour were injected intraperitoneally with 10–11 units of asparaginase (specific activity = 1,000–4,500 u/mg protein), while the controls were injected with an equal volume of the buffer. After either 2 or 18 h, the animals were killed and ribonuclease (RNase) activity determined by the method of Shortman[6]. The tumours were removed and immediately placed in ice-cold 0·15 M sodium chloride solution. They were then trimmed to remove connective tissue and blood vessels, weighed and homogenized in 0·44 M sucrose to give a 10 per cent homogenate. The homogenate was centrifuged at 17,000*g* for 60 min and the supernatant was assayed for RNase activity. The assay mixture contained 0·1 ml. of 1 per cent ribonucleic acid (RNA) in 10^{-2} M ethylenediamine tetraacetic acid, 0·1 ml. of water or of 10^{-2} M *para*-chloromercuribenzoate (*p*CMB), 0·2 ml. of buffer (acetate, 0·03 M, *p*H 5·8, or veronal, 0·03 M, *p*H 7·8) and 0·1 ml. of the supernatant. After incubation at 37° C for 30 min, the tubes were cooled in ice and 0·6 ml. of cold acid–alcohol (1 N hydrochloric acid in 76 per cent ethyl alcohol) was added. Cold acid–alcohol was added to controls which had not been incubated, immediately after the addition of the supernatant. The resulting

Table 1. PURIFICATION OF ASPARAGINASE

	Units (u)	Protein (mg)	Sp. act. (u/mg)	Recovery (per cent)	Purification (x)
Crude extract	25,000	4,000	6·4		
Ammonium sulphate 55–100 per cent	15,700	1,100	14·3	61	2·2

18 h	71 ± 5 (43% increase)	109 ± 15	112 ± 6 (66% increase)	186 ± 25		

One unit is that amount of enzyme which will produce an optical density change of 1·0 in 30 min.

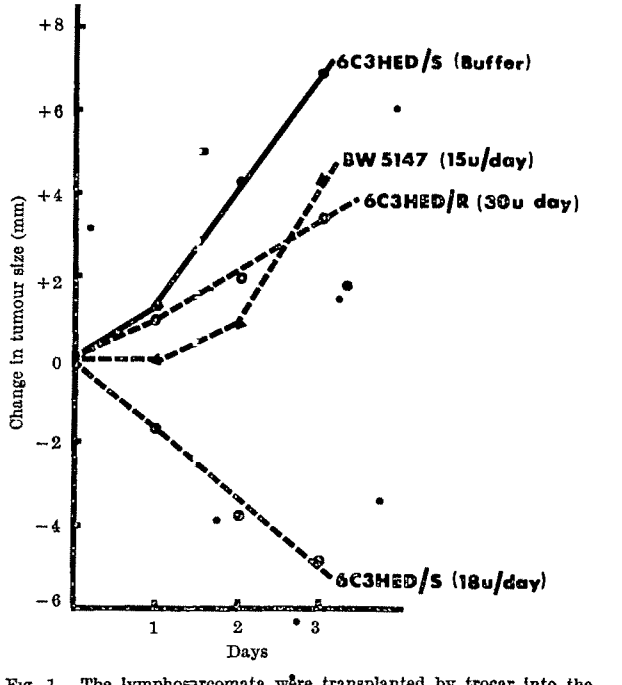

Fig. 1. The lymphosarcomata were transplanted by trocar into the right flank of the female host animals (*C3H/HeJ* and *AKR/J*) obtained from Jackson Memorial Laboratories, Bar Harbor, Maine, 4 days before testing began. The tumour-bearing mice were injected intraperitoneally twice daily, at least 6 h apart for 3 days with the asparaginase solution or an equal volume of the buffer. The tumour sizes reported represent the average diameter obtained by measuring with calipers in three directions before the first injection each day.

precipitate was removed by centrifugation, the supernatant diluted six times with distilled water, and the optical density at 260 mμ was determined. The difference between the optical density of the incubated sample and that of the unincubated sample was taken as a measure of RNase activity.

Table 2 shows that although there is little or no change in the levels of any of the RNases in either of the resistant tumours, there is an 80 per cent increase in the alkaline RNase of the post-mitochondrial fraction of the sensitive tumour within 2 h after treatment with asparaginase. The level of the acid RNase is not significantly changed in the sensitive tumour during the first 2 h, but there is a 43 per cent increase over the control 18 h after treatment. The raised level of the alkaline RNase (inhibited RNase) persists for at least 18 h. The increase in alkaline RNase seen in the presence of *p*CMB is not significantly different in tumours from treated and control animals.

Because asparaginase gives rise to increased RNase activity only in tumours which regress following treatment, and has no effect on the levels of RNase in tumours which are resistant to the antilymphoma action of asparaginase, it is possible that the mechanism of regression caused by asparaginase might involve activation of RNase. MacLeod, King and Hollander[7] have shown that *in vivo* treatment with 9-α-fluoro-prednisolone produces an increase in acid RNase of lymphosarcoma *P*1798 before any visible reduction in size of the tumour occurs. The similarity of the asparaginase effect to that of the 9-α-fluoro-prednisolone on the corticoid-sensitive lymphosarcoma suggests a generalized mechanism of lymphocytolysis involving RNase. This is supported by examples correlating regression of tumours with increased acid RNase recently reported by Ambellan and Hollander[8]. As RNase is a possible regulator of protein synthesis, its increased activity could lead to cell destruction. Furthermore, messenger RNA has been reported to be particularly sensitive to pancreatic (alkaline) RNase[9], thus causing disaggregation of polysomes[10]. This observation is relevant because the rise in RNase reported here is in the soluble portion of the cell.

The cytotoxic effect of asparaginase on *6C3HED* cells *in vitro* reported by Borella *et al.*[11] was accompanied by a reduction in the amount of tritiated cytidine taken up by the cells. Such a decrease could be caused by an increased rate of RNA destruction by RNase which has been activated by asparaginase as well as by a decrease in RNA biosynthesis.

Recently, El Asmar and Greenberg[12] reported that *in vivo* treatments of *6C3HED* lymphosarcoma with a glutaminase-asparaginase preparation from a Pseudomonad inhibited both the growth of the tumour and the incorporation of labelled glycine and adenine. The effect was ascribed to the impairment of purine synthesis by the depletion of glutamine. The same result could be obtained by the activation of RNase by means of the asparaginase activity in the preparation. The nucleotides released from RNA by the action of the activated RNase would dilute the labelled pool of purines and thereby reduce the incorporation of the labelled compounds.

Ledoux[13] has demonstrated that direct injections of pancreatic RNase are effective in causing regression of tumours, but rather large amounts of material were necessary. In the investigation reported here, a maximum of 10 μg of protein was given and no RNase activity could be detected in the samples administered. This difference suggests that internal stimulation of the endogenous enzyme is more effective than administration of the same activity from another source.

There are several possible mechanisms by which asparaginase may stimulate RNase: (1) by removing an inhibitor other than that which is destroyed by *p*CMB; (2) by releasing the enzyme from some inactive, bound form; (3) by binding to the enzyme to produce a synergistic effect. The removal of an inhibitor is the most tempting mechanism. An analogy to this mechanism has recently been reported by Wiernick and MacLeod[14], who found that the removal of inhibitors of alkaline RNase by acid treatment[15] activated the enzyme so that 9-α-fluoro-prednisolone no longer induced an increase in thymus RNase.

We thank Dr. John Broome for the generous gift of his resistant strain of *6C3HED*.

The "Pink Spot" and Schizophrenia

THE idea that the "pink spot" is uniquely associated with schizophrenia[1–3] is now in doubt because of its reported presence in normal individuals[4,5] and in patients suffering from Parkinson's disease[6]. Additionally, some doubt must be cast on its identification as β-3,4-dimethoxyphenylethylamine (DMPE)[1,7]. The evidence supporting the finding that the "pink spot" is DMPE rests on its almost exact correspondence with DMPE in certain paper chromatographic[1,4,7] and gas chromatographic[8,9] systems, the chromatographic similarity of prepared derivatives[1,7] and the similarity of the melting point range of the hydrochlorides[22]. This indirect identification of the "pink spot" as DMPE is of great interest because of the hypothesis[10,11] that in schizophrenia abnormal methylation of catecholamines might occur. This hypothesis is strengthened by the chemical similarity between DMPE and the hallucinogenic substance mescaline and also by the observation that the feeding of substances capable of donating a methyl group can cause an exacerbation of schizophrenic symptoms[12–14].

In this laboratory urine samples containing about 300 mg of creatinine (usually taken from a urine specimen collected over a 24 h period) were extracted with chloroform according to the procedure described by Friedhoff and van Winkle[1]. The final dried extract in chloroform was applied in the proportions 150, 75 and 75 mg of creatinine, respectively, to three 5 cm strips of Whatman number 2 quality paper. Authentic DMPE (25 μg) was overspotted on one of the 75 mg strips. Descending chromatography in butanol : acetic acid : water, 60 : 15 : 25 (v/v), was allowed to proceed overnight (15 h). This length of run (40–43 cm) was sufficient to allow a good separation of the pink spot zone from other constituents of the urine extract,

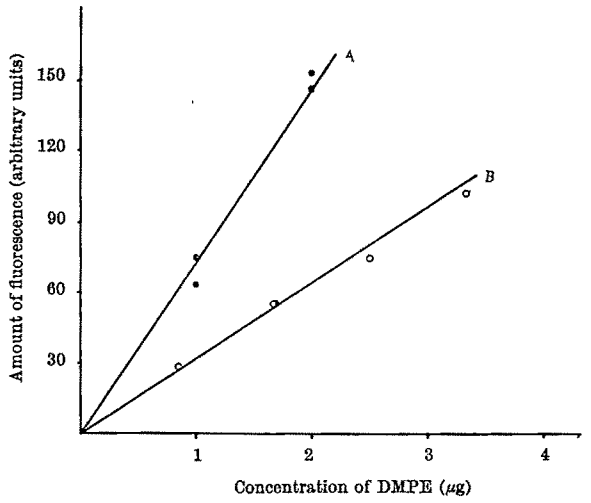

Fig. 1. Recovery of authentic DMPE added to urine. According to the procedure described by Friedhoff and van Winkle[1] 5, 10, 15 and 20 μg respectively of DMPE were added to four 100 ml. samples of "normal" urine and extracted in chloroform (3 × 50 ml.). Equal portions of each of the alkaline chloroform extracts were spotted, separated and rendered fluorescent by the glycine–formalin treatment (see text). The amount of fluorescence was measured on a paper strip scanning device, arranged for fluorescence measurements, using primary filter Chance *OX*1 (365 mμ) and secondary filter Chance *OY*8 (cut off below 450 mμ). Standards (curve *A*), run at the same time, show that over the range 0–20 μg the recovery (43 per cent) was constant.

including on occasions various drug metabolites. The 150 mg and the 75 mg+25 μg DMPE strips were sprayed with ninhydrin-pyridine reagent, heated for 2 min at 100° C, and, after noting the positions and colours of the separated zones, dipped through a modified Ehrlich reagent[15]. In order to be sure whether or not a particular sample was positive it was essential that the zone on the 150 mg strip corresponded almost exactly with the less concentrated strip containing the authentic DMPE, and that the correct sequence of colour changes occurs. This is important because several "pink spots" can be found in the urines of those patients excreting drug metabolites (see also refs. 4, 5 and 16). In a study of thirty-one urines, obtained so far as possible from patients selected according to the diagnostic criteria suggested by Bourdillon *et al.*[3], only one was found to exhibit a clearly defined "pink spot", although a ninhydrin positive substance was seen in the appropriate position in two others. Nothing was seen at this position in extracts of the urine from five "normal" subjects. Because it is necessary to have at least 5 μg of DMPE on the paper strip for the formation of a definitive "pink spot" it may be that more positives would have been found if larger amounts had been separated.

In an attempt to increase the sensitivity of the identification of the "pink spot" the fluorimetric procedures of Seiler and Weichmann[17] and Bell and Somerville[18] were investigated using urine to which authentic DMPE had been added. The acid glycine–formalin treatment of Bell and Somerville was finally selected on the basis of its greater sensitivity. It is possible to obtain quantitative values from these strips by using a paper strip scanning device[19] arranged for fluorescence measurements. Fig. 1 shows that a constant proportion (43 per cent) of added DMPE within the range 0–20 μg is recovered from urine. Other experiments have shown that, while on a particular occasion the recovery of added DMPE is reproducible, it is not necessarily the same proportion as on a different occasion.

It was surprising to find that the 75 mg strip from the positive urine did not fluoresce after the glycine–formalin treatment. In order to decide whether this lack of fluorescence was caused by inhibition of the formation of the fluorophore by a contaminating substance present in the alkaline chloroform extract and possessing a similar R_F value, 10 μg of DMPE was added to two qualitatively positive, but quantitatively different, samples of the single positive "pink spot" urine obtained on different days. After chromatography and development of the fluorophore, scanning revealed that the same proportion of the added DMPE (55 per cent) was recovered from both urines. This clearly indicates that in this particular urine the "pink spot" is not DMPE. Recent work[20,21] along different lines also concludes that the "pink spot" is not DMPE. At this stage it is difficult to assess how much importance to attach to the finding of the "pink spot" in schizophrenic patients, at least until more careful studies with respect to the influence of gut bacteria, diet, drug therapy, etc., have been performed. It is essential, however, that an unambiguous chemical identification be obtained as soon as possible.

Identity of the "Pink Spot"

A NUMBER of authors have now reported the occurrence of "pink spot" in the urine of schizophrenics[1]. Its identification as β-3,4-dimethoxyphenylethylamine (DMPE) rests on paper chromatographic evidence and a melting point provided by Friedhoff and Van Winkle[2] together with the gas chromatographic evidence of Sen and McGeer[8]. The pink spot produced from DMPE by successive treatments with ninhydrin and Ehrlich's reagent is evanescent and some 5–10 μg are required on the paper after chromatography in order to be certain of its occurrence. Drug metabolites can seriously interfere with its determination by this technique. We find that DMPE is readily detected by its reaction with formaldehyde on paper[4], and that it can be separated by high voltage electrophoresis from urinary metabolites of 'Largactil' (2,000 mg/day), 'Stelazine' (540 mg/day), 'Nardil', 'Disipal' (300 mg/day), barbiturates and haloperidol (2·25 mg/day). We have examined urines from

Table 1. PARTITION COEFFICIENT OF DMPE BETWEEN ETHYLENE DICHLORIDE OR ISOAMYL ALCOHOL AND GLYCINE SODIUM HYDROXIDE BUFFERS (0·05 M) OF VARYING *p*H

	*p*H					
Solvent	8·68	9·15	9·65	10·08	10·4	11·6*
Ethylene dichloride	0·59	1·60	3·51	5·68	7·51	5·69

* 0·1 N sodium carbonate.

patients during treatment with these drugs (at the doses quoted), and find that their metabolites give no fluorescence with formaldehyde and do not interfere with the formaldehyde fluorescence of added DMPE. ('Tofranil' metabolites, however, had a native fluorescence which may interfere at high doses.) Even when overloading of the paper has caused tailing of the DMPE and overlap with metabolite spots, the fluorescence still develops normally. The fluorophore can be eluted with 0·4 N sodium hydroxide in methanol, and after acidification with hydrochloric acid it can be measured quantitatively in a fluorimeter at 360 mμ activation/460 mμ fluorescence. In case of tailing on the electrophoresis paper, the eluted fluorophore can be re-run on thin layer plates of silica gel using *n*-butanol : water : acetic acid (60 : 20 : 20), or isopropanol : methyl acetate : water : concentrated ammonia (35 : 45 : 15 : 5), in order to separate it from traces of drug metabolites or other urinary constituents.

For the examination of schizophrenic urines we use 24 h collections and extract either 500 ml. or the whole sample (whichever is the less) with 3 × 1/3 volume of re-distilled ethylene dichloride. Since DMPE is a water-soluble base of *p*K 9·86 (determined by Mr. P. J. Taylor using potentiometric titration at an ionic strength $\mu = 0{\cdot}01$) the extraction at *p*H 9·0 used by previous workers is not favourable to complete recovery. Table 1 shows the partition coefficient of DMPE between organic solvents and aqueous buffers of varying *p*H. This was measured by shaking the DMPE in buffer (100 μg/ml.) with a third of its volume of organic solvent and reading the optical density of each phase at 279 mμ. We have adopted *p*H 10·5 as standard for the extractions and at this *p*H solutions of DMPE are stable for at least several days at 4° C. After drying the extract with sodium sulphate and evaporating it to dryness under vacuum at 40°–50° C, the residue is triturated with 50–100 μl. 0·01 N hydrochloric acid, and three equal portions of the solution are applied to Whatman No. 1 paper soaked in 0·1 M phosphate buffer *p*H 6·2. 10 μg DMPE is spotted over the middle sample and the electrophoresis is run at 4 kV for 1·5 h. After oven drying at 80° C, half the paper is stained by ninhydrin/Ehrlich and the other by glycine/formaldehyde. Markers of DMPE alone are also run on each half. Using this technique, 25 μg DMPE added to 500 ml. of normal urine can be detected by the pink spot reaction and the recovery as measured by elution of the formaldehyde fluorophore is 50–60 per cent. Two authentic "pink spot" urines supplied by Dr. A. Pauline Ridges were examined by this method and gave pink spots at the position corresponding to DMPE on both paper chromatography and electrophoresis, but no formaldehyde fluorescence. We have now examined another thirty-eight urine samples from twenty-seven schizophrenic patients selected according to the "Schneider positive, non-paranoid" criteria of Bourdillon *et al.*[5] which correlate with a high incidence of "pink spot". We have found only four positives, two of which were from one patient (N. P.), and none of these gave formaldehyde fluorescence. N. P. is a chronic patient and the first sample was obtained during treatment with 'Largactil'. The second and stronger positive was obtained when all medication had been stopped for 26 days. Intermediate samples were negative. These positive samples have all been re-examined with the same result, using fresh portions of the same urines. Standards of DMPE added to urine, extracted and run at the same time gave good fluorescence. Although the "pink spots" from schizophrenic urines had the same colour and fading characteristics as those from DMPE standards, their appearance on the electrophoresis paper was different because they tended to form streaks running ahead of the standard, rather than compact spots.

For patients who were specially selected, the incidence of "pink spots" is disappointingly low, though this could result partly from the fact that some of the samples were of small volume and in these cases there may not have been enough material on the paper for detection. From the evidence of the four positives which we have obtained, as well as those supplied by Dr. Ridges, it seems to us that these particular "pink spots" at least could not have been β-3,4-dimethoxyphenylethylamine, although at present we have no other information as to their identity.

We thank Dr. D. Eccleston, Craig House Hospital, Edinburgh, Dr. F. A. Jenner, Hollymoor Hospital, Birmingham, Dr. D. Hughes, Parkside Hospital, Macclesfield, and Dr. A. P. Ridges, Department of Medicine, University of Liverpool, for the supply of urine samples.

Effect of Reduced Glutathione on Haem Synthesis in Rat Liver during the Postnatal Period

GROWTH is subordinate to the development of function in the liver of the rat during the first 2 weeks after birth[1]. In this period the activities of some respiratory enzymes in the liver increase to adult levels. Dawkins found that the rates at which some substrates are oxidized increase greatly in the first few days after birth[2]. He also demonstrated a marked increase over this period in the concentration of co-factors of the respiratory enzymes. The rate-limiting factor controlling these processes is not at present known.

The oxidative function of these respiratory enzymes is connected with their prosthetic group, which in many cases is haem[3]. The increase in the activity of haemoproteins after birth may be related to the rate of synthesis of haem. A low level of haem synthesis would be expected to limit the development of aerobic metabolism in the liver. It has been shown[4] that haem synthesis in adult rats is increased in the presence of sulphydryl reagents such as reduced glutathione (GSH) or ascorbic acid.

The present experiments were designed to investigate the effect of GSH on haem synthetase which catalyses the insertion of iron into protoporphyrin. The activity of this enzyme was determined in extracts of isolated rat liver mitochondria from rats aged 1–21 days. The method used was a modification of that of Labbe[5]. Mitochondrial extracts were prepared in 0·25 M sucrose solution containing 1 per cent oleic acid. The incubation mixtures contained 0·08 μmoles ferrous sulphate, 0·08 μmoles protoporphyrin IX and, when indicated, 20 μmoles GSH per ml.

The protoporphyrin was dissolved in 0·1 per cent oleic acid at *p*H 8·5. Haem synthetase activity was expressed as mμmoles protoporphyrin consumed/30 min/g fresh liver. Preliminary experiments showed that proto-

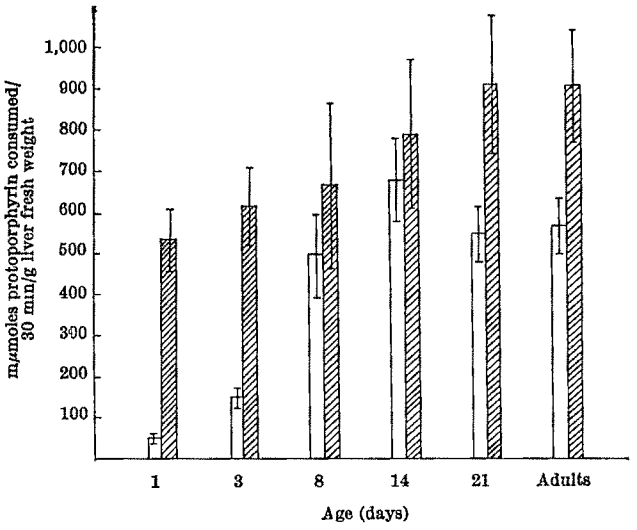

Fig. 1. The effect of GSH on haem synthetase activity in extracts of isolated rat liver mitochondria during the postnatal period. The columns represent the means of the results of between four and seven enzyme preparations. In the first 14 days the livers of between three and five animals were used for one enzyme preparation. The ranges show the standard deviations. White columns, without GSH; hatched columns, with GSH.

porphyrin consumption was stoichiometric to haem formation. Haem labelled with iron-59 was isolated and determined as haemin by the method of Labbe and Nishida[6]. The conditions used in the experiments with iron-59 were identical to those with non-labelled iron. GSH was determined by the method of Grunert and Phillips[7].

Fig. 1 shows that the protoporphyrin consumption with GSH increases within 21 days from 540 to 900 mμmoles/30 min/g liver fresh weight, whereas the activity without GSH increases from 49 to nearly 600 mμmoles/30 min/g liver fresh weight. This implies that the GSH-activation of haem synthetase is increased by a factor of eleven at the first day and only by a factor of 1·5 in adults. Two possible explanations of this change in the effect of GSH during the postnatal period can be advanced: (1) the concentration of GSH in the extracts of newborn liver might be lower, or (2) the breakdown of the added GSH might be increased. Preliminary experiments indicate that the first assumption is more likely, because the GSH-content of the mitochondrial extracts is only 25 per cent of that of adults.

Regulation of enzyme activity during development by the concentration of ascorbic acid was demonstrated for the enzyme *p*-hydroxyphenylpyruvate oxidase by Kretchmer[8]. Haem synthetase provides a further example of the concentration of a sulphydryl reagent regulating enzyme activity in the postnatal period.

We thank Prof. A. Künkel for his help in the experiments with iron-59.

PHYSIOLOGY

Receptive Field Properties of the Superior Colliculus of the Rabbit

ALTHOUGH richly endowed with both sensory and motor information[1], the superior colliculus has in recent years been considered to play a very small part—literally that of a vestigial body—in the vision among higher mammals. In view of its intimate relationships with many central nervous centres[1] and its homologous significance (as in the frog), a fuller reappraisal of its role in vision seems timely. Analysis of the receptive fields of these collicular cells was found a particularly effective approach here since levels both more peripheral (the retinal ganglion cells[2]) and parallel (the lateral geniculate body[3]) in the main visual pathway of the rabbit have been similarly investigated. There have also been related studies at several synaptic levels in the cat[4–6], frog[7] and monkey[8].

The direction of this preliminary investigation was to determine qualitatively the scope of visual information represented in this centre—in particular its more important "trigger features"[2].

The twelve adult hybrids the fields of which are described here were investigated under moderate photopic conditions (background illumination of 1 ft.-L.). They were maintained under light urethane anaesthesia (5·5 ml./kg body weight of a 20 per cent solution in saline). This dosage was found from earlier work at the retinal ganglion and lateral geniculate levels to be no more detrimental to cell responsiveness than decerebrate and *encéphale isolé* techniques. Recordings were made only when spontaneous activity was prevalent in the midbrain and withdrawal reflexes of the forelimbs were easily obtained.

The animal was supported during the experiment in a stereotoxic frame designed not to impair the visual field. The lids of the tested (right) eye were sutured well back and the pupil dilated with two drops of phenylephrine hydrochloride (10 per cent, viscous). Eye movements were seldom encountered, making paralysis of the extraocular muscles unnecessary.

The eye was then refracted and fitted with a contact lens to protect the cornea from drying and to bring the retina into conjugacy with the testing plane. 57 cm from the eye. For plotting purposes, horizontal and vertical zero were taken from a line projecting from the area centralis (20° below the lower margin of the optic disk[9]) through the centre of the pupil into visual space.

An aperture in the skull 4 mm long and 3 mm wide over the left superior colliculus allowed the passage of a stainless steel microelectrode (average resistance, 40 mΩ) to any region of this body. Sealing the hole with a 4 per cent agar gel minimized pulsation so that cells could be maintained for from several minutes up to two hours time. One recording site, usually the deepest, was marked by a deposit of metallic iron on each penetration. These locations were readily identified in frozen sections later made of each brain, appearing as Prussian blue reactions (50–100μ in diameter) to the potassium ferrocyanide included in the formal–saline perfusion solution.

Decline of response to repeated stimulation[10] is a common property of these cells, and localization had to be based on spontaneous discharge as the electrode was lowered rather than on provocative searching techniques. Once localized, the receptive field of the cell was first mapped with a $\frac{3}{4}^{c}$ diameter light spot (6 ft.-L.) found most effective for defining the whole-field boundaries as well as the discrete response zones within. Further testing with diffuse illumination and a variety of specific targets (such as straight edges, lines, contours, etc.) both of light and shadow, moving and still, followed.

In categorizing the sixty receptive fields described here (Table 1), three major classes were evident: (1) those giving the same mode of response throughout their domain; twenty-three of these have been found and they are referred to here as homogeneous fields; (2) those of

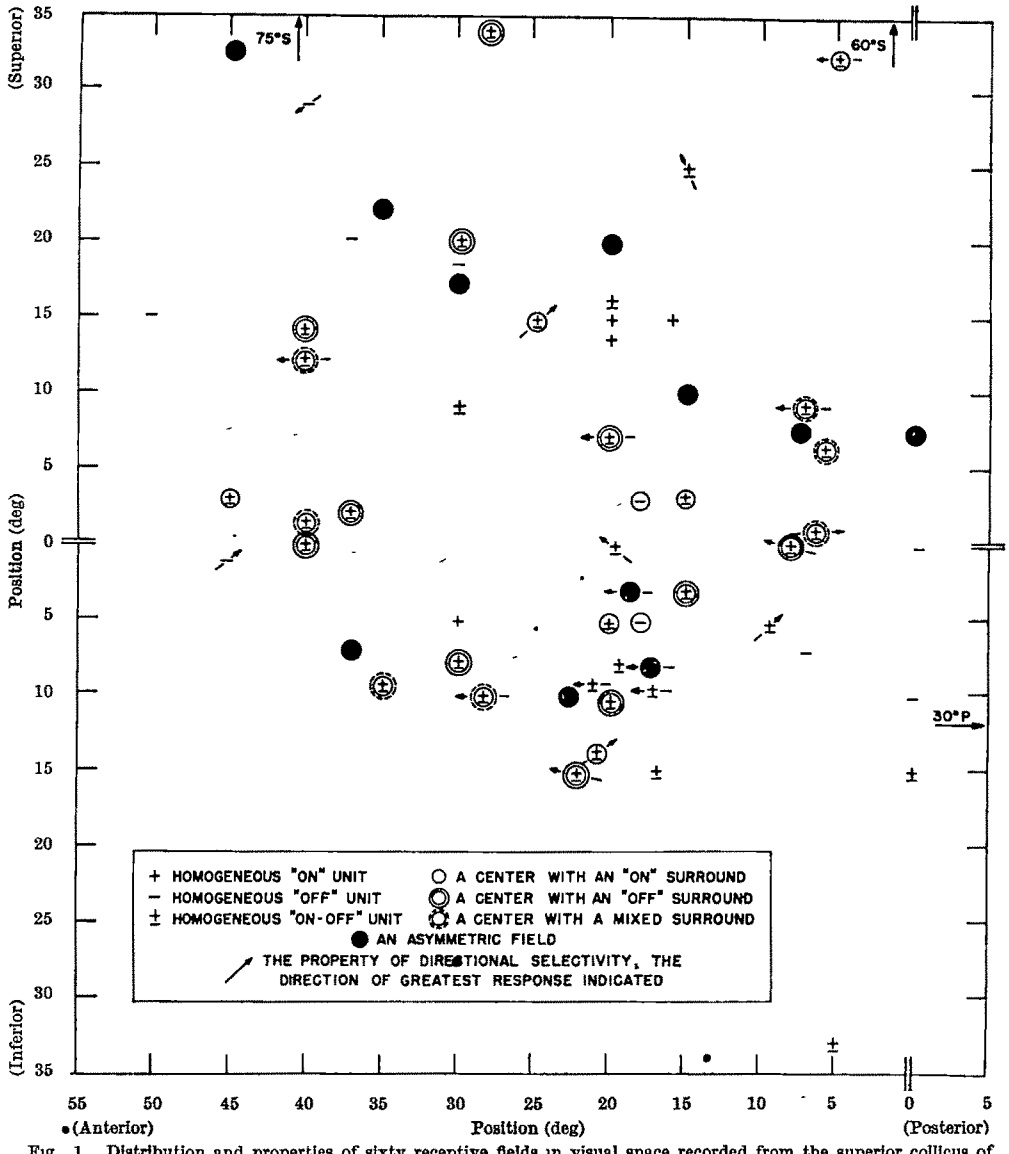

Fig. 1. Distribution and properties of sixty receptive fields in visual space recorded from the superior colliculus of rabbit.

classic concentric geometry with centre and surround producing opposing modes of response; twenty-six of these were found; and finally (3) a group of eleven fields generally asymmetric in outline and always asymmetric in internal geometry, often incorporating several response zones of distinctive character. Fig. 1 shows the distribution of these sixty fields in visual space together with some of their sub-distinctions.

Those fields "homogeneous" in response were of three descriptions: four responded only at "on" of the stimulus; eight responded only at "off"; and eleven responded at both "on" and "off". Although this uniformity was not found to change over a wide photopic range, diffuse light stimulation, generally resulting in a greatly reduced response from the field or its complete elimination, suggested the presence of lateral influence.

Most distinctive of these three forms were the "on" responders, with the smallest average diameter, 8·2° ($\sigma = \pm 3{\cdot}5°$). While reacting briskly to movement, either of light or shadow, none were directionally selective nor were they sensitive to particular ranges of velocity.

In contrast, the "off" and "on–off" responders were more varied and often considerably larger, with average diameters of 27° and 21° respectively. They were, in addition, located throughout a greater range of eccentricity in the visual field, their centres being found up to 50°

Table 1

Field geometry	*N*	Percentage	Diam. $\bar{x}°$	Diam. $\sigma°$	Diam. range°	Eccent. $\bar{x}°$	Eccent. $\sigma°$	Eccent. range	*DS* *N*	*DS* Percentage of class

* Badly skewed distribution, many more large fields than small being represented. *DS*, directional selectivity.

from the optic axis. These cells were often difficult to map with a flashing spot, responding sluggishly and seeming to decline readily in response to repeated stimulation. Movements, especially of edges or detailed targets, were found to be more effective stimuli and seven of these cells showed a well-developed directional selectivity. In addition, a few were more responsive to fast targets (5°/sec or more), while one was sensitive only to very slow movement of low amplitude. Scanning for fine (or distant) movement seemed the forte of these cells.

Slightly more common were cells with fields arranged concentrically. Least frequent among those studied was the off-centre, on-surround form (on-centre, off-surround forms were not found). Since only two were mapped, little can be said about their properties except that their surrounds were sharply defined and well developed in each case. Both were extremely sensitive to small movements, but neither was directionally selective. Their overall diameters were 15° in each case.

While the zones of the fields already described were well defined, those of the balance of the concentric fields were not. All had a large central area, responding both at the onset and at the cessation of the stimulus, and were encircled by a marginally developed "off" surround (eleven cases), "on" surround (six cases), or a surround giving either "off" or "on" depending on the portion of the rim being tested (seven cases). Each group contained a large range of diameters, some as small as 4°, others reaching 80°. The eccentricity of their centres varied from 7° to 50°. Their functional characteristics included a sluggishness in responding to repeated static stimuli, a high sensitivity to direction of movement (ten out of twenty-four cells) and occasionally a predilection for limited ranges of velocity.

Apart from the two major classes just described, the homogeneous and concentric forms, one other population stood out. The common characteristic of these eleven fields was their asymmetry, as mentioned earlier. Most had a distinctive "off" responding band dividing their field irregularly, the remainder of it being either "on" or "on–off" in character. Three contained local regions which were directionally selective. While static stimuli were not particularly effective, moving targets of some detail were quite effective. Their frequent large diameters (up to 103°) and range of eccentricities (up to 85°) make them, like the homogeneous fields, well suited for scanning.

Of comparative interest is the geometrical likeness of the first two classes to the "simple" fields of the lateral geniculate nucleus of this animal described by Arden[3]—particularly the poorly developed surrounds common to both sites. Similarly, there are both functional and geometrical resemblances between the "complex" fields of the lateral geniculate and the asymmetric variety found here. There seem to be primary differences in the range of field sizes and the lower frequency of the complex forms in the superior colliculus. Of course, differences in testing conditions and selectivity of electrodes cannot be ruled out as selective factors.

In contrast to the unlayered lateral geniculate body of the rabbit, however, the stratified superior colliculus lends itself to the possible ordering of groups of cells with overlapping fields into functional columns, catering to specific orientations of stimuli and balances of ocular dominance as described in the cat cortex by Hubel and Wiesel. While the cells whose fields have been described here have been localized in successive layers (for example, stratum opticum, stratum griseum superficiale and the stratum griseum intermediate) only the first hints of such ordering are evident so far, but a clearer relationship between specific layers and receptive field geometry is promising.

This extensive interchange of sensory and motor information in the superior colliculus, representing a rich repertoire of properties—among them, movement, velocity and directional sensitivities—makes this centre an appealing one for renewed examination, not only relative to its own analytical structure, but also with regard to its functional influence on eye movements, pupillary control, and other visually dependent behaviour.

Convergence of Inputs on Deiters Neurones

ON the basis of anatomical studies, Deiters nucleus has been divided into parts projecting to different levels of the spinal cord, and it has been suggested that these parts are not functionally equivalent[1]. We have recently shown that those Deiters cells which project to the lumbosacral cord can be strongly facilitated by electrical stimulation of peripheral nerves; the polysynaptic pathway through which facilitation is produced does not traverse the cerebellum, and can be activated by stimulation of all types of afferents other than Group I fibres from muscle[2]. In the present experiments the effects of peripheral and labyrinthine inputs on Deiters cells that send axons to the lumbosacral cord have been compared with the effects of those inputs on Deiters cells that send axons to more rostral spinal segments. The results of this single unit physiological analysis have in many respects confirmed the interpretation of the organization of Deiters nucleus proposed by Brodal and his collaborators[1].

All experiments have been performed on acutely decerebellated cats, usually anaesthetized with chloralose–urethane, paralysed with 'Flaxedil' and artificially respired. The stimulating and recording equipment, and much of the dissection and preparation of the animal, were as previously described[2]. The vestibulospinal tract was stimulated antidromically with two sets of electrodes, each consisting of a pair of narrow strips of platinum foil (thickness 0·002 in., interelectrode distance 7 mm) attached to a thin piece of plastic. One electrode pair was inserted under the spinal cord at *C3–C4*, the other at *L3–L4*. We have designated as *C* cells those Deiters cells activated antidromically only by cervical cord stimulation. This group of cells includes cells projecting to the cervical, thoracic and upper lumbar cord. Cells also activated antidromically as a result of lumbar stimulation have been designated *L* cells. These units belong to the "hindlimb" part of Deiters nucleus[3], and project to the lumbosacral cord. Glass micropipettes, filled with 2 M sodium chloride saturated with fast green FCF and selected for initial resistances of 3–8 MΩ, were used to record the activity of single units extracellularly, and, when desired, to mark the position of the electrode tip[2,4]. During an experiment, several fast green marks were made with the recording electrode and these marks were afterwards used to estimate the position of units as being in the rostral, middle or caudal part of Deiters nucleus. Cells were found by searching the appropriate region of the medulla while stimulating the spinal cord at a rate of 5 stimuli/sec. Once a cell was encountered and identified attempts were made to modify its activity by stimulation of various forelimb and hindlimb nerves with 40 μsec rectangular pulses, delivered through bright platinum electrodes at a repetition rate of 1 a sec. The effect of impulses in the vestibular nerve on Deiters cells was also

investigated in some experiments. Stimuli to the membranous labyrinth were delivered through a fine platinum ball electrode, inserted as deeply as possible through the ipsilateral fenestra vestibuli, and held in place with dental cement.

The results to be described were obtained from twenty-four cats, in which 127 *L* cells and eighty-eight *C* cells were found in electrode tracks located in all parts of the nucleus. As might be expected from previous anatomical[3] and physiological[2,5] investigations, *L* cells were relatively more numerous in the caudal part of Deiters nucleus. In caudal tracks *L* cells outnumbered *C* cells fifty to twenty-six (*L*/*C* ratio 1·9), while in rostral tracks forty-seven *L* cells and forty-five *C* cells were encountered (*L*/*C* ratio 1·05). The remaining thirty *L* and sixteen *C* cells were approximately in the middle of the nucleus.

We have previously reported that many *L* cells discharge spontaneously in the type of preparation used in our experiments[2]; and many *C* cells that fired spontaneously were found in the present investigation. Systematic tracking in different regions of the nucleus, however, revealed an interesting difference between these regions: spontaneously firing cells were much more prevalent in the caudal part of Deiters nucleus than in the rostral part. Thus of 69 cells that were studied satisfactorily in the caudal half, fifty-one (74 per cent) exhibited ongoing activity. In comparison, only thirty-six of eighty cells in the rostral half, or 45 per cent, discharged spontaneously. Rostral *C* cells showed the least spontaneous activity (15 of 39, 38 per cent) while caudal *L* cells showed the most (39 of 46, 85 per cent). Study of seventeen tracks in which three or more cells were encountered (and in which there were non-spontaneous cells) revealed that the non-spontaneous cells were most likely to be cells in the middle or at the bottom of the track.

In a previous paper[2] it was shown that stimulation of mixed or cutaneous nerves at 1/sec facilitated many *L* cells, with a latency of about 20 msec and a duration of 100–200 msec. The facilitation was usually revealed as an increase (often of 100 per cent or more) of ongoing activity, and was rarely strong enough to cause previously silent cells to discharge. With stimulation of muscle nerves single shocks were not very effective, and triple shocks (at 300/sec) were required to bring about any significant facilitation. In the present experiments similar results were obtained in a number of *C* cells: fifteen cells that were carefully studied were facilitated in the same way as *L* cells described previously and as *L* cells seen in this series of experiments. Facilitation of *C* and *L* cells was produced by stimulation of the same peripheral nerves and was of approximately the same magnitude. Of the ten *C* cells studied that had known locations, however, eight were in the caudal or middle parts of the nucleus, and therefore can be assumed to have been mainly cells projecting to the thoracic and upper lumbar (above *L*3) cord[3]. While these cells received a similar input from the periphery as did *L* cells, less is known about rostral *C* cells; many of these *C* cells presumably project to the cervical cord[3]. Only fifteen spontaneous rostral *C* cells were encountered, and it was possible to test the effect of limb nerve stimulation on eight of these; two showed typical effects and six some facilitation. Similar results were obtained with nineteen spontaneous rostral *L* cells. It is reasonable to suggest that *L* and *C* cells located in the rostral part of Deiters nucleus received the same facilitatory inputs as did cells located more caudally, and that the relative lack of information on facilitation of rostral cells resulted from the comparatively large number that were non-spontaneous and therefore could not reveal the excitability change produced by peripheral stimulation. Apparently the distribution of facilitatory inputs from the periphery to Deiters cells in decerebellated cats is more widespread than would have been predicted from anatomical data such as the distribution of spinovestibular fibres[1].

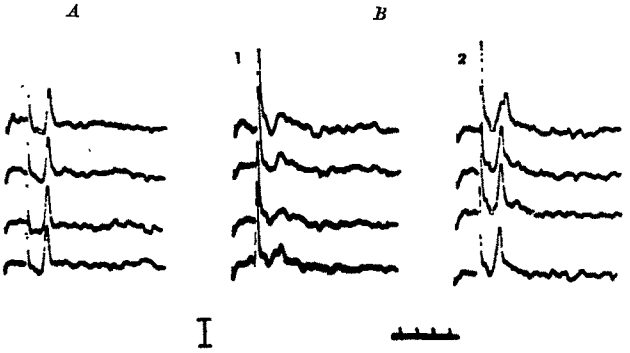

Fig. 1. Effect of stimulation of the labyrinth on a non-spontaneous *C* cell located in the very rostral part of Deiters nucleus. *A*, Antidromic response to stimulation of the cervical cord at 1/sec; *B*, response to stimulation of labyrinth; *B*1, with a stimulus of 1·8 V a small *P* wave is seen superimposed on the end of the stimulus artefact, and an *N*1 wave of about 300 μV starts at 0·9 msec; *B*2, when the stimulus is raised to 2·0 V a spike occurs in every sweep, at 1·0–1·5 msec. Extracellular recording with fast green electrode. Time marks 1 msec, voltage calibration 500 μV.

Stimulation of the labyrinth at 1/sec with an electrode inserted into the fenestra vestibuli produced, in many parts of the nucleus, field potentials similar to those recently described[6]. The delay in the arrival of afferent impulses, as measured from the stimulus artefact to the summit of the *P* wave[6], was usually 0·4 msec. A large negative (*N*1) deflexion, presumably consisting of post-synaptic potentials and spikes, usually had a latency of 0·8–0·9 msec. Of ninety-one cells studied for vestibular effects, thirty-three fired on top of this *N*1 potential at a latency of 0·9–2·0 msec after the stimulus artefact (latency with strong shocks 0·9–1·4 msec), as shown in Fig. 1. The latency of this firing was such that the responses can safely be considered monosynaptic. Almost certainly, other cells also received a monosynaptic input from the labyrinth; in the absence of firing, however, such an input cannot be detected with extracellular recording. Some polysynaptic firing was also observed; this will be described in a subsequent publication.

While stimulation of the labyrinth fired both *C* and *L* cells monosynaptically, such firing was present in a considerably greater fraction of the former. Thus, monosynaptic responses were seen in only twelve of fifty-five *L* cells (22 per cent), but in twenty-one of thirty-six *C* cells (58 per cent). While stimulation of peripheral nerves usually caused detectable effects only in spontaneous cells, stimulation of the labyrinth produced monosynaptic firing mainly in non-spontaneous cells: monosynaptic firing was seen in twenty-six of forty-four non-spontaneous cells, in only seven of forty-two spontaneous cells. The biggest single group of cells monosynaptically activated by the labyrinth consisted of twelve non-spontaneous rostral *C* cells; in contrast, only one spontaneous caudal *L* cell responded monosynaptically. Parenthetically, the monosynaptic response of non-spontaneous cells demonstrates the power of the input from the labyrinth: at 1/sec most cells responded to every shock.

As stated above, non-spontaneous cells were usually found in the middle or at the bottom of electrode tracks. Analysis of twenty-four tracks, including the seventeen already described, showed that monosynaptic activation by the labyrinth was also usually found in the middle or at the bottom of electrode tracks. This result correlates well with the finding that primary vestibular fibres terminate only on cells of the rostroventral region of Deiters nucleus[7].

Our findings are in agreement with many predictions based mainly on anatomical studies[1]. In particular our results provide further evidence for a functional subdivision of Deiters nucleus. The rostral part of the nucleus contains many cells projecting to the rostral levels of the spinal cord, and it is among these cells that monosynaptic

input from the labyrinth is found most often. The rostral and caudal parts of the nucleus are also differentiated by the level of spontaneous activity. Such activity is found especially frequently in the more dorsal, caudal cells, that include many cells projecting to the lumbosacral cord. It is interesting to note that a direct input from the labyrinth, and non-spontaneity, are largely found in the same population of cells. This suggests a need for further studies to test the responsiveness of Deiters cells, identified by antidromic invasion and location, in animals whose position in space can be modified in the course of the experiment.

Determination of Regional Blood Flow by means of Small Semiconductor Detectors and Red Cells tagged with Phosphorus-32

THE determination of regional blood flow is of great interest both from a clinical and a physiological point of view. Several methods for doing this are available. Most of them, however, have the limitation that they give the blood flow in comparatively large masses of tissue, which may include parenchyma with different functions and different blood flows. The thermocouple[1], the hydrogen gas electrode[2] and the noble gas method (local-injection technique) offer the possibility of making measurements within small and anatomically well-defined regions. These methods must, however, be calibrated and can only be used in certain types of tissues, such as muscles and skin, because they will determine not only the blood flow but also the lymph flow, and in the kidneys the urine flow[2].

To supplement the available methods, we evaluated an indicator-dilution technique to measure local blood flow using small semiconductor detectors primarily sensitive to beta-rays and using phosphorus-32-tagged red cells as the indicator. Needle detectors were put into the parenchyma, and end detectors on the surface of the organ. We have applied the method to the kidneys.

The needle detector itself consists of a tube of stainless steel or aluminium with a wall thickness of about 50μ at the tip of the tube, where a lithium-drifted *p-i-n* silicon crystal is placed. The smallest detector used has an outer diameter of 1·1 mm. The length of the sensitive part of the semiconductor is 2·5 mm and the diameter 0·9 mm. The largest one has an outer diameter of 2·5 mm. The corresponding sensitive part is 4·5 mm long and 1·9 mm in diameter. The detectors were made by *AB* Atomenergi, Sweden, and were operated with a bias voltage of 20–50 V. The pulses were amplified by a charge-sensitive preamplifier and a linear amplifier and were recorded on a scaler with an automatic print-out (2·5 times per sec)[3].

The counting-rate efficiency for the smallest detector was 1,500 c.p.m. and for the largest 6,000 c.p.m., when the detectors were placed in a solution of phosphorus-32 of concentration 1 μc ml.

The end detector used was a common phosphor-diffused semiconductor detector. This detector is enclosed in a stainless steel capsule with a 15μ aluminium window. The analysing system was essentially the same as for the needle detector, except for the print-out, where a decimal pip method was used[4].

Twenty-five experiments were performed on six dogs which had been anaesthetized with chloralose. The left kidney and the renal artery were exposed by an incision in the flank. A lumbar artery leaving the aorta at the same level as the renal artery was dissected free and a catheter was inserted through this into the renal artery. The needle detector was inserted into the medulla and the end detector was placed on the surface of the kidney. After determination of the background activity, 0·2–0·5 ml. of plasma containing a suspension on the phosphorus-32-tagged red cells (0·2–2 mc./ml.) was injected into the catheter. The pulses from the needle and the end detector were recorded simultaneously. The indicator-dilution curves from typical experiments are shown in Figs. 1 and 2.

Five minutes later, when the tagged red cells were equilibrated in the total blood volume of the body, the intrarenal activity was determined by the detectors. Then 5–10 ml. of blood was taken and the activity determined using the same detectors. The blood volume (V) in the region investigated was calculated by dividing the

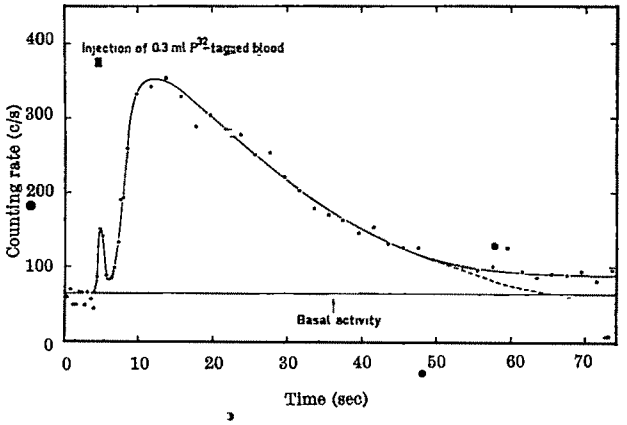

Fig. 1. Recording from a needle detector in the inner zone of the renal medulla. The dots represent the experimental values. The dashed line is extrapolated from the exponential slope of the curve. The basal activity depends on earlier injections of radioactive blood.

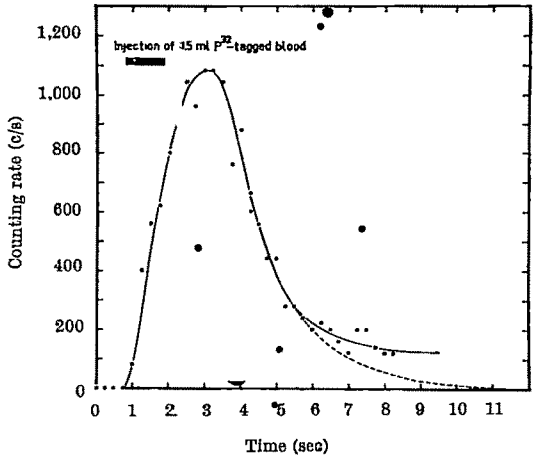

Fig. 2. Recording from an end detector on the renal cortex. The experimental values are represented by the dots and the dashed line is extrapolated from the exponential slope of the curve.

intrarenal activity by the blood activity. To determine blood flow we used the following equations[5]:

$$\bar{t} = \left\{ 1/c(t)_{max} \right\} \int_0^\infty c(t)\, dt \qquad (1)$$

where $\bar{t}$ is the mean transit time, $c(t)$ the recorded activity and $c(t)_{max}$ the peak value of $c(t)$, and

$$\varphi = V/\bar{t}, \qquad (2)$$

where φ is the blood flow and V the calculated blood volume in the region investigated.

Fig. 1 shows a recording from a needle detector placed in the inner zone of the renal medulla. The first peak arises from the activity passing through the interlobar arteries. The counting rate then rises very quickly to a peak value ($c(t)_{max}$) and then decreases exponentially. The dashed line is an extrapolation of the exponential decrease of the activity.

The mean transit time of the actual experiment was calculated to be 24 sec, corresponding to a blood flow of 0·5 ml./min. ml. tissue. Fig. 2 shows a recording from an end detector placed on the renal cortex. The mean transit time and the blood flow were calculated as 3·2 sec and 3·3 ml./min. ml. tissue, respectively.

The semiconductor fulfils excellently the requirements of a detector for local blood-flow measurements. The method is dependent primarily on the fact that the semiconductor records beta-particles. The energy of these particles determines the volume measured which in the case of phosphorus-32 is about 0·2–0·5 cm³, depending on the size of the detector used. Gamma detectors, even greatly collimated ones, do not afford the possibility of such local application. Other advantages of the semiconductor detector are its great efficiency relative to its small size, its extreme stability and long life and also its ability to record high activity[6]. In these latter respects the semiconductor detector is superior to Geiger–Müller tubes.

A drawback of the needle detector is that it damages the surrounding tissues when inserted into the organ; this in turn gives rise to a non-perfused zone around the detector. The estimated blood volume will therefore be too small. This error, however, has no effect on the determination of blood-flow described earlier, because the calculated mean transit time refers to the calculated blood volume and not to the true blood volume in the investigated region.

The results, though few, show a very low rate of flow in the medulla compared with the high flow in the cortex. These results agree with those obtained by Kramer *et al.*[7]. The calculated cortical blood flow may have been underestimated, owing to the comparatively long injection time.

We consider that the method described is valuable for blood-flow determinations not only in the kidneys but also in other organs, such as brain, liver, heart and bone marrow. To evaluate this method, it seems necessary to study the accumulation and washing-out rates after continuous injections of tagged red cells. The method also makes it possible to use krypton-85 for the blood-flow measurements, as this isotope has a suitable beta-energy.

Central Mechanism of Hyperaesthesia

IT is common experience that inflamed tissues are hypersensitive to pain. Direct experiments have shown that this hypersensitivity may result from the increased sensitivity of the receptors in the injured tissues[1]. On the other hand, MacKenzie[2], as far back as 1893, suggested that hypersensitivity could be the result of increased sensitivity of structures in the central nervous system. According to this investigator, sensory impulses arising in the injured tissues create an "irritable focus" in the segment of the spinal cord at which they enter. As a result a stimulus which would not evoke a sensation of pain in undamaged tissue begins to do so, if the afferent impulses set up by the stimulus reach the "irritable focus". Participation of central mechanisms in the development of hyperaesthesia was then confirmed by a number of observations[3–7]. It has not yet been made clear, however, just where this "irritable focus" is created—that is, at which synaptic relay the facilitation elicited by impulses arising in the injured tissues occurs. A number

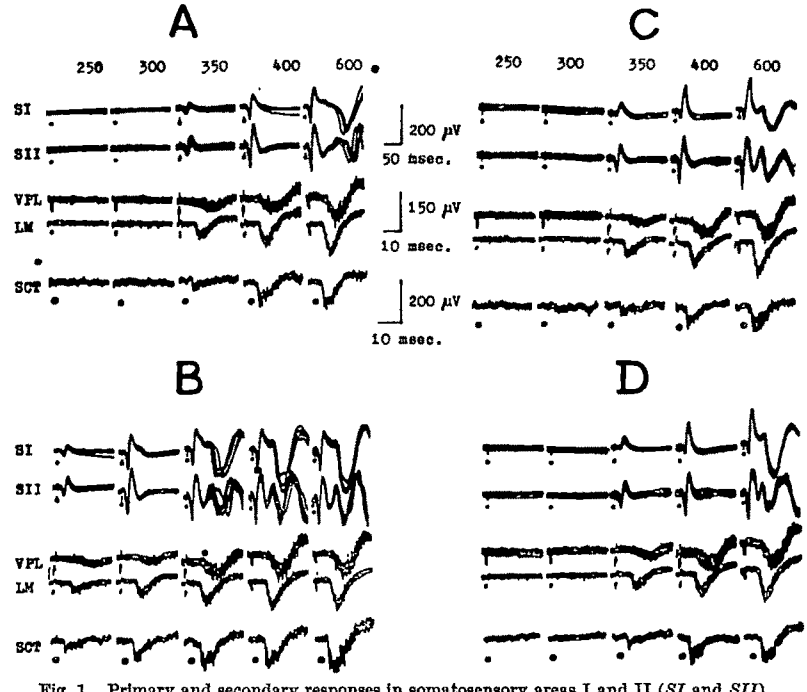

Fig. 1. Primary and secondary responses in somatosensory areas I and II (*SI* and *SII*), evoked potentials in the ventralis postero-lateralis nucleus of thalamus (*VPL*), in the medial lemniscus (*LM*), and in the spinocervical tract (*SCT*) set up by stimulation of the superficial peroneal nerves of right (*A*, *B*) and left (*C*, *D*) hind limbs before (*A*, *C*) and after (*B*, *D*) the development of the inflammation in the right hind paw. A marked facilitation of all responses elicited by stimulation of the nerve of the damaged hind limb is seen (*B*). The numbers indicate the strength of stimulus in mV. Each record has been formed by superposition of five traces. The black points beneath the individual records mark the moment of stimulation. Upward deflexions signal negativity in all records.

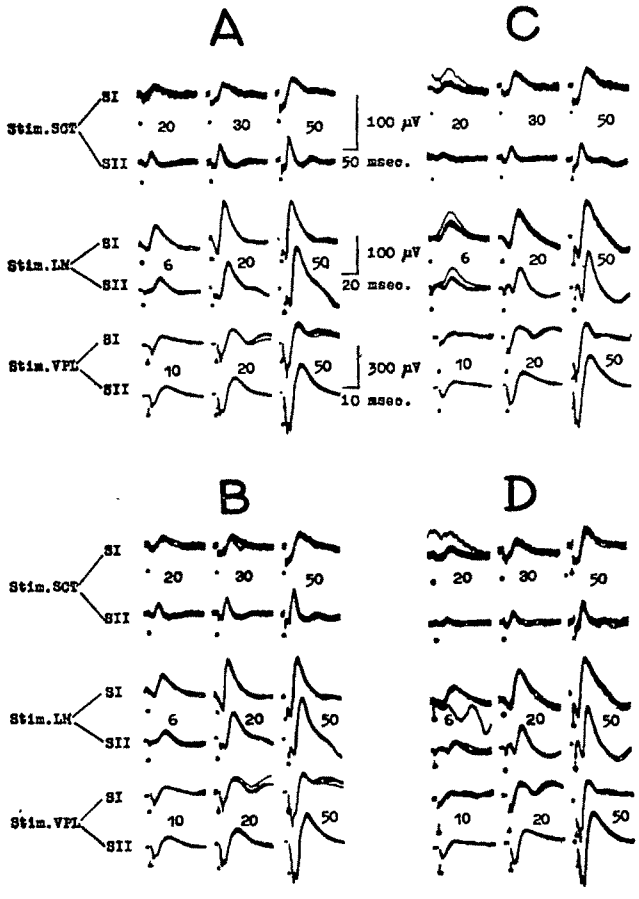

Fig. 2. Primary responses in somatosensory areas I and II (*SI* and *SII*) of the left (*A*, *B*) and right (*C*, *D*) hemispheres elicited by stimulation of the contralateral spinocervical tract (*Stim. SCT*), of the contralateral medial lemniscus (*Stim. LM*), and of the ipsilateral ventralis postero-lateralis nucleus of the thalamus (*Stim. VPL*) before (*A*, *C*) and after (*B*, *D*) the development of the inflammation in the right hind paw. It can be seen that responses did not change after the damage of the right hind paw. Each record has been formed by superposition of five traces. Remaining notation as in Fig. 1.

of suggestions have been made previously[5,8,9], but none is satisfactory.

This investigation was undertaken to elucidate the problem of finding a central mechanism. For this purpose we studied the action of the impulses arising in the inflamed area on the hind limb of experimental animals on the excitability in all synaptic relays of the specific projection pathway along which the information from the injured hind limb reaches the cerebral cortex.

The experiments were performed on eighty-five cats anaesthetized with 'Nembutal'. The inflammation was evoked in one of the hind paws of the animal by a subcutaneous injection of turpentine (0·5–1·0 c.c.). The excitability of the synaptic relays in the specific projection pathway along which the information from the injured hind limb reaches the cerebral cortex was tested by means of the evoked potentials recorded from somatosensory areas I and II, from the ventralis postero-lateralis nucleus of the thalamus, from the medial lemniscus, and from the spinocervical tract, after the first synaptic relay in the dorsal horn of the lumbosacral segments of the spinal cord[10]. Responses were elicited in these structures either by electrical stimulation of the superficial peroneal nerve along which impulses from the inflamed area on the hind limb were propagated, or by stimulation of the spinocervical tract, medial lemniscus or ventralis postero-lateralis nucleus. As a control, similar responses were recorded in the specific projection pathway of the undamaged hind limb.

As a result of our investigations it was first of all established that impulses from the inflamed area on the hind limb facilitated the primary and secondary cortical responses evoked by the stimulation of the nerve from the injured hind limb. As shown in Fig. 1 *A*, the weakest stimulus which would elicit the primary responses in somatosensory areas I and II before the damage of the hind limb was 350 mV. The secondary discharges were evoked by a stronger stimulation—600 mV. Two hours after the injection of turpentine the right paw was very swollen and by this time the threshold for the initiation of cortical responses to stimulation of the damaged hind limb nerve was markedly lowered. The primary and secondary responses in somatosensory areas I and II now began to appear on stimulation of this nerve by current pulses produced by voltages of 250 mV and 350 mV respectively (Fig. 1 *B*). Similar facilitation was then established for the responses elicited by stimulation of the nerve from the damaged hind limb in all the remaining relays of the same specific projection pathway—in the ventralis postero-lateralis nucleus, medial lemniscus and spinocervical tract (Fig. 1 *B*). By contrast, it was found that the threshold for the initiation of the same responses to stimulation of the undamaged hind-limb nerve did not usually change under very deep anaesthesia (Fig. 1 *C*, *D*), neither did the responses elicited by the stimulation of the central structures (ventralis postero-lateralis nucleus, medial lemniscus or spinocervical tract) (Fig. 2).

Thus it seems that the impulses from the inflamed area in the hind paw facilitate the first synaptic relay of the spinocervical tract and do not elicit any detectable changes in the excitability of higher relays of the same specific somatosensory projection pathway. As a result of this, the weak afferent volley from the periphery which normally does not reach the cerebral cortex will begin to do so after the injury to the hind limb. Thus, the facilitation of the first synaptic relay of the spinocervical tract may be considered as one cause of the hypersensitivity of inflamed tissue.

Nitrogen Balance Experiments: some Theoretical Considerations

Miller and Payne[1] have raised anew the problem of how to explain net protein utilizations (NPU) greater than 100 per cent. They offer a conventional answer, that the metabolic or endogenous loss of nitrogen can be reduced in certain cases and that this results in calculated efficiencies greater than 100 per cent. The examples cited of such high utilizations are of two types

$$\mathrm{NPU} = 100\,(\mathrm{Bal}+M)/I \qquad (1)$$

$$\mathrm{Bal} = aI+bI^2+c \qquad (2)$$

$$\mathrm{NPU} = 100\,\mathrm{dBal}/\mathrm{d}I \qquad (2a)$$

where I, Bal, and M are nitrogen intake, nitrogen balance, and endogenous urinary and faecal nitrogen excretion, respectively, and a, b and c are constants.

The high utilization values referred to by Miller and Payne were taken from Allison *et al.*[2] and Anderson and Nasset[3], who obtained them by means of equation (1); other values were taken from Forbes *et al.*[4] by way of equations (2) and (2*a*). The high results by equation (1) are illogical and require explanation, while the finding that the instantaneous slope of the curvilinear regression line may be greater than unity merely indicates that the utilization of an intake increment may be greater than the increment itself. This is quite possible provided the slope is less than unity below and above the intake range where it was found to exceed this value. There are indications[5–7] that growth, nitrogen balance and nitrogen retention may vary with the intake of protein, amino acids, or vitamins by sigmoid response curves. The alleged demonstration, however, of slope values greater than unity in curves describing the relationship between nitrogen balance and nitrogen intake[1,4] refers to the intake range where no observations were recorded, and for this reason they may, therefore, be artefacts.

It remains to be explained how values greater than 100 per cent can be obtained for net protein utilization by equation (1). It has been assumed that the feeding of some special proteins or amino-acids reduces the endogenous excretion; it may, however, be that the protein-free feeding prescribed for its determination[8] results in nitrogen being excreted in excess of the inevitable nitrogen loss which it is intended to account for in the experimental animal given protein in its diet. It will be noted that when Miller and Payne[1] constructed their theoretical curves they used a higher endogenous excretion (about 250 mg N/day/kg body weight$^{0.73}$) than the mean extrapolated value corresponding to the experimentally obtained curves[4] (about 175 mg N/day/kg body-weight$^{0.75}$). This tallies with my previous objection[9] that Miller and Payne's[10] estimate of the maintenance item is higher than that usually accepted. It also emphasizes that such estimates tend to be imprecise.

Ashworth was one of the first to report biological values greater than 100 per cent[11]. He pointed out that when complete proteins are given at low levels, the endogenous excretion represents almost the total excretion and that "therefore any variations in the endogenous nitrogen excretion reflect as variations in the biological values. Hence the importance for the evaluation of biological values of protein of a broad knowledge of the factors influencing endogenous nitrogen excretion".

Acceptance of net protein utilizations and biological values greater than 100 per cent will invalidate these concepts as quantities estimating the fractions of ingested and absorbed protein utilized by the experimental animal. Reduction of the endogenous excretion would only be suspected in the few cases when the calculated values of net protein utilization were greater than 100 per cent, but it is unlikely that the hypothetical reduction would be restricted to these cases. Thus the meaning of the calculated measures will become obscure. Before these generally accepted terms are deprived of their original meaning, serious consideration should be given to the problem of whether findings at variance with it can be explained so that its significance can be retained.

It seems to be rational first to question whether the methods used for the estimation of endogenous nitrogen excretion are adequate for conclusions to be drawn regarding the possibility of reducing it by dietary means[12].

In the same way as net protein utilization greater than 100 per cent invalidates this concept, protein scores greater than 100 per cent deprive this quantity of a logical meaning. In this case the obvious answer is either that the reference values chosen are too low or that the protein sources may contain amino-acids in excess of requirements[13]. When the relationship between net protein utilization and protein score is considered[1] it should be based on the premise that both qualities should vary between zero and 100 per cent until it can be proved that this is not so.

Driving the Sodium Pump backwards to form Adenosine Triphosphate

IF the ionic pump in the red cell membrane expels three sodium ions and takes up about two potassium ions for each molecule of adenosine triphosphate (ATP) hydrolysed[1–5], under physiological conditions the free energy available to drive the reaction forwards must be quite small—about 3,000 cal. By arranging that the concentration gradients for sodium and potassium are even more adverse, it should be thermodynamically possible to run the pump backwards and synthesize ATP, though, of course, theory cannot predict that the reaction would occur at a measurable rate. Investigators who have looked for ATP–inorganic phosphate (P_i) exchange associated with "transport ATPase" activity[6,7] have never found it, but they have always looked in broken cell preparations where ionic concentrations must be the same on both sides of the membrane and where, in consequence, the free energy change for the overall reaction is likely to be heavily in favour of ATP breakdown. An ingenious attempt to reverse the sodium pump in perfused squid axons failed, but it failed in such a way as to leave the possibility of reversal still an open question[8]. More encouraging was the finding that red cells with intact membranes show peculiar behaviour when placed in solutions lacking potassium, and the effect of internal phosphate concentration on this behaviour suggests that the final stage of ATP hydrolysis—P_i release—may be reversible[9].

About a year ago, we attempted to reverse the sodium pump by preparing resealed red cell ghosts containing potassium in high concentration, ADP, AMP and $^{32}P_i$, and incubating them in media rich in sodium and containing no potassium. After 15 min, heavy labelling of both ATP and ADP could be demonstrated, but this labelling was not prevented by ouabain and occurred equally well when the outside solution contained potassium instead of sodium. The labelling was therefore presumably the result of residual glycolysis rather than reversal of the pump. Schrier and Doak[10] have shown that triose phosphate dehydrogenase and, to a lesser extent, phosphoglycerate kinase are partly bound to the membrane in red cells, and glycolytic ATP–P_i exchange in red cell membranes has recently been reported by Ronquist and Ågren[11].

Since triose phosphate dehydrogenase is very sensitive to iodoacetate and iodoacetamide, whereas the transport ATPase is rather insensitive[12,13], it seemed worthwhile to repeat the original experiment in the presence of fairly high concentrations of these inhibitors. A further modification was to omit AMP and include ATP. The inclusion

Table 1. INCORPORATION OF $^{32}P_i$ INTO ATP IN FOUR SEPARATE EXPERIMENTS

Composition of ghosts before sealing (mM)	Fraction of total counts incorporated into "energy-rich" phosphate* in 15 min (per cent) "Na medium"†	"Na medium" + ouabain (5×10^{-5} g/ml.)	"K medium"
ATP 1; P_i 5; Na 2; K 140; Mg 7; IAc 2	0·663	0·412	0·391
ATP 1; P_i 5; ADP 2; Na 4·8; K 134; Mg 9; IAc 2	0·697	0·571	0·538
ATP 1; P_i 5; Na 2; K 147; Mg 7; IAc 2; Iodoacetamide 5; NADH 1	0 344	0 261	0 228
ATP 1; P_i 5; Na 0; K 147; Mg 7; IAc 2; Iodoacetamide 5	0·302	0·235	0·206

* The ratio ATP counts/ADP counts was always about 3 : 1, but as ADP is presumably labelled from ATP by adenylate kinase activity it is convenient to consider merely total "energy-rich" phosphate.

† The "Na medium" contained (mM). Na, 140; Mg, 7; *tris* (*p*H 7·4), 5; IAc, 2. The "K medium" was similar but with potassium replacing 95 per cent of the sodium.

Table 2. INCORPORATION OF $^{32}P_i$ INTO ATP AND ADP

	Relative specific activities of nucleotides (Counts per mole nucleotide × 100) "Na medium"*	Counts per mole P_i "Na medium" + oligomycin (10 μg/ml.)	"K medium"
ATP	1 89	1·57	1·37
ADP	0·89	0·83	0·72

* The "Na medium" was the same as in Table 1. The "K medium" was similar to the "Na medium" but with potassium replacing 90 per cent of the sodium. The composition of the ghosts before sealing was (mM): ATP 1; P_i 5; Na 0·2; K 150; Mg 7; IAc 2.

of AMP in the original experiment was intended to hold ATP at a low concentration through residual adenylate kinase activity[2]. It is possible, however, that ATP may be needed to "prime" the system[8], so in most of the later experiments the cells were lysed in solutions containing ATP as the only nucleotide. With 5 mM P_i and 1 mM ATP in the lysing solution, about one-third of the ATP trapped in the cells is split during the pre-incubation necessary for resealing; for the main part of the experiment the ratios P_i : ADP : ATP are therefore something like 15 : 1 : 2.

The results of four experiments are shown in Table 1. In these experiments cells were prepared with the compositions shown in column 1 and, after sealing[14] and washing, were incubated in sodium media with and without ouabain and in potassium media. After 15 min the cells were treated with trichloroacetic acid, unlabelled P_i, ATP and ADP were added to act as carriers, and the nucleotides were separated on 'Dowex' 1 columns. The amount of radioactivity found in each fraction was expressed as a percentage of the total radioactivity originally in the inorganic phosphate.

It is clear that with a high concentration of external sodium and zero external potassium there appears to be an extra incorporation of P_i into ATP, and this extra incorporation is greatly diminished in the presence of ouabain. A separate experiment showed that ouabain did not affect the rate of incorporation of P_i when cells were suspended in a potassium medium.

A weakness of this kind of experiment is that because unlabelled nucleotides are added it is not possible to estimate the specific activities of the nucleotides in the cells. In the presence of external potassium, extra splitting of ATP through activation of the transport ATPase could lead to a lower concentration of ATP and therefore to fewer ATP counts even if the rate of formation of ATP were the same. With the very low concentration of internal sodium and the short period of incubation, the effect is likely to be small, and in any event it would not explain the ouabain result. Nevertheless, the difficulty can be overcome by carrying out the experiment on a scale sufficiently large to avoid the need for carriers, and estimating specific activities by direct comparison of counts and 259 mμ absorption. The results of such an experiment are summarized in Table 2 and show that $^{32}P_i$ incorporation really is greater in the sodium medium.

In this experiment oligomycin was used instead of a cardiac glycoside. At a concentration of 10 μg/ml. (60 μg/mg protein) it partly inhibited the extra P_i incorporation associated with external sodium, and this result is in agreement with the partial inhibition of ATPase activity and of sodium movements caused by similar concentrations of oligomycin[12,15–18].

Reversal of the sodium pump leading to the formation of ATP is interesting because of its possible relevance to oxidative phosphorylation in mitochondria as well as for the light it may throw on the mechanism of the pump. The rate of the reversed reaction observed in these experiments was, very roughly, 40 μmoles/l. sealed ghosts/h, that is, about 46 per cent of the rate of the forward reaction in ghosts containing similar amounts of ATP, ADP and P_i but with a normal distribution of cations, and about 2 per cent of the rate of the forward reaction in fresh red cells under physiological conditions.

PHARMACOLOGY

Determination of Nicotine and its Metabolite, Cotinine, in Urine by Gas Chromatography

A VARIETY of methods have been described for the identification and determination of nicotine in biological fluids[1–4]; however, they lack sensitivity, specificity and are tedious for routine analysis.

Gas chromatography has been used both qualitatively and quantitatively to detect nicotine and related compounds in tobacco and in cigarette smoke[5]. In investigations of the excretion of amphetamine, nicotine was found to be eliminated in the urine of smokers[6,7] and a gas chromatographic method for the determination of nicotine and its metabolite cotinine in biological fluids was described by McNiven *et al.*[8].

We have been using a simple quantitative gas chromatographic method for the determination of nicotine and cotinine in urine for about a year. In this method, nicotine and cotinine showed single well resolved symmetrical peaks, and no interfering substances near these peaks were found in the hundreds of extracts of urine analysed from many subjects. Absolute recoveries of these compounds and their standards from urine were as follows: nicotine (90–95 per cent), chlorphentermine hydrochloride (90–95 per cent), cotinine (85–90 per cent), and lignocaine hydrochloride (85–90 per cent). A relative recovery of 95–100 per cent for nicotine and cotinine was obtained with respect to their internal standards which are added to the urine at the start of the assay procedure.

The sensitivity of this method makes it possible to use small samples and, in all, the analysis takes about 6 h for sixteen samples.

The procedure for nicotine was to add 5 ml. of urine and 0·1 ml. of 5 N hydrochloric acid to 1 ml. internal marker solution (chlorphentermine hydrochloride, 5 μg base/ml. in distilled water) in a glass stoppered centrifuge tube. The solution was extracted with 3 × 2·5 ml. of freshly distilled 'AnalaR' diethyl ether, centrifuging to break any emulsion. The ethereal extract was discarded and the urine made alkaline with 5 N sodium hydroxide (0·5 ml.). A further 3 × 2·5 ml. diethyl ether extracts were combined in a 'Quickfit' test-tube, finely tapered at the base, and concentrated to about 50 μl. at 42° C; 3–5 μl. of this solution was injected on to the column using a 10 μl. Hamilton syringe.

A similar procedure was used for cotinine except that there was: (*a*) no acid solvent extraction; (*b*) N ammonium hydroxide in place of the 5 N sodium hydroxide; (*c*) freshly distilled methylene dichloride as the extracting solvent; (*d*) lignocaine hydrochloride, 5 μg base/ml. in distilled water, as the internal standard.

A Perkin Elmer *F*11 chromatograph equipped with a flame ionization detector and a 0–5 mV Leeds and Northrup Speedomax *G* recorder, model *S*, were used. The chromatographic column was stainless steel tubing 1/8 in. outer diameter, 1 m in length and packed with 80–100 mesh 'Diatoport *S*' coated with 5 per cent w/w potassium hydroxide and 2 per cent w/w 'Carbowax 20 *M*'. The operating conditions used were: hydrogen pressure, 15 lb./in.²; air pressure, 25 lb./in.²; nitrogen flow rate, 33 ml./min.; stream split ratio 1 : 3; injection block temperature about 250° C; oven temperature 135° C (nicotine), and 209° C (cotinine). The column was silanized *in situ* with 2 × 5 μl. of hexamethyldisilizane after equilibrating for 24 h at the operating conditions.

The concentrations of nicotine and cotinine were obtained by calculating the ratio of peak height of the compound to that of the internal marker and relating this to a previously constructed calibration curve of the compound in urine.

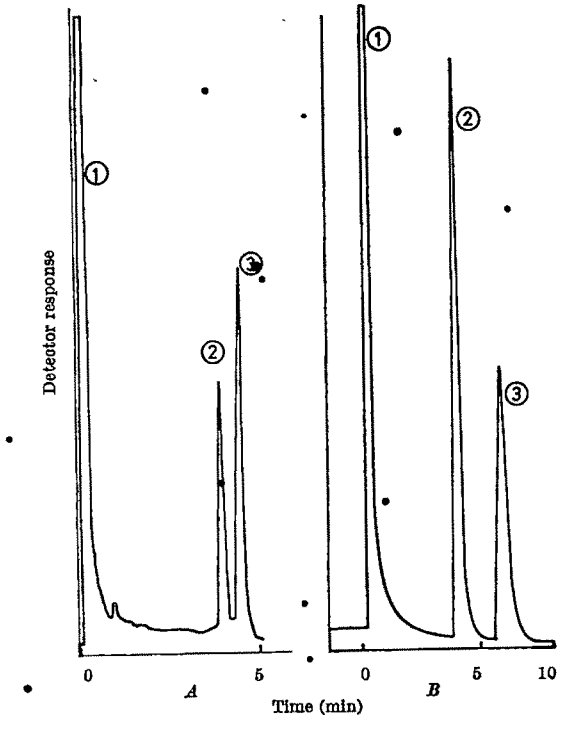

Fig. 1. *A*, Chromatogram of nicotine from urine: (1) ether (solvent); (2) nicotine; (3) chlorphentermine. *B*, Chromatogram of cotinine from urine; (1) methylene dichloride; (2) lignocaine; (3) cotinine.

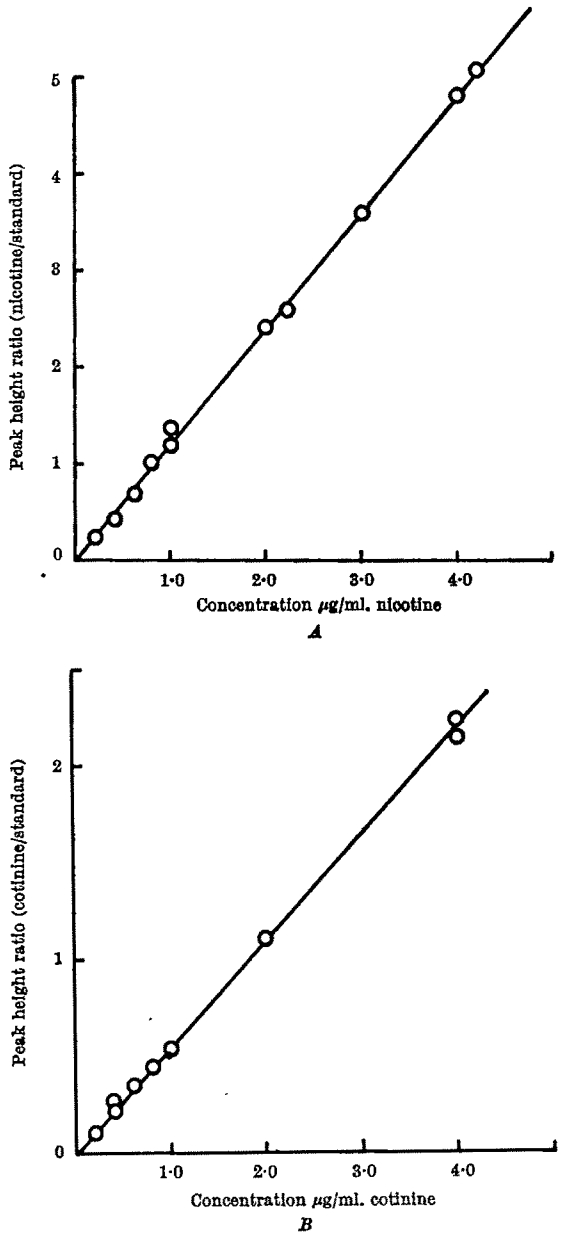

Fig. 2. *A*, Calibration curve for nicotine. *B*, Calibration curve for cotinine.

Figs. 1*A* and 1*B* show chromatograms of nicotine, and cotinine with their internal standards. No deterioration of the compounds in urine occurred when they were stored for 2 weeks at 4° C, and the extracts and concentrates were stable for 24 h at 4° C.

Figs. 2*A* and 2*B* show calibration curves for nicotine and cotinine. A consistent linear detector response was obtained for both compounds over the range 0·2–10·0 μg base/ml. urine. Sixteen analyses of a urine sample containing 1·0 μg of nicotine base/ml. gave a standard deviation of 0·04 μg/ml.; similarly for cotinine (2 μg base/ml. sample), a standard deviation of 0·05 μg/ml. was obtained.

Using the procedure described for the determination of nicotine, it was found that the rate of nicotine excretion in urine was influenced by the *p*H of the urine (see also refs. 7, 9), and by the rate of flow of the urine; the greater the rate of flow, the greater the excretion of nicotine. This was also found to apply to the urinary excretion of cotinine. Subjects who simultaneously smoked two cigarettes after abstaining from smoking for a period of 24 h excreted 0·25–0·60 mg cotinine (in

24 h) and 0·10–0·50 mg nicotine (in 24 h) under normal conditions, 0·30–0·90 mg cotinine (in 22 h) and 0·50–0·80 mg nicotine (in 8 h) when the urine was made acidic after the oral administration of ammonium chloride, and 0·30–0·40 mg cotinine (in 36 h), and less than 0·06 mg nicotine (in 36 h) when the urine was made alkaline after the oral administration of sodium bicarbonate.

Absorption of nicotine from the lungs and excretion in the urine were found to be extremely rapid, as the greatest rate of excretion was in the period 0–15 min after smoking. The rate of nicotine excretion under acidic conditions fell very rapidly to less than 0·1 μg/min 8 h after smoking the two cigarettes. The elimination of nicotine did not appear to follow first order kinetics, and this is being further investigated. The peak level of cotinine excretion was found to be at about 2 h after smoking.

The subjects were heavy smokers (twenty cigarettes a day), and intermittent smokers (between two and five cigarettes a week), and for the purpose of the experiments inhaled the smoke from the non-filter cigarettes used.

We thank Prof. H. McKennis, jun., for generously supplying us with cotinine and the Tobacco Research Council for financial assistance.

HAEMATOLOGY

Rapid Induction of *in vivo* Fibrinolysis with D-Gluconyl-L-tyrosine

RECENTLY I reported[1] lysis of thrombi in the veins and arteries of animals with sodium gluconate and a dialysable constituent of fibrin extract or whole blood. The ultraviolet absorption spectrum of fibrin extract displayed a maximum at 275 mμ and a minimum at 247 mμ. These values happen to coincide closely with those recorded for tyrosine. This finding suggested that L-tyrosine might be successfully substituted for fibrin extract and, if this was so, that a peptide formed from the amino-acid and gluconic acid would also be fibrinolytic.

Clots were induced in the jugular veins of dogs as previously described[1], and infusions administered locally without the admission of blood. A mixture of 100 mg of L-tyrosine and 1 g of sodium gluconate lysed such thrombi, while L-alanine with gluconate or L-tyrosine with sodium glucuronate were inactive. D-Gluconyl-L-tyrosine was prepared by the method of Iacobellis[2]. One hundred milligrams in 1 ml. of distilled water injected into a leg vein was sufficient to restore within 15 min the flow of blood in occluded jugular veins of dogs weighing 12–13 kg.

The compound did not lyse fibrin clots *in vitro*. It may be visualized as the prosthetic group of a larger molecule, presumably a protein.

IMMUNOLOGY

Complement-fixing Antibodies in Monkeys bearing Tumours induced by Rous Sarcoma Virus

ROUS sarcoma virus (RSV) produces tumours in rodents, monkeys, sheep and dogs[1–7]. RSV tumours in hamsters, guinea-pigs and rats contain complement-fixing (CF) antigens which elicit antibodies to homologous virus-free RSV-induced hamster tumour antigens, virus-containing RSV-induced chicken tumours, and antigens induced by the growth of several strains of avian leukosis viruses in chicken embryo fibroblast (CEF) tissue cultures[7,8].

Recently, using methods previously described[8–10], we observed the production of antibodies specific for avian leukosis in the serum of a rhesus monkey (kindly supplied by F. J. Rauscher) which developed tumours after inoculation at birth with the Schmidt–Ruppin (*SR*) strain of RSV. This monkey, the offspring of a healthy young mother, was bled for a serum sample when less than 24 h old and then inoculated subcutaneously over both the right and left lower back with 0·5 ml. of *SR*-RSV prepared from chicken wing web tumours[8].

A small subcutaneous tumour was first noted at the site of injection on the right side 21 days after inoculation of the virus. Several subcutaneous tumours afterwards developed and grew progressively at both inoculation sites. Tumours which developed on the left side were excised 7 days after they were first noted. An attempt to establish cells from the excised tumours in tissue culture was unsuccessful. Tumours recurred rapidly at the site of the operation and were readily detectable 7 days after excision. In a second attempt to establish tumour cells in tissue culture, sub-total excisions of the tumours on both sides were performed 85 days after their onset. Cells from this biopsy were successfully grown in tissue culture and were carried through sixteen subpassages (cultures established and carried by C. H. Calisher). Postoperatively, we noticed at the excision sites the formation of firm subcutaneous masses which were indistinguishable from tumour tissue by palpation, but these regressed rapidly and left no gross evidence of tumours 6 weeks later.

Five to six weeks after the onset of tumours, CF antibodies appeared in the monkey serum which reacted with *SR* strain hamster tumour antigens and the antigens found in chicken tumours induced by both *SR* and Bryan strains of RSV but not with the virus-induced hamster tumour antigens of *SV*40 virus, polyoma virus or adenovirus types 7 and 12. The monkey sera with the highest antibody titres against RSV hamster and chicken tumour antigens also reacted specifically with antigens present in CEF cultures of both resistance-inducing factor (RIF) and avian erythroblastosis virus (AEV), but all sera were negative when tested against cell pack preparations of uninoculated CEF cultures used at the same dilutions as the avian leukosis antigens. The progress of specific CF antibody formation is illustrated in Table 1 which shows the reactions of representative serial sera tested against 4–8 units of the specific antigens listed. Antibody titres generally increased during the period of tumour residence but fell to undetectable levels within 3 weeks of subtotal excision and subsequent regression of the tumours. Three of the sera with high CF antibody titres were negative at 1 : 10 dilution when tested for neutralizing antibodies against both *SR* and Bryan strains of RSV. Ten months after excision, tumours did not recur, and serum taken at that time did not react in CF tests with RSV antigens.

Despite the development of CF antibodies, we were unable to demonstrate CF antigens in a 20 per cent extract of tumour tissue excised from this monkey when it was tested at 1 : 5 dilution versus three of the highest titred homologous monkey sera or against standard

sera of high titre from hamsters bearing transplanted *SR* strain tumours[8]. Cells grown in tissue culture from the second tumour biopsy of this monkey were prepared into cell pack antigens[11]. Such preparations remained negative for RSV CF antigens after sixteen subpassages in tissue culture.

In another experiment, a 20 per cent extract of a tumour induced by *SR*-RSV from a second rhesus monkey (kindly provided by Dr. Sarah Stewart of the National Cancer Institute) was found to react at 1 : 2 dilution with a single serum from the host monkey and with a positive serum from the monkey reported above. This extract of monkey tumour, however, failed to react with 4–8 units of standard antiserum pools from hamsters bearing tumours induced by RSV. On the other hand, the reactive serum from the second monkey contained CF antibodies to titres of 1 : 40 with RSV hamster tumour antigen and 1 : 20 with RSV chicken tumour antigen. This serum and a CF-negative serum drawn 2 weeks later during a period of spontaneous rapid tumour regression did not contain neutralizing antibodies against either *SR* or Bryan strains of RSV.

Cells from the second monkey's tumour were established in tissue culture but could not be propagated beyond the first subpassage. Concentrated cell pack antigens[11] prepared from these cultured cells did not fix complement with sera from monkeys or hamsters bearing RSV-induced tumours. Cells from the primary culture and first subculture were disrupted with ultrasonic vibrations at various intervals after they were planted in tissue culture. Clarified tissue culture fluids from the sonicated tumour cells were negative for infectious virus when tested in CEF roller tubes for the formation of RSV foci[12] and in COFAL tests[13] for the induction of specific antigens.

In summary, the data indicated that tumours induced by RSV in rhesus monkeys elicited CF antibodies to both hamster and chicken RSV tumour antigens and to the antigens of several avian leukosis viruses grown in CEF; although no CF antigens could be detected in these tumours with standard sera from hamsters carrying RSV-induced tumours. While it is possible that the avian sarcoma CF antibodies, demonstrated in the sera of tumorous monkeys, were elicited by replication of infectious RSV in the host, the absence of neutralizing antibodies in these sera and the inability to recover infectious virus from tumour tissue seem to make this event unlikely. The antibodies appeared quite late after virus inoculation, reached highest titres at the peak of tumour growth and fell to undetectable levels with regression of the tumours. Similar dependence of serum antibodies on the presence of intact progressively growing tumours was noted by Huebner *et al.*[8] in hamsters and guinea-pigs which developed tumours after inoculation with RSV.

Origin and Specificity of Mononuclear Cells in Delayed Hypersensitivity Reactions

UNDER the microscope, infiltrations of mononuclear cells are characteristic of delayed hypersensitivity reactions[1–3]. Several investigations have indicated that the reactivity is bound to these cells[4–7], and the majority of the infiltrating cells have been shown to be haematogenous[8].

Two groups of the same inbred Sprague–Dawley strain rats were sensitized simultaneously; the donor group was injected with heat killed tubercle bacilli in mineral oil and the recipients with bovine serum albumin (BSA) in complete Freund's adjuvant[9] (all injections were made into the left hind foot pad). Three times a day on days 10–12 after the sensitization, 1 μc./g of tritiated thymidine was injected intraperitoneally into the donors. On the fourteenth day the donors were killed and separate cell suspensions were made from the draining popliteal lymph nodes, axillary lymph nodes, spleen and thymus. Various recipients, which had been skin tested 4 h earlier with tuberculin, BSA and turpentine, were injected intravenously with 44×10^6 cells of each suspension. The recipients were biopsied 20 h after the transfer of the cells. The number of labelled cells was determined from autoradiographs exposed for 6 weeks. The results are given in Table 1, where the data are calculated to correspond to 4×10^6 labelled donor cells, which was the actual number of injected labelled cells from the draining lymph node. In this suspension, the proportion of labelled cells was 9 per cent, in the axillary lymph node 5 per cent, in the spleen 14 per cent and in the thymus 36 per cent.

Cells taken from the draining lymph node were found in the delayed skin reactions in larger numbers than cells taken from the non-draining lymph nodes and the spleen. Only an insignificant number of thymus cells were found in the skin sites. Cells from the draining node also seemed

to have some specificity, because the donors were only sensitized to tuberculin and in this reaction there were more labelled cells than in the BSA reaction. Scarcely any labelled cells could be found in the non-specific and non-immunologic turpentine reaction. The spleen of all the recipients contained labelled cells in the same order of magnitude at the time of biopsy. Only occasionally could single cells be found in the recipient thymuses among the 10,000 cells counted.

Table 1. NUMBER OF LABELLED CELLS FOUND IN RECIPIENTS (Per 100 63 power fields)

Donor cells taken from	Tuberculin (OT 1 : 25)	Bovine serum albumin (30 μg)	Turpentine (1 : 10)	Spleen*
Draining lymph node	28	13	1	4
Non-draining lymph node	9	7	0	3
Spleen	4	3	2	2
Thymus	0	0·5	0	5

* Per 10,000 cells.

In an analogous experiment in which the cells were labelled *in vitro* with tritiated leucine (100 μc./ml.), the findings confirmed the previous results except in specificity. Equal numbers of labelled cells were found in both tuberculin and BSA reactions, and again only very few cells in the turpentine reaction. Among the injected cells as well as in the recipients, the number of labelled cells was proportionally higher (90–95 per cent of the injected cells were labelled) than among the cells labelled with thymidine[10].

Thus the thymus cells from a sensitized animal do not have the same capacity to remain in delayed skin reactions as do cells of the peripheral lymphoid organs and spleen. The draining node contains more "informed" cells than the other lymphoid organs studied, and by using thymidine a cell population could be labelled that showed some degree of specificity, whereas with leucine no immunological specificity was observed. This would indicate that synthesis of deoxyribonucleic acid and cell division are involved in the formation of cells reacting specifically in the delayed hypersensitivity reactions. This work has been supported by the U.S. Public Health Service and by the Sigrid Jusélius Foundation, Helsinki.

Adjuvant Principle of Pertussis Vaccine in the Mouse

IT is well known that the vaccines of many Gram-negative bacteria greatly enhance the antibody response to unrelated antigens administered to animals at about the same time, or as combined immunizing agents. The most familiar example is the increased potency of diphtheria and tetanus toxoids when combined with pertussis vaccine. Many investigators have attributed this heightened response to the heat-stable lipopolysaccharide endotoxins of this class of bacteria. Farthing[1] tested the effect of heating pertussis vaccine for 1 h at 100° C on its ability to enhance antibody response to diphtheria toxoid in guinea-pigs. He found no effect which he could ascribe to heat, and went on to show that extracted endotoxin was responsible for the increase in antibody titre.

Although *Bordetella pertussis* shares with other bacteria this ability to enhance antibody formation to unrelated antigens, it appears unique in respect to the variety and intensity of its biological effects. Pertussis vaccine and fractions thereof have been found capable of sensitizing certain strains of mice and rats to a wide spectrum of physical and chemical stresses and stressor agents, including histamine, endotoxin, anaphylactic shock and experimental allergic encephalomyelitis[2]. Several of these effects have been shown to be markedly depressed by heat[3]. This led us to question whether the antigenic adjuvant property of this vaccine for the mouse might not also be heat labile.

Groups of 36 *CFW* female mice were injected subcutaneously with four graded (two-fold) injections of plain tetanus toxoid, from 0·8 to 6·4 flocculatory units (Lf). Each dosage group was divided into three subgroups of twelve animals; one of these received at the same time an intraperitoneal injection of 1 ml. of pertussis vaccine (19×10^9 cells), a second received a similar injection except that the vaccine had been heated 100° C for 40 min, while the third was not given the associated injection. A group of twelve additional mice served as untreated controls. Fourteen days after these injections all mice were challenged by intramuscular injection of fifteen times the minimum lethal dose of tetanus toxin. The time taken for the animals to die and the associated symptoms were scored according to the method devised by Ipsen[4], as follows

Score	Day of death
0	1, 2
2	3, 4
3	5, 6, 7
4	>7 with tetanus
6	>7 no tetanus

All the untreated controls died in the first 2 days. Fig. 1 shows the mean response for each group of twelve mice and the least squares regression lines drawn to the average slope. At all dose levels, toxoid associated with the unheated vaccine injection resulted in greater protection than toxoid alone. Conversely, toxoid associated with heated vaccine was actually less protective than the injection of toxoid only. These results confirmed an earlier experiment in which there had been a similar rank order correlation among the three treatments at all dose levels of toxoid used.

The unexpected depression of protection resulting from the heated vaccine may possibly be explained as antigenic competition, for the "foreign" solids in the vaccine exceeded those of the toxoid in weight by a factor of more than 500. (The high dose of toxoid contained 0·022 mg dry weight whereas the vaccine solids weighed 12 mg.) If this were the correct explanation, it would emphasize the extraordinary potency of this heat-labile adjuvant which first had to overcome the competition for immunocompetent cells and then effect a further marked increase in apparent toxoid antigenicity.

Neither the identity of this thermo-labile adjuvant nor its mechanism of action can be determined from this experiment. A growing body of evidence leads us to suspect, however, that the protective antigen is the immunological adjuvant for mice in pertussis vaccine. The destructive effect of heat on this antigen is well known. Furthermore, we recently presented evidence that the protective and histamine sensitizing properties of pertussis vaccine can be dual manifestations of a single bacterial component[5]. It has been found[6] that the histamine-sensitizing factor (HSF), purified by various methods, is capable of enhancing the sensitivity of mice to active anaphylaxis; presumably this is mediated by way of

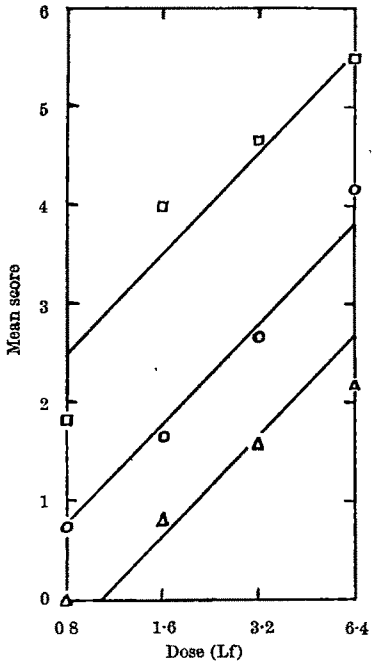

Fig. 1. Effect of the intraperitoneal injections of heated and unheated pertussis vaccine in mice on the protective potency of tetanus toxoid injected subcutaneously at the same time. Upper line: pertussis vaccine, intraperitoneally, toxoid subcutaneously. Middle line: toxoid only, subcutaneously. Lower line: heated vaccine intraperitoneally, toxoid, subcutaneously. Each point is the mean response of twelve mice challenged after 2 weeks with fifteen times the minimum lethal dose of tetanus toxin.

stimulation of the mechanism responsible for antibody formation[7]. Thus the presence of an adjuvant in the mouse may be linked with the specific protective antigen of pertussis vaccine.

In addition to altering the reactivity of certain experimental animals to a wide variety of stresses, administration of pertussis vaccine, as well as overt whooping cough infection, result in a marked and characteristic lymphocytosis. Although the mechanism by which *B. pertussis* exerts this leucocytotic response has not been delineated, stimulation of the production of immunocompetent cells could possibly explain the adjuvant effect associated with *B. pertussis*. Morse has recently demonstrated that the ability of pertussis vaccine to promote leucocytosis closely resembles its ability to make organisms sensitive to histamine. Both these phenomena are labile to heat, and take the same time to achieve maximum response (about 4 days). Moreover, intravenous administration of *B. pertussis* markedly augments both sensitivity to histamine and the degree of leucocytosis, as compared with other routes of inoculation[8].

Recently, Fishel presented evidence that hypersensitivity to histamine induced by pertussis vaccine is mediated primarily through a functional neurological imbalance—specifically, blockade of the beta-receptors of the adrenergic division of the autonomic nervous system[9]. His results have been confirmed by others[6]. Although certain of the characteristic effects of endotoxins are also believed to be induced by way of autonomic nervous pathways, Rosenblatt and Johnson[10] presented evidence that the adrenergic system is not involved in the adjuvant effect of endotoxins in rabbits. It is quite possible, however, that such neurological mechanisms are basically responsible for the heightened antibody response in mice vaccinated with pertussis vaccine. Guinea-pigs and rabbits are reported to be incapable of exhibiting enhanced sensitivity to histamine as a consequence of pertussis vaccination[11], whereas injection of either HSF or beta-adrenergic blocking agents greatly increases the sensitivity of mice to histamine. This species difference in reactivity to histamine following pertussis vaccination could be related to our finding that a heat labile *B. pertussis* component, quite possibly the immunogen, is the effective adjuvant in mice, whereas the heat stable endotoxin performs this function in guinea-pigs[1] and rabbits[12]. Purified protective and endotoxin fractions of *B. pertussis*, as well as adrenergic blocking agents, are at present being evaluated in these three species in order to ascertain their effects on haemodynamic responses and leucocytic mobilization in relation to enhanced antibody production.

This investigation was supported by the National Institute for Allergy and Infectious Diseases through the Massachusetts Health Research Institute. We thank Edward J. Broderick and Anthony Pellegrino for competent technical assistance.

Modification of Poor Growth of Parental Marrow Cells in F_1 Hybrid Mice

ACCORDING to the present genetic theory, parental (P) strain cells transplanted to an F_1 hybrid introduce no foreign antigen to the host, incite no homograft response, and survive indefinitely. This has been shown experimentally with $P \rightarrow F_1$ skin grafts. Some P-strain tumour cells, however, have been shown to grow poorly in F_1 hybrids[1]; and transplants of antibody-forming and haemopoietic cells from certain P strains fail to grow in F_1 hybrids at a rate comparable to that seen in isologous controls[2,3]. One of the puzzling features of this phenomenon is the fact that morphologically intact $P \rightarrow F_1$ skin grafts survive even in strain combinations where grafts of dissociated cells fail.

Recently, morphologically intact grafts of lymphoid tissue have also been shown to survive in $P \rightarrow F_1$ strain combinations. After early changes indicative of a graft-versus-host response, the histological appearance of such lymphoid slice grafts reverts to that of the normal host lymphoid tissues. Indefinite survival of at least some donor elements is shown by successful secondary transplantation of these grafts back to P-strain mice after more than two years of residence in an F_1 host[4].

The present experiments were undertaken to determine whether the presence of such morphologically intact P-strain lymphoid grafts in an F_1 host may potentiate the survival of a suspension of P-strain bone marrow cells. It seemed that stroma of the parental type might prove a more suitable "home" for transplanted parental cells than the F_1 stroma. It also seemed possible that the

† These mice came from a different stock pool from those of groups 1 and 2: mice of group 3 were only 8 weeks old, more than 2·5 weeks younger than others represented.

‡ Grafts were in place 19 days before irradiation in Exp. I, 21 days in Exp. II.

Injection of *B6* spleen cell suspensions before irradiation was also able to reproduce the augmented growth of *B6* marrow in $B6D2F_1$ hosts (Table 2, group 1). Furthermore, a spleen slice graft in place for 12 days, but removed before irradiation of the host (Table 2, group 5), was as effective as an intact spleen slice graft (Table 2, group 3) or an injection of dissociated cells (Table 2, group 1).

Injections of parental lymph node cells before irradiation were just as effective as spleen cell injections in potential of parental marrow growth, whereas injections of parental thymus or bone marrow resulted in little or no increase in the growth of subsequent marrow transplants (Table 2, groups 6–9). This suggests that the effect depends on the immunological capability of the cells injected. Cells derived from lymph node and spleen

parental tissue graft might provide necessary elements found in intact tissues, but not in cell suspensions.

Spleen slices from *P*-strain mice (*C57 BL/6*, hereafter called *B6*) were therefore grafted on to the kidney surface of F_1 hybrids (*C57BL/6* female × *DBA/2* male, hereafter called $B6D2F_1$) according to the technique described by Wheeler *et al.*[5]. There is good evidence of poor growth after $P \rightarrow F_1$ bone marrow transplantation in this combination of strains. The host animals were 10–14 weeks old and were subjected to 900 r total body irradiation about 3 weeks after spleen slice grafting. In all cases, mice received 10^6 *B6* marrow cells intravenously 18–22 h after irradiation. Proliferation of donor erythropoietic cells was assessed a week later by measuring the uptake of iron-59 into red cells and spleens of these chimeras (details of method given by Goodman and Mathews[6]). Spleen weights were recorded in some experiments, and gross and microscopic observations were made of the spleen slice graft and the host spleen. The results were compared with groups of non-operated animals, sham operations, and grafts of F_1 spleen. Other experimental groups were injected with *P* or F_1 spleen cell suspensions before irradiation. In a final group, *B6* spleen grafts which had resided 12 days in a $B6D2F_1$ host were excised the day before irradiation of the host.

Table 1 presents the results of two experiments which show clearly that the growth of *B6* marrow cells in irradiated $B6D2F_1$ hosts was dramatically improved by the presence of a previous *B6* spleen slice graft on the kidney of the host. In addition to showing marked potentiation of the uptake of iron-59, those mice carrying *B6* slice grafts had large nodular spleens weighing 97 mg (average of seven mice), whereas control animals with $B6D2F_1$ grafts had small dark spleens without nodules and with an average weight of 21 mg (average of seven mice). Thus, the experimental data strikingly confirmed the original concept that the presence of a *P*-strain spleen graft in an F_1 hybrid may facilitate the subsequent growth of *P*-strain marrow cells injected after total body irradiation.

One explanation which comes quickly to mind is that the transplanted *P*-strain marrow cells "home" to the *P*-strain spleen slice graft and proliferate there preferentially. Further experiments leave little doubt, however, that the continued presence of the *P*-strain tissue stroma is not essential to modify the phenomenon of poor growth. are known to be capable of initiating a much more marked graft-versus-host response than those derived from thymus or bone marrow. Presumably by the time of irradiation, cells grafted from spleen or lymph node have gone through many cell divisions and have widely colonized the host. These cells may also have produced antibodies directed against the foreign F_1 antigens.

Moller has reported that antigenically different cells were mutually cytotoxic when brought into close contact *in vitro*[7]. Extracts of foreign antigens have also been found to inhibit the growth of tumour cells *in vitro*[8]. The inhibition of *P*-strain marrow cell growth seen in the present experiments may likewise be due to contact with foreign F_1 antigens. If so, the augmentation of marrow growth by pre-treatment with lymphoid grafts could be explained by masking these inhibiting foreign antigens or by the presence of syngeneic sites where transplanted *P*-strain stem cells can grow free of contact with foreign antigens.

In summary, these experiments indicate that the growth of *P*-strain marrow grafts in irradiated F_1 hosts can be dramatically augmented by various techniques which have in common the introduction of immunologically competent *P*-strain lymphoid cells into the F_1 host before irradiation.

PATHOLOGY

Skin Tumours and Sarcomata induced in Rats by *N*-Hydroxy-2-acetylaminofluorene

IT has been recently found that when 2-acetylaminofluorene (AAF) and several other carcinogenic amines are administered to rats, *N*-hydroxylation of the compound occurs *in vivo*[1,2]. Using AAF, or several other amines, it has been shown that the *N*-hydroxy metabolite (N—OH—AAF) was a more active carcinogen than the parent compound[3].

It was therefore proposed that N—OH—AAF may be the proximate carcinogen when AAF is administered to rats[4]. In the course of some preliminary experiments we have obtained additional evidence for this proposition.

Ten 8-week-old male MRC rats (210 g), were injected once subcutaneously on the back with 5 mg of N—OH—AAF dissolved in 0·5 ml. of warm olive oil. A week later a shaved area of interscapular skin was painted with a 2 per cent solution of N—OH—AAF in acetone, using a fine hair brush. The rats were painted at first three times, and later five times a week until the fortieth week, when they had been treated 125 times. The animals were given powdered laboratory chow and as much water as they wanted to drink. Once a week they were weighed and carefully inspected. At the twentieth week signs of skin irritation and exudation appeared, and by the thirty-third week ulcers were present on most of the animals. At the thirty-fifth week a crop of skin tumours suddenly arose, and their progress was recorded weekly on graph paper maps. One rat died of pneumonia at 25 weeks without any other lesions, and the remaining nine rats were killed when their tumours caused a decline in health.

A total of ten subcutaneous tumours occurred near the site of the initial injection in seven of the nine surviving rats. Eight of these were invasive fibrosarcomata, and two were well differentiated, relatively benign, fibrous tumours. Most of the subcutaneous tumours were a little distant from the original site of injection, no doubt as a result of migration of the oily solution. The latent period for the subcutaneous tumours varied from 20 to 44 weeks, with a mean latency of 29·6 weeks.

The earliest skin tumour in the painted area was found in the twenty-first week, and by the thirty-seventh week all the surviving rats had tumours in the painted areas. Six out of nine rats survived longer than 35 weeks, and had a total of sixty skin tumours. The number of skin tumours on each rat increased steadily from the twenty-fifth to the fifty-second week, when the final animal was killed. Only four of the original sixty tumours regressed. Of the fifty-six tumours which persisted, twenty (36 per cent) showed a steady increase in size, and were found on histological examination to be invasive carcinomata. The majority of the carcinomata were of the squamous type, but a few were basal-cell carcinomata. The morphology of the benign tumours was similar to that described for mouse skin tumours[5]. Six rats had eight primary tumours which arose at a distance from the painted areas, namely in the Zymbal glands, breast, and lungs. One of the Zymbal tumours and one of the breast tumours metastasized widely.

The induction of malignant skin tumours in rats by painting with N—OH—AAF was striking in view of the usual refractoriness of rat skin to chemical carcinogens. In rats painted with the parent compounds 2-AAF and 2-AF, skin tumours are very rare, and nearly always occur at a distance from the painted area. The present results, therefore, provide strong evidence for the local action of N—OH—AAF as a direct carcinogen for rat skin and subcutaneous tissue, without metabolic modification. It is considered that the single subcutaneous injection at the beginning of the experiment could not have much influenced the response of the skin. The experiments are being repeated and skin tumours have already been obtained by painting alone. The occurrence of sarcomata at or near the site of injection is also of interest in that they appear to have been caused by a single injection, whereas in work reported previously, multiple injections were given[6]. The fact that combined treatment was given complicates this interpretation, however, because the occurrence of distant neoplasms indicates that there must have been significant absorption either of N—OH—AAF or of its parent amines. Furthermore, it is impossible, at present, to state what influence the painting may have had in the appearance of the subcutaneous tumours.

This work was supported by the U.S. Public Health Service. We thank Dr. J. H. Weisburger of the National Cancer Institute, Bethesda, for the generous gifts of *N*-hydroxyacetylaminofluorene.

Extraction of a Cancer Factor from Ehrlich Ascites Carcinoma

INVESTIGATIONS at present in progress in our laboratory on the inhibitory action of several nucleases of cobra venom on the growth *in vitro* and *in vivo* of the Ehrlich ascites carcinoma[1] have prompted us to study the RNA metabolism in that tumour cell.

Besides several studies[2–6] on the behaviour of the Ehrlich cell in its natural environment, some workers[4,7,8] have examined its behaviour in an artificial environment. They conclude that at low temperatures, and after washings repeated over relatively long periods, the carbohydrate metabolism of these cells remains almost unaffected, whereas their phosphorus metabolism is modified.

These investigations show that when the Ehrlich cell is maintained *in vitro* in an isotonic solution, it survives but undergoes at the same time a gradual decrease in vitality which corresponds to a decrease in virulence; it appears, moreover, that this decrease is associated with the modification of various metabolic pathways, particularly those of the intracellular ribonucleic acids.

It is important to notice that all these workers studied the behaviour of metabolites inside the tumour cell. Our experiments, however, were designed to observe what happens outside the tumour cell and to examine whether or not the decrease in virulence is simply related to the escape of essential metabolites.

What is the fate of the nucleic acids responsible for protein synthesis? We considered the possibility that they escape from the cell by diffusion and have tried to verify this experimentally.

When centrifuged from the cells and examined in ultraviolet light, freshly withdrawn ascitic fluid shows an absorption curve with a peak of 278 mμ, which is characteristic of proteins. In agreement with Klein *et al.*[5], we did not find that the ascitic fluid contained nucleic acid or oligonucleotides.

To follow the course of the diffusion of materials out of the cells, we studied their absorption spectra. If the cells, separated from the supernatant fluid, are placed again in suspension in a saline isotonic solution for 10

to 30 min and centrifuged once more, the maximum absorption of the supernatant fluid occurs at 265 mμ. In the course of the subsequent washings, the maximum is soon stabilized at 260 mμ, which is the characteristic wavelength of nucleic acids.

During the successive washings, the optical density at 260 mμ increases, then decreases, and is finally stabilized, indicating that nucleic acids escape out of the cell by diffusion, until some equilibrium is reached.

The cells were examined under the microscope in the course of several experiments consisting of six to twelve washings. Their morphological structure seems to be unaffected.

Are those Ehrlich cells, which have thus been deprived of their extractable nucleic acids and have remained apparently unchanged, still alive and virulent?

To answer this question, mice were given 2,000,000 cells treated in the way described earlier, by intraperitoneal injection. After 26 days, only one animal out of ten developed an ascites tumour, whereas the ten reference animals that had been injected with fresh unwashed cells all developed a cancer on the ninth day and died about the twenty-third day.

As noted by the authors mentioned, the loss of intracellular RNA leads to a decrease in virulence. Our experiment has shown that an almost total loss of virulence can be obtained by diffusion of nucleic acids outside the cell.

Is it possible that the materials that have escaped out of the cell by diffusion would restore the original virulence?

In order to investigate this point, we carried out some preliminary experiments, the exact conditions of which remain to be further defined.

One batch of ascites cells was washed 8 times. Ten Swiss mice were given 2,000,000 cells intraperitoneally (at a count of 100 million cells per ml.). By the twenty-third day, only one animal had developed ascites.

Meanwhile, ten other mice received 2 million cells from the same batch, but mixed with the extracted factor, passed through a 'Millipore' filter (1·2μ). From the tenth day onwards, six animals developed ascites. This experiment seems to show that the cells have recovered their vitality and virulence.

Is the separated factor by itself able to induce a cancer in a healthy animal?

So far, we have not been able to observe any tumour formation in a mouse or in its offspring by injecting the extractable factor directly by subcutaneous or intraperitoneal routes. This is not surprising because, in such an experiment, the extractable factor does not come into direct contact with an adequate cellular sub-stratum. We think it would be rewarding to inject the product directly into mammary glands containing the type of cells from which the Ehrlich carcinoma originated. The few observations that we had the opportunity of making lead us to think that, under definite conditions, the healthy cells of mammary glands of mice in lactation are liable to develop an ascites or solid tumour by induction.

Those experiments, which still require closer verification, seem to point to the existence of a cancer factor escaping from the Ehrlich cell, when this cell is kept in an isotonic but non-nutritive environment, in this case a saline isotonic solution.

This factor would tend to restore their virulence to cells which have formerly been deprived of it and might even induce a cancer in cells that are healthy but embryologically receptive.

We then tried to determine the chemical nature of the separated factor. For that purpose, the supernatant fluids were mixed, centrifuged and subjected to dialysis in order to eliminate sodium chloride. The obtained solution was then lyophilized. Our measurements show that, on average, the total substance lost by diffusion amounts to 80×10^{-12} g per cell. The separated substance consists mainly of a ribonucleoprotein mixture or combination. The presence of proteins was revealed by the Folin–Ciocalteau reaction; that of ribonucleic acids by the following techniques: (*a*) pyronin reaction; (*b*) ultraviolet spectrometry: maximum at 260 mμ with *p*H effects; (*c*) orcinol reaction: shows the presence of ribose; (*d*) phosphomolybdic reaction: reveals the presence of phosphorus; (*e*) diphenylamine test: shows that the DNA is absent; (*f*) ultracentrifugation: main peak corresponding to a sedimentation coefficient, $S = 2$.

We have separated materials from ascites cells which may be ribonucleic acid, with or without protein in association, and which seem to interfere with the propagation of the Ehrlich carcinoma in the peritoneal fluid of the Swiss mouse.

Further experiments are necessary to characterize the material concerned (S) and a wider range of experimental conditions will make it possible to assess the biological significance of this separated ribonucleic factor.

These experiments were carried out in the Laboratory of Biochemistry of the I.I.F.–I.M.C., CERIA, Brussels.

We thank the Province de Brabant, the F. W. Breth Foundation, New York, and M. G. Mattens, Brussels, for the financial and moral support given to this work.

CYTOLOGY

Synapses on Neurosecretory Cells of the Supra-optic Nucleus in White Mice

Few observations have been reported on the ultrastructure of synapses between nerve fibres and the perikarya of neurosecretory cells. Electron microscope observations on synapses on perikarya and on branches of neurosecretory cells of the pre-optic nucleus in teleosts —perch and trout—have been published[1,2], and recently short preliminary reports on the ultrastructure of synapses on cells of the supra-optic nucleus of white mice[3] and rats[4] have appeared. Further details of synapses on the neurosecretory cells of the supra-optic nucleus of white mice are reported here.

Adult male white mice weighing 20–24 g served as material for our investigations. Pieces of brain were fixed by immersion in 1 per cent osmium tetroxide solution after Caulfield and Sjöstrand. Sections were studied with a *JEM-5g* electron microscope.

A considerable number of synapses was observed within the supra-optic nucleus on the perikarya as well as on the branches of the neurosecretory cells. Sometimes several axosomatic synapses were seen on the surface of the perikaryon of one neurosecretory cell. These were of typical ultrastructural form. The synaptic plates varied in length from 0·9μ to 1·4μ, and showed a clearly defined presynaptic membrane. Some concentration of osmiophilic material was found in the axoplasm close to the presynaptic membrane, together with optically empty synaptic vesicles 250–550 Å in diameter. In some plates, many of these vesicles were concentrated in groups near the presynaptic membrane in the region of the trans-

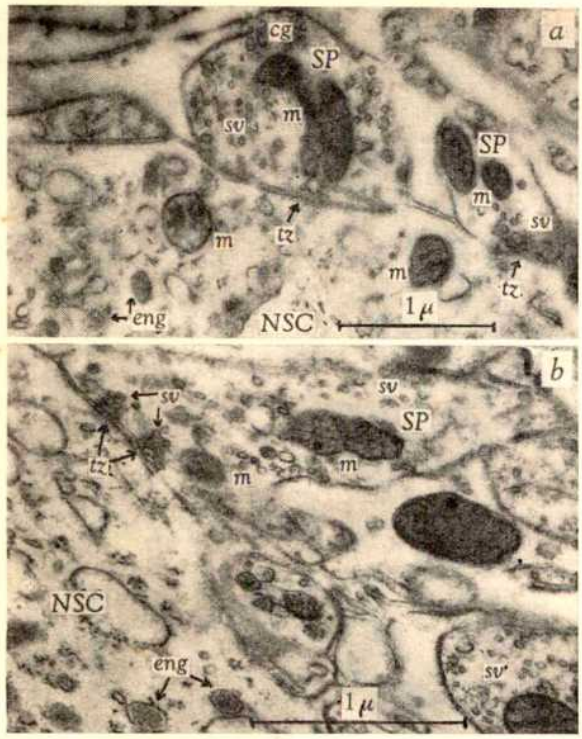

Fig. 1. Synaptic plates (*SP*) containing synaptic vesicles (*sv*) and "catecholamine" granules (*cg*) on a perikaryon of neurosecretory cells (*NSC*) in the cytoplasma of which elementary neurosecretory granules (*eng*) and mitochondria (*m*) can be seen. *tz*, Transmission zone. *a*, × *c.* 20,900; *b*, × *c.* 27,870.

mission zone; in others they were distributed more evenly through the axoplasm.

The postsynaptic membranes were sharply outlined, and a concentration of osmiophilic substance in the form of a narrow strip in some places near the postsynaptic membrane was sometimes observed. The synaptic cleft was enlarged, in some places reaching 640 Å, and contained a narrow strip of a substance of low osmiophility.

Vesicles with electron dense content were observed in the perikarya of the neurosecretory cells and in many synaptic plates (Fig. 1). The vesicles of 1600–3000 Å in diameter in the neurosecretory cells and in some branches are typical elementary neurosecretory granules which have been described in the posterior pituitary gland in our earlier publications[5]. Vesicles in synaptic plates of 900–1000 Å in diameter having electron dense content resembled in their size and appearance catecholamine granules in adrenergic synapses[6]. Besides these granules and synaptic vesicles, mitochondria were usually found in the synaptic plates; in these mitochondria the cristae were few, and usually longitudinally arranged.

Thus our observations indicate that neurosecretory cells of the supra-optic nucleus in white mice are innervated by the neural fibres which seem to belong to adrenergic neurones. Further investigations, however, are required to determine the nature of these fibres.

BIOLOGY

Organochlorine Insecticide Residues in Soil Invertebrates

THE uptake and transmission of organochlorine insecticide residues in food chains has been described for an aquatic ecosystem[1]. There is, however, little information relating to the terrestrial sphere in respect of insecticide concentrations occurring in invertebrates which form the food of many common species of birds[2,3]. During 1965, an attempt was made to remedy this situation by collecting soil and invertebrates from ten widely separated arable fields and from two apple orchards around Huntingdon which were known to have received recent applications of a number of organochlorine insecticides. The soils varied from sandy loam to clay loam and peaty loam.

The availability of soil invertebrates to birds was determined by the use of pitfall traps which contained a solution of 0·1 per cent phenylmercury acetate and 0·8 per cent formaldehyde to prevent predation and decay. Beetles, predominantly Carabidae, small numbers of other arthropods and earthworms of up to eight species were caught at all twelve sites. Worm samples from the orchards were also collected by the application of dilute formaldehyde[4] and slugs were collected at some sites by searching the vegetation and soil surface. Analyses were performed whenever the sample collected was large enough to be representative. The beetle samples analysed consisted of separate 4–10 g quantities of *Harpalus rufipes* and *Agonum dorsale* (Carabidae) from most of the sites, two samples of mixed large carabids, two of Staphylinidae and one of Elateridae. Twenty soil cores 15 cm deep were taken in each field, bulked and sub-sampled. In the orchards ten cores were taken underneath trees one to two metres from the trunks and ten cores from the lanes between trees.

The samples were ground with anhydrous sodium sulphate and extracted with mixtures of acetone–hexane by means of a Soxhlet apparatus. The extracts were cleaned on a partially de-activated alumina column[5] and then examined by gas–liquid chromatography using silicone and 'Apiezon' columns and electron capture detectors. Considerable interference with the working of the electron capture detectors was noticed when examining those samples which had come into contact with the mercury compound in the traps. This interference was satisfactorily reduced by subjecting the sample extracts to a dimethylformamide–hexane partition[6] before the alumina column treatment. The interfering substance was identified by infra-red and X-ray fluorescence spectroscopy as diphenylmercury, which, being covalent in character, was extracted by the hexane. It was at first thought that diphenylmercury might be a metabolic product formed by the invertebrates, but further investigation revealed its presence as an impurity in the phenylmercury acetate.

The results for the arable sites are summarized in Table 1. The soil residues are probably typical of many arable soils[7]. Samples of beetles from all ten sites contained both dieldrin and *pp'*-DDE in amounts up to 0·2 and 2·2 p.p.m. respectively and there was no obvious difference between groups of beetles. Residues of dieldrin in worm samples were between two and ten times those in soils from corresponding sites and both dieldrin and *pp'*-DDT were generally rather higher than in corresponding beetle samples. The presence of aldrin in three of the worm samples was confirmed by thin layer chromatography. It was found, however, that, when hexane containing dieldrin and phenylmercury acetate was injected on to the gas chromatographic columns, a new peak corresponding to aldrin appeared on the chromatogram. It is therefore possible that the peaks for aldrin from the worm samples derive partly from reduction of dieldrin on the chromatographic columns and partly from

the aldrin present in the soil in the food tract of the worms. Dieldrin residues may be expected to decline in the future as a result of the restrictions on the use of aldrinated fertilizers and of dieldrin treatment for carrot fly.

All samples from the two orchard sites (Table 2) contained *pp'*-DDT, *pp'*-TDE and *pp'*-DDE, usually in large concentrations compared with those from the arable sites. The orchard soils also differ from the arable soils in that the organochlorine compounds are very largely concentrated at the top of the soil profile. The rate of application of DDT in one orchard was considerably higher than that recorded by Stringer and Pickard[3] and the residues in worms and slugs from this site are among the highest recorded for invertebrates.

All the animals were active and apparently healthy at the time of capture and there is no evidence to suggest that the concentration of residues found in them are unusual. None of the samples was collected within 2 months of the final application of organochlorine insecticide; higher residue levels than those reported here might therefore be expected in samples of invertebrates collected, or eaten by birds, shortly after spray applications.

Variation associated with an *Aegilops umbellulata* Chromosome Segment incorporated in Wheat

THE polyacrylamide gel electrophoresis technique for the analysis of soluble plant proteins has amply demonstrated its usefulness and capacity to be repeated[1,2]. Using the method of disk electrophoresis[3,4] it is possible to resolve the proteins into a number of fractions, based on their electrophoretic mobility and the molecular sieving action of gels, with high reproducibility. The technique is being used in this laboratory to investigate variation in the spectrum of soluble plant proteins associated with known genetic loci, chromosome segments and individual chromosomes. The observations reported here show variation in protein pattern associated with a chromosome segment from *Aegilops umbellulata* Zhuk. transferred to *Triticum aestivum* L. ssp. *vulgare* (Vill., Host) Mac Key, variety 'Chinese Spring' by Sears[5]. This is of interest as a well analysed example of introgression or translocation of genetic material between allied genera which incorporated resistance to leaf rust (*Puccinia triticina* Eriks.) in bread wheat. Recent reports indicate that the *umbellulata* segment is substituted for a terminal piece of the wheat chromosome 6*B* (ref. 6), is inherited as a single dominant[7], and controls seedling and field resistance to common races of leaf rust.

Seeds of single plants of wheat variety 'Chinese Spring' and of 'Chinese Spring' with the introgressed *umbellulata* segment (*CI* 13296) obtained from Dr. E. R. Sears as well as bulk seeds provided by Dr. J. C. Craddock, were used in this investigation. Ten grams of dry seeds (about 12 per cent moisture) were ground in a hand operated coffee grinder. The flour obtained was stored overnight in a cold room at 5° C ± 2; all further work was done at this temperature. The flour was homogenized in 100 ml. of 0·01 M sodium pyrophosphate buffer containing 10^{-4} M EDTA and 0·7 ml. of mercaptoethanol. The slurry was filtered through cheese cloth and the filtrate centrifuged at 16,000 r.p.m. in a 'Lourdes' centrifuge for 1 h. The supernatant was gel filtered through 'Sephadex *G*-50' coarse beads (Pharmacia, Uppsala, Sweden) and eluted by 0·01 M phosphate buffer *p*H 7·5, containing 2 ml./l. mercaptoethanol. The protein fraction eluted was concentrated in cellulose dialysing tubing under partial vacuum for 12 h.

For extracting leaf proteins, seedlings were raised in stainless steel trays lined with cellulose wadding hydrated with Hoagland's nutrient solution. Seeds were germinated in the dark at 24° C for 48 h and later grown under continuous illumination of about 800 ft.-candles in a controlled environment. Leaves were harvested 12 days after planting and immediately frozen at −20° C. Fifty grams of frozen leaf tissue was used for each extraction. Chlorophyll was removed by repeated homogenization of the leaves in cold acetone (−5 to −10° C) until the residue was free from green pigment. The residue was dried in the cold to remove traces of acetone and then dissolved in 50 ml. of sodium pyrophosphate buffer of *p*H 8·2. The remainder of the procedure was the same as that followed for seed proteins except that with the leaf proteins an unresolved fraction was obtained as a thick band at the upper part of the gel, which prevents the separation of other proteins into distinct bands. To reduce this unresolved protein fraction, leaf extracts were gel filtered through a 7 per cent agar column and eluted by phosphate buffer of *p*H 7·5. The concentrated extracts were made to 0·25 M sucrose to increase the density, before placing on the gels for electrophoresis. Protein estimations in the final extracts were in the range 0·4–0·5 per cent, as shown using Folin-Ciocalteau reagent.

Electrophoresis was carried out in an apparatus similar to that described by Davis[4], mainly using standard 7·5 per cent acrylamide gels. In some cases, 15 per cent acrylamide gels were also used as the supporting medium, but most of the protein bands were found to resolve better on 7·5 per cent gels. The gels were prepared by mixing the stock solutions *A* and *C* of Davis[4] with boiled distilled water in the proportions 1 : 2 : 1, respectively, and an equal volume of 0·1 per cent ammonium persulphate in boiled distilled water was added to the mixture. The solution was degassed and placed in 'Pyrex' glass

tubes (6 mm × 10 cm). Gels were allowed to polymerize at room temperature. Gels obtained this way stack at *p*H 8·3 and run at *p*H 9·5.

Tris-glycine buffer of *p*H 8·3 (*tris* hydroxymethyl aminomethane 6 g and glycine 28·8 g made to 1 l. and diluted ten times) or *tris*-boric buffer (*tris* 431 g, disodium ethylenediaminetetracetate 37 g and boric acid 220 g made to 1 l. and diluted twenty times) of the same *p*H were used in the electrode vessels. *Tris*-boric buffer was found to give better resolution in certain regions. Seed proteins were run for 1 h at a potential difference of 480 V from a power supply of constant output, resulting in a current of 20 m.amp in *tris*-glycine buffer. In *tris*-boric buffer, a potential difference of 300 V gave a current of 30 m.amp. During the 60 min period, the front formed by the tracking dye (bromophenol blue) moved a distance of about 8 cm. Leaf proteins were better resolved when electrophoresis was continued for 45 min, and the front migrated 5–6 cm. After the run, gels were removed from the glass tubes and stained with 1 per cent Amido-Schwarz 10 *B* (Schmid and Co., Stuttgart, Germany) in 7 per cent acetic acid for 1 h. Gels were washed with 7 per cent acetic acid and destained electrophoretically until they were clear in an apparatus similar to that used for making the run. Destained gels were stored in 7 per cent acetic acid for observation.

Representative electropherograms of seed and leaf proteins of 'Chinese Spring' wheat and of the same variety with the introgressed *umbellulata* segment are shown in Figs. 1 and 2 along with diagrammatic representations. Fig. 1 shows the presence of two bands (marked with arrows) in the seed proteins of the introgressive type (*CI* 13296) that are not found in the parental variety, and one band in the latter is not present in the electropherogram of *CI* 13296. Similarly, in the electropherogram of leaf proteins (Fig. 2), one additional band is present

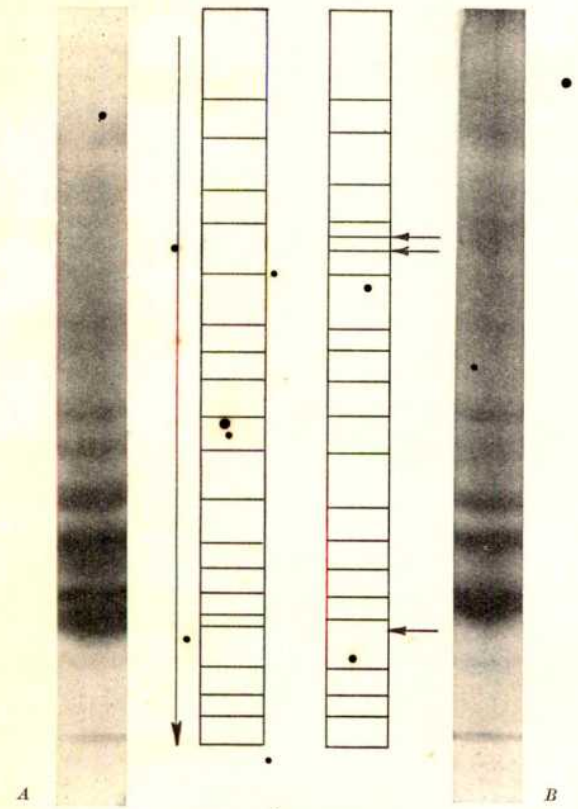

Fig. 1. Electropherograms for soluble seed proteins of wheat extracted in pyrophosphate buffer along with a diagrammatic representation; *A*, 'Chinese Spring'; *B*, 'Chinese Spring' with substituted *umbellulata* chromosome segment. Origin is at the top and the vertical arrow indicates migration of proteins toward anode. Variation in the two patterns is marked with arrows.

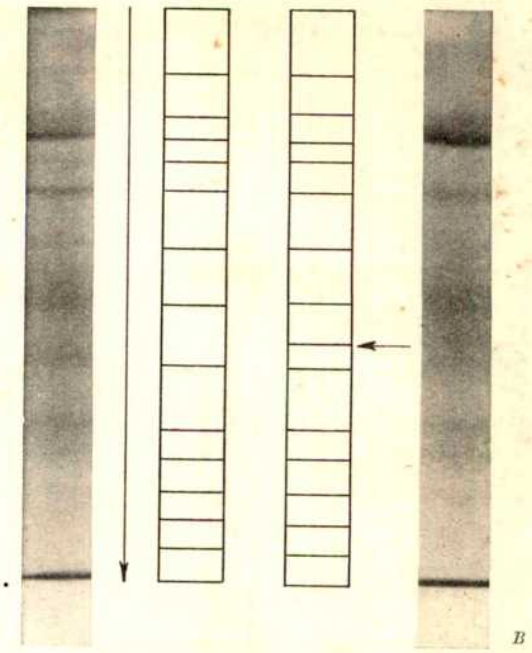

Fig. 2. Electropherograms for soluble leaf proteins of wheat extracted in pyrophosphate buffer along with a diagrammatic representation; *A*, 'Chinese Spring', *B*, 'Chinese Spring' with substituted *umbellulata* chromosome segment.

in *CI* 13296. These additional bands have been found in all four seed samples from single plants grown at Columbia, Missouri and in the bulk seeds obtained from Beltsville, Maryland. It is known that qualitatively similar patterns are obtained under uniform conditions of extraction and electrophoresis; and varieties of similar genotype have similar protein components[8,9]. In this material, therefore, the additional protein bands can confidently be interpreted as causally related to the genetic information carried by the introgressed *umbellulata* segment. The missing band in seed proteins may be due either to loss of the terminal region of wheat chromosome 6*B* or to suppression of synthesis of this protein by the introgressed *umbellulata* segment. It is planned to isolate and identify the missing and additional proteins and determine their possible relationship, if any, to the mechanism of rust resistance incorporated with the addition of the *umbellulata* segment. These results also indicate possibilities for analysing effects of introgressed genetic material in higher plants in terms of the proteins produced.

We thank Dr. E. R. Sears, U.S. Department of Agriculture, Columbia, Missouri, and Dr. J. C. Craddock, U.S. Department of Agriculture, Beltsville, Maryland, for providing the seeds, and Dr. H. W. Siegelman, U.S. Department of Agriculture, Beltsville, Maryland, and Dr. C. H. W. Hirs, Brookhaven National Laboratory, for their help and suggestions on electrophoresis. Spiral Growth of Nacre

INTERESTING spiral patterns (Fig. 1) were found on the growing inner surface of nacre when the fresh inner surface of pelecypod shells was observed under a microscope using a vertical illuminator. The pattern was explained by invoking the theory of Liesegang's rings[1,2]. This communication deals with the phenomenon as an aspect of spiral growth.

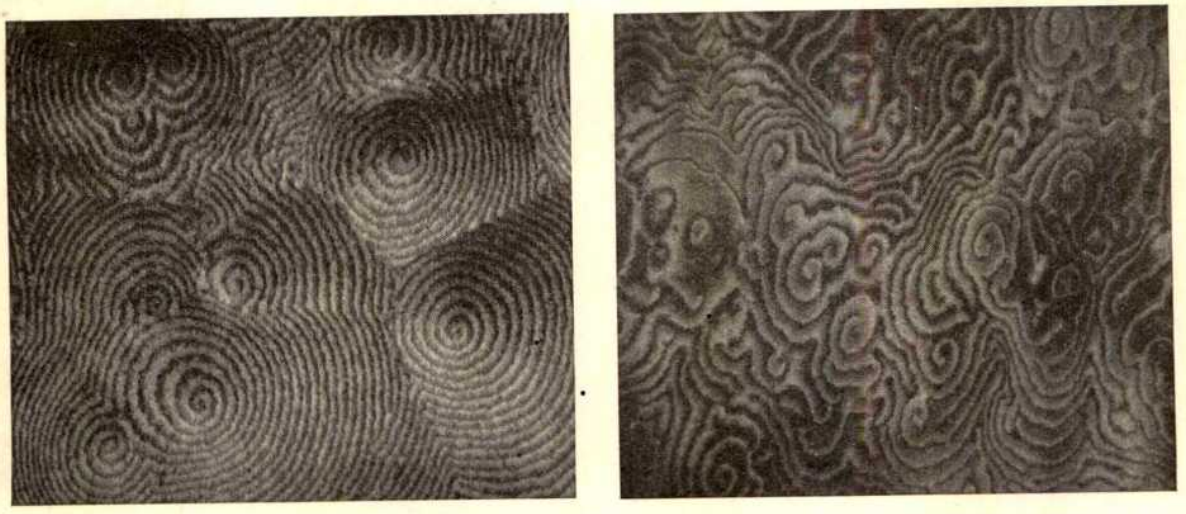

Fig. 1. Typical spiral growth of nacre in *Pinctada martensii* (left, ×85) and in *Hyriopsis schlegeli* (right, ×50).

It has been considered that the shells of molluscs crystallize in complicated ways from a specific solution ("extrapallial fluid") which is below the critical supersaturation required for homogeneous nucleation. They are built up from an organic substance "conchiolin" combined with microcrystals of calcium minerals. Investigations using Laue photographs and polarizing and electron microscopes revealed that the nacre of pelecypod shells was not a single crystal but consisted of mosaic aggregates of aragonite microcrystals having *b* and *c* axes nearly parallel to the horizontal and vertical directions of growth and with the (001) plane of aragonite nearly parallel to the growing inner surface of the nacre. Spiral patterns in the genus *Pinctada* are more often found in the anterio-ventral regions and the inside regions along the pallial impressions, where the vectors[3] indicating the direction of growth are usually deflected, than in other flat ventral regions.

The spiral pattern is observed at the edges of mineral lamellae which emerge on the growing surface of the nacre. Generally speaking, the highest point is the top of the spiral from which a ledge descends step by step outwards. The height of each step of the spirals is in the range 1000–5000 Å, which is equal to the thickness of one lamella, except near the central parts of the spirals, where the step height is less than 1000 Å. The spirals are usually nearly circular; their precise shape, however, varies with the species and physiological condition of the animal, and from region to region in a single shell. It was further shown[3] that the density of spirals per unit area, the distance between two steps, and the number of steps in one spiral depend on the precipitation rate of calcium carbonate.

Nacre grows by the advance of growth fronts of mineral terraces which begin from deformed, misfitting or boundary portions on the nacreous surface. Spiral growth hills are concentrated in particular portions of the surface of the nacre. For example, in the genus *Pinctada*, growth of nacre starts in the narrow parts along the pallial impression where curvature of nacre occurs during the morphogenesis of the shell and where misfit occurs between two groups of microcrystals of different orientations at small angles. In the nacre of *Pinctada martensii*, new microcrystals tend to grow on the boundary between two underlying microcrystals, though this does not always occur in the nacre of *Penna attenuata*. It is thought that a small amount of conchiolin condenses along these boundary regions.

It is interesting to note that the ratios of right-handed to left-handed spirals in anterior and posterior regions of a shell tend to bear an inverse relationship to each other where the vector of the shell growth in the anterior region is opposite in direction to that in the posterior region. When two adjacent spirals have the same sign they tend to develop into a superior spiral, whereas if they have opposite signs a closed loop is developed.

These observations show that tilted or twisted boundaries at small angles tend to occur between two microcrystals or between any two blocks with slightly different vectors of shell growth which interfere with each other during the morphogenesis of a shell. Screw dislocations then develop, giving rise to spiral growth hills on the nacreous surface. It should be emphasized that the spiral pattern of nacre can be reasonably explained by Frank's screw dislocation theory[4] of the spiral growth of single crystals.

I thank Prof. T. Sudo for encouragement and useful discussion and Prof. E. Suito and Dr. I. Sunagawa for their helpful advice.

RADIOBIOLOGY

Effects of X-rays on Metamorphosis and Adult Life Span of Flour Beetles

IT has been shown that the adult life span is reduced when young mice are irradiated with X-rays[1] and when the parasitoid wasp, *Habrobracon*, is irradiated during the immature stages of its life cycle[2–4]. Lamb and Maynard Smith[5] recently reviewed the reduction of insect life spans by radiation and postulated that radiations shorten life by inducing mutations in somatic cells. When the young pupa is irradiated, it might be expected that any lethal effect of alteration of genetic material due to radiation would be eliminated during the subsequent developmental crises (stages) instead of occurring after the adult stage had successfully developed.

This investigation was undertaken to determine whether metamorphosis and length of life could be altered when flour beetle pupae were treated with X-rays.

T. confusum Duval ('Chicago Standard' stock) pupae, age 25–26 days, were sexed and irradiated. The X-ray unit operated at 250 kV, 0·86 mm copper half value layer, 0·25 mm copper and 1·0 mm aluminium filtration. The anode was 2·5 in. from the subject and the apparatus delivered approximately 1 kr./min. Doses were 0, 1, 2·5, 5, 7·5, 10, 20, 30, 40, 50, 60 and 70 kr. Each of five replicates at each dose contained ten pupae of each sex in 10 g food. Deaths were noted twice weekly. Culture conditions were $29 \pm 1^{\circ}$ C and 60–75 per cent relative humidity.

Not all dose curves are presented (Fig. 1); those omitted fall in the position expected. Lethality data for males and females were combined because, as with *Habrobracon*[6], sex makes no significant difference. Rockstein *et al.*[7] reported, however, that the emergence of adult female house flies from pupae treated with X-rays was more sensitive than that of males. Age and physiological condition are other factors which might also cause organisms to show differential sensitivities to radiations, but in this experiment these variables were controlled.

The emergence of adults from pupae given 1 or 2·5 kr. was comparable to that of controls (Fig. 1, day 0). The numbers of individuals unable to complete metamorphosis increased progressively for doses from 5 to 70 kr., but metamorphosis was not delayed. Failure of metamorphosis reached about 35 per cent for 7·5–50 kr. and about 55 per cent at 70 kr. Some individuals given 5 kr. and greater doses died when partially metamorphosed, that is, when the thorax and head were adult but the elytra, although pigmented, was pupal in size and position and the abdomen retained pupal characteristics. In addition to these abnormalities, some individuals dying after 30 kr. or more were unable to cast off their meconium, making the gut a cul-de-sac. Death probably resulted from intestinal obstruction rather than from starvation, because heavily irradiated insects are known to feed after exposure to radiation[8–11].

The reduction of the length of life of adults irradiated as pupae was also a sensitive indicator of X-ray damage (Fig. 1). Mortality increased progressively with increasing exposures. The precipitous curves of lethality from 7·5 kr. and higher exposures indicated an early and frequent type of lethality which approached 100 per cent after 9 days. The lethality curve for 2·5 kr. rose gradually, reaching a plateau by day 9 at 10–15 per cent. The 5 kr. curve had a gradual slope which levelled off by day 16 at about 60 per cent lethality.

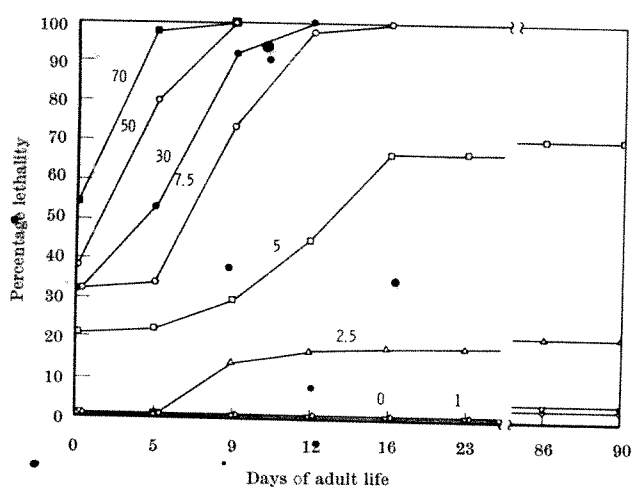

Fig. 1. Percentage lethality during adult life of *Tribolium confusum* irradiated in the pupal stage when 25 or 26 days old. Numbers on the curves refer to the dose in kr.

The exact causes of the mortality induced by radiation remain unknown. Nuclear effects induced by radiation are difficult to separate from cytoplasmic effects in this system; nevertheless, speculation from the data concerning these causes is interesting.

The 26-day-old pupae and day-old adults both required an X-ray dose of 4 kr. for induction of sterility[12], indicating no changes in meiotic activity between these developmental stages. Dick[13] and Erdman[14] found that *T. confusum* females were not sexually mature until day 5 of adult life; consequently, a differential radiosensitivity of germ cells was expected between sexually immature and mature adults. Actively dividing meiotic cells in sexually mature flour beetles (11 days old) were killed by 6 kr. (ref. 12). 100 per cent lethality was achieved with a minimal dose of 7·5 kr. (Fig. 1). This dose is similar to the 6 kr. required to kill dividing meiotic cells and suggests that lethality at 7·5 kr. may be due to adverse effects of radiation on cell division(s). Because 26-day-old pupae and 1- and 11-day-old adults died within a month of a dose of X-rays of 8 kr. (ref. 13), however, it was thought unlikely that cell divisions (mitosis) were factors in lethality. Until the necessary cytological investigations are carried out, the possible effects on lethality of the frequencies of cell divisions and their occurrence in specific tissue(s) cannot be discounted. Death in these irradiated pupae was probably due to chemical alteration of the cytoplasm by radiation and not to nuclear (chromosomal) effects, because pupae have adult structures and the most obvious changes into adults are movement and pigmentation. Antimetabolites could result from radiation-induced alterations in the chemistry of pigment formation. Certain biochemical processes continue from juvenile stages into the adult[15]. Interruption of such processes with subsequent induced cytoplasmic damage[16] could explain the adverse effects of irradiating the pupae on their metamorphosis and adult life span.

Comparative Radioprotective Effectiveness of Compressed Gases

EBERT *et al.* showed that nitrogen and noble gases have a radioprotective effect in experiments on bean seedlings when under pressure. They consider this effect to result from the adsorption displacement of oxygen from radiosensitive cell structures[1–3]. This hypothesis has, however, been criticized by other workers[4–9]. Another mechanism is probably involved in the protective effect of compressed gases. Protection may be caused by inhibition of the diffusion oxygen which penetrates radiosensitive meristemal cells by way of the intracellular gas spaces[6–9].

This other hypothesis makes it possible to calculate the protective effectiveness of some gases if the oxygen diffusion coefficients for these gases are known. It is difficult to calculate the absolute pressure under which the protective effect is achieved, as many of the required parameters are unknown (path length of oxygen diffusion in extracellular gas spaces, loss of oxygen owing to consumption during diffusion, etc.). We therefore determined for the different gases the relative concentrations (pressures) which exert equal effects. These are directly proportional to the oxygen diffusion coefficients for these gases:

$$\frac{P_{N_2}}{D_{O_2\text{-}N_2}} = \frac{P_{Ar}}{D_{O_2\text{-}Ar}} = \frac{P_{He}}{D_{O_2\text{-}He}}$$

Here P_{N_2}, P_{Ar}, P_{He} are equally effective pressures of nitrogen, argon and helium. $D_{O_2\text{-}N_2}$, $D_{O_2\text{-}Ar}$, $D_{O_2\text{-}He}$ are the oxygen diffusion coefficients in these gases.

P_{N_2} was taken as 1. To check whether the values calculated are in accord with experimental results we determined the protective effect of the various gases on bean seedlings of *Vicia faba* 'Russkii chernii'. The apparatus was operated at 18 kVp. and 20 m.amp, producing 45 r./min. The seedlings were irradiated in rotating steel chambers. Dosimetry inside the chamber was carried out using an *RM-1M* roentgenometer. The average growth rate of the main root was taken as a measure of the degree of injury. Five measurements were taken of the growth rate of ten roots from the 4th to 9th day after irradiation. The gases used contained no more than 0·01 per cent of oxygen (the nitrogen samples contained less than 0·001 per cent oxygen). The gases were introduced into the chamber 10 min before irradiation and were left in the chamber for 5 min afterwards. Details of the technique are given in ref. 4. Fig. 1 shows dose curves for the determination of the radiosensitivity of seedlings in the presence of gases. From Fig. 1 we obtained values for the gas pressures which entirely or by 50 per cent suppress the oxygen-dependent radiosensitivity of the seedlings. These values were determined by interpolating or, in the case of helium, extrapolating the curves of Fig. 2.

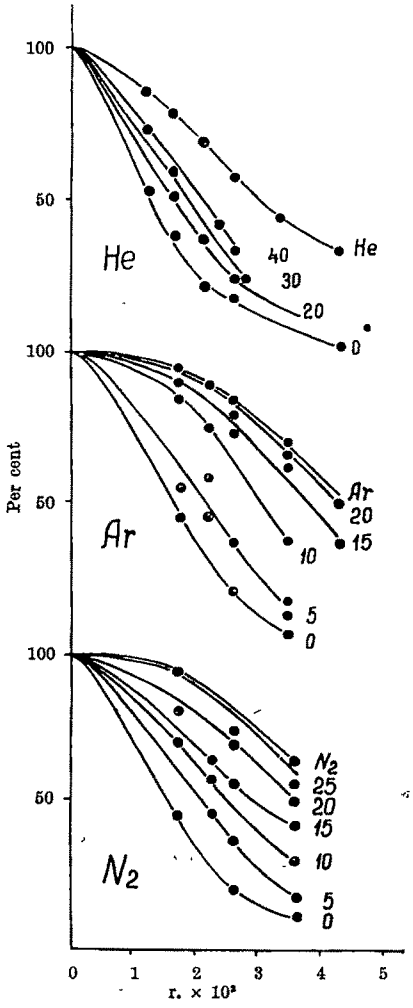

Fig. 1. Growth rate of bean seedlings under different gas pressures. Abscissa, dosage in r. Ordinate, growth rate as percentage of the growth rate of the control. Numbers on figure denote pressure (atm) of gases added to 1 atm air. Dose-effect curves for irradiation in the absence of air are denoted respectively by He, Ar and N_2.

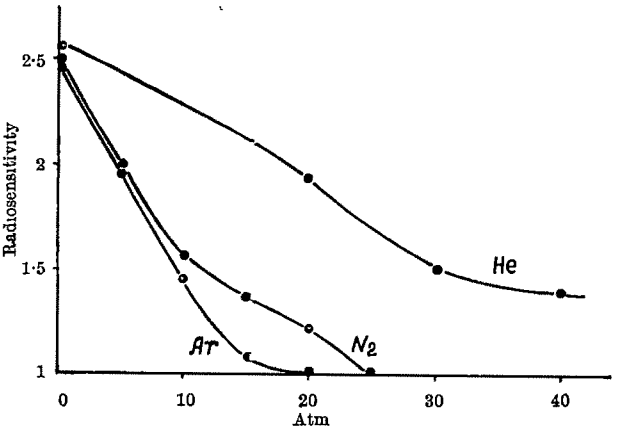

Fig. 2. Effect of helium, nitrogen and argon on the radiosensitivity of bean seedlings. Abscissa, gas pressure added to air (atm). Ordinate, radiosensitivity. Radiosensitivity in the absence of air is taken as unity.

Our experimental data are in good agreement with the theoretical predictions using the diffusion hypothesis. These results are not in accord with the data of Ebert *et al.* (Table 1).

Table 1. Calculated and Experimental Values for Equally Effective Pressures of Nitrogen, Argon and Helium

Gases		Nitrogen	Argon	Helium
Diffusion coefficients of oxygen $D_{O_2\text{-gas}}$ (cm²/sec)		0·241 (ref. 10)	0·224 (ref. 11)	0·661 (ref. 12)
Calculated relative equally effective pressures		1	0·93	2·74
Equally effective pressures according to Ebert (ref. 1) (atmospheres)	1. Complete repression of oxygen effect	21	5	110 extrapolation
	2. 50 per cent decrease of oxygen effect	12·5	2	55
	3. Relatively equally effective pressures (average of 1 and 2)	1	0·2	4·82
Equally effective pressures according to our data (atmospheres)	1. Complete repression of oxygen effect	25	20	67 extrapolation
	2. 50 per cent decrease of oxygen effect	8·1	6·9	23
	3. Relatively equally effective pressures (average of 1 and 2)	1	0·82	2·76

We conclude that the adsorption hypothesis for the protective action of compressed gases does not correspond with the results of experiment. The protection is caused by inhibition of the diffusion of oxygen in the extracellular gas spaces of the root.

SOIL SCIENCE

Extraction of Organic Matter from Soils by means of Ultrasonic Dispersion in Aqueous Acetylacetone

THE extraction of organic matter from soils[1–4] in a form suitable for chemical examination requires a reagent in which the organic material is largely unaltered, uncontaminated with extraneous ions or compounds, and capable of ready purification. Martin and Reeve[5,6] found that acetylacetone was an effective extractant of organic matter from *B* horizons of podzol soils. Recent experiments have shown that the amounts of organic matter extracted in boiling anhydrous formic acid increase with addition of metal complexing agents such as hydrofluoric acid and acetylacetone[7]. The present investigation was begun to explore further the use of acetylacetone as a suitable extractant of organic matter, particularly the organic phosphorus component in soils.

The soils used consisted of eight surface samples as follows: (1) acid brown forest; (2) low humic gley; (3) and (4) iron podzol; (5) brown forest; (6) and (7) podzol; (8) chernozem. Samples 1–5 came from Scotland and samples 6–8 from Canada. All but No. 2 were well-drained. Samples 1, 2, 3 and 8 were clay loams, sample 4 was a coarse sandy loam, sample 5 a loam, and samples 6 and 7 were silt loams.

Total nitrogen was determined by Kjeldahl digestion, carbon by the method of Walkley and Black[8], and sulphur according to Butters and Chenery[9] with a seed suspension added to improve sensitivity. Organic phosphorus in the soils was determined according to Mehta *et al.*[10]. Organic phosphorus in the extracts was obtained as the difference between total phosphorus measured after digestion in perchloric acid[10] and inorganic phosphorus determined according to Martin and Doty[11]. All determinations were made in duplicate on each of two extracts.

In a preliminary investigation, boiling anhydrous formic acid containing acetylacetone[7] was tried out as an extractant, but was abandoned when it was found to extract only 11, 7, and 10 per cent of the total organic phosphorus in samples 1, 3 and 5 respectively. On the other hand, four successive 24 h extractions with aqueous 0·2 M acetylacetone (*p*H 7·3) following an acid pretreatment removed 63, 75 and 64 per cent of the total organic phosphorus in these three soils.

Table 1. EXTRACTION OF SOIL ORGANIC PHOSPHORUS (SOIL 1) USING ULTRASONIC DISPERSION AND 0·2 M ACETYLACETONE (*p*H 7·5)

Extract	Extraction time (h)	Organic phosphorus as a percentage of total 1 h ultrasonic	2 h ultrasonic
1	18	54	62
2	23	12	11
3	23	8	10
4	23	4	4
5*	18	8	6
Total		86	93

* Ultrasonic treatment repeated after fourth extraction.

Table 2. EFFECT OF HIGH SPEED CENTRIFUGATION ON CARBON, NITROGEN, SULPHUR AND ORGANIC PHOSPHORUS CONTENT OF ACETYLACETONE EXTRACTS AFTER ETHER EXTRACTION (SOIL 1)

Treatment	Organic phosphorus	Carbon	Nitrogen	Sulphur
	as percentage of the total			
Not centrifuged	101	103	98	100
Centrifuged	84	87	74	105

The 0·2 M acetylacetone at *p*H 7·3 was a more effective extractant of organic phosphorus than 1·0 M acetylacetone at *p*H 4·3, and adjustment of the *p*H of the 0·2 M solution to 8·0 or 8·5 with dilute sodium hydroxide extracted a further 5–11 per cent of the organic phosphorus from the three soils.

Because further increases in the *p*H of the extracting solution were not desirable, and longer shaking periods did not significantly increase the yield of organic phosphorus, the effect of dispersion of the soils with ultrasonic vibration[12,13] before extraction was investigated with one soil. Four successive extractions following initial ultrasonic treatment of 1 or 2 h removed 78 and 87 per cent, respectively, of the total organic phosphorus (Table 1) compared with 63 per cent removed by acetylacetone alone. Further ultrasonic treatments of 1 or 2 h followed by a fifth extraction increased the yield of organic phosphorus by 8 or 6 per cent, respectively. A large part of the extracted organic phosphorus was found in the initial extract.

Because the removal of excess acetylacetone and its complexes is an essential requirement of the method, the extracts were combined and extracted with ether. Analysis of the ether-insoluble material showed that the organic phosphorus content did not decline with ether extraction. Furthermore, it was found that the aqueous phase contained a large proportion of the soil carbon, nitrogen and sulphur as well as the organic phosphorus. Because the aqueous phase exhibited some cloudiness at this stage, portions were clarified by high speed centrifugation (about 16,000 r.p.m.). The carbon, nitrogen and organic phosphorus content of the extract declined, while sulphur remained about the same, following high speed centrifugation (Table 2). This indicated that some of the extracted carbon, nitrogen and organic phosphorus was closely associated with the finely suspended material, probably fine clay, removed by centrifugation.

The final procedure as developed for extraction of soil organic matter was as follows: Two-gram samples of soil (< 100 mesh) were mechanically shaken with 40 ml. of 0·1N hydrochloric acid for 30 min and centrifuged at about 3,000 r.p.m. Following a second acid treatment, the samples were transferred to 50 ml. beakers with 30 ml. of 0·2 M acetylacetone (*p*H 8·0) and given a 2-h ultrasonic treatment. Suspensions were transferred to centrifuge bottles with 10 ml. of acetylacetone solution, and the *p*H adjusted to *p*H 8·0 with 3N sodium hydroxide. Samples were then shaken for 16 h and centrifuged. The residues were then extracted four times with 40 ml. of acetylacetone using shaking periods of about 24 h. Before the fourth extraction the ultrasonic treatment was repeated. Acetylacetone and its complexes were removed from the combined extracts with diethyl ether in an upward displacement liquid-liquid extractor. The ether extracted solutions were clarified by high speed centrifugation (approximately 16,000 r.p.m.).

The organic matter of the eight soils described previously was extracted with this procedure, and analyses were made for carbon, nitrogen, sulphur and organic phosphorus.

The acetylacetone method removed a large proportion of the organic phosphorus from all soils (Table 3). Four of the values agreed closely, one was lower, whereas the remaining three were higher than those obtained for total phosphorus by the Mehta method. Although these

Table 3. TOTAL ORGANIC PHOSPHORUS, CARBON, NITROGEN AND SULPHUR CONTENT OF EIGHT SOILS AND AMOUNTS OF THESE CONSTITUENTS EXTRACTED WITH ACETYLACETONE AFTER ULTRASONIC DISPERSION

Sample	Organic phosphorus		Carbon		Nitrogen		Sulphur	
	Total	Acetylacetone	Total	Acetylacetone	Total	Acetylacetone	Total	Acetylacetone
	mg phosphorus/100 g soil		per cent		per cent		per cent	
(1)	81	78	3·8	3·44	0·39	0·25	0·065	0·052
(2)	31	31	2·3	2·06	0 20	0·11	0·035	0·031
(3)	72	86	5·0	3·40	0·36	0·21	0 049	0·044
(4)	59	67	3·1	3·11	0·26	0·16	0·055	0 049
(5)	49	42	2·3	2·02	0·22	0·11	0·037	0 035
(6)	35	35	1·9	1·94	0·18	0·10	0·020	0·026
(7)	41	43	2·7	2·41	0·24	0·11	0·029	0·029
(8)	48	58	6 6	5·54	0·59	0·40	0·059	0·050

high values (samples 3, 4 and 8) may suggest an overestimation of organic phosphorus obtained with acetylacetone, they were in agreement with total organic phosphorus values available for two of the soils (samples 3 and 8) by an ignition method. Thus, it would appear that the Mehta method may have underestimated the total organic phosphorus content of these particular samples.

In addition to the organic phosphorus, the method effectively extracted sulphur from all samples (85–100 per cent). The efficiency of this extraction was confirmed by the small amount of sulphur found in the soil residues. The method was least effective for the extraction of nitrogen, removing only 48–68 per cent of the total. Although the carbon values show an apparent extraction of 68–100 per cent of the total carbon in the different soils, incomplete removal of the extracting reagent may be expected to contribute to its overestimation. This was confirmed when it was found that the soil residues still retained 12–29 per cent of the total carbon.

The use of ultrasonic dispersion in conjunction with acetylacetone was found to increase the effectiveness of this reagent in extracting organic matter from a variety of soils. The main advantages of this method are its high efficiency in extracting organic phosphorus and sulphur, the mild nature of the extractant and the ease with which the extracted material can be prepared for chemical analysis.

This research was carried out while one of us (R.L.H.) was a visiting worker at the Macaulay Institute for Soil Research.

MICROBIOLOGY

Role of Amino-acids in the Germination of Bacterial Spores by Subtilisin

BACTERIAL spores are characteristically resistant to desiccation, heat, irradiation, chemicals and to attack by enzymes. Resistance to enzymes is an attribute that must have important survival value for spores, because spores may come into contact with a variety of hydrolytic enzymes secreted by micro-organisms and other flora and fauna in their natural habitat, the soil. Previous reports that two lytic enzymes, lysozyme and an enzyme which can be extracted from *B. cereus* spores, will attack spores, were based on experiments in which the spores were first treated with reagents which rupture disulphide bonds[1,2]. This sensitization treatment was probably necessary to expose the substrates to the action of the enzymes[3,4].

A recent report[5] that the proteolytic enzyme subtilisin directly attacked spores of strains of *B. subtilis*, *B. cereus* and *B. licheniformis* was therefore of interest as the first report of a direct action of an enzyme on untreated bacterial spores. Spores incubated with subtilisin became dark when seen with the phase contrast microscope, and could be stained with methylene blue; they released dipicolinic acid and lost their resistance to heat, and the optical density of spore suspensions decreased. These reactions are characteristic of what is usually considered to be normal spore germination, that is, germination induced by germinants like L-alanine or inosine. It was presumed that subtilisin directly attacked some component of the spore, probably protein in the spore coat, and that this attack resulted in the germination-like changes[5].

During an investigation of the germination requirements of spores of a strain of *B. subtilis* (*globigii*), we incubated spores with subtilisin (Worthington Biochemical Corp., Freehold, New Jersey) and found them to germinate, confirming the observation of Sierra[5]. Spores of the *B. subtilis* (*globigii*) strain used normally require L-alanine in order to germinate, and their germination in L-alanine is inhibited by D-alanine[6,7]. When D-alanine was included with subtilisin, it was found to inhibit the germination induced by subtilisin (Table 1). It seemed possible that L-alanine was formed during incubation of subtilisin, for example by enzyme autodigestion or by degradation of some contaminating protein in the samples of subtilisin. L-Alanine so formed would then be expected to act as a germinant in the usual way. This seemed even more likely when it was found that when subtilisin was preincubated in buffer at 37° C for 1 h (to allow proteolysis to occur) and then added to the germination mixture it caused more rapid germination than when it was not preincubated (Table 1). Inosine, but not L-alanine, will germinate unheated spores of *B. cereus PX*; subtilisin had no effect on spores of this organism when tested under the conditions described in Table 1. Spores of *B. megaterium NCTC* 7581 will germinate in inosine plus L-alanine (or plus some other amino-acids) but not in inosine or L-alanine alone. Table 2 shows that, for germination of these spores, subtilisin could be substituted effectively for L-alanine, but not for inosine, and it was ineffective as a germinant alone.

Table 1. GERMINATION OF *B. subtilis* SPORES BY ALANINE AND BY SUBTILISIN

Mixtures*	Germination† (%) after incubation of spores in mixtures at 37° C for 30 min	60 min	90 min
No addition	2·0	2·5	1·5
L-alanine	18	34·5	41
D-alanine	1·5	2·0	2·0
Subtilisin	7·5	33	43·5
Subtilisin + D-alanine	2·5	2·5	2·0
Subtilisin preincubated‡	9·5	42	53
Subtilisin preincubated‡ + D-alanine	1·5	1·5	2 0

* All mixtures contained sodium phosphate buffer (0·1 M *p*H 8·0): isomers of alanine were used at 5 mM, and subtilisin at 40 mg/ml.
† Germination was estimated by counting the numbers of bright and dark spores at intervals using a phase contrast microscope.
‡ Spores or spores + D-alanine were added after preincubation of subtilisin solution at 37° C for 1 h.

Table 2. GERMINATION OF *B. megaterium* SPORES BY ALANINE, INOSINE AND SUBTILISIN

	Germination (%) after incubation of spores in mixtures at 37° C for 5 min	15 min
No addition	1	1
L-alanine	1	1
Inosine	1·5	2·0
L-alanine + inosine	65	98
Subtilisin	1	1
Subtilisin + L-alanine	2·5	9·5
Subtilisin + inosine	58	98·5

Experimental conditions as for Table 1. Inosine was used at mM.

Finally, subtilisin (40 mg/ml.) was incubated alone in buffer (0·1 M sodium phosphate at *p*H 8·0) at 37° C and samples taken at intervals over a period of 2·5 h. These were boiled for 10 min, dried at 100° C and extracted with butanol/phenol (2 : 3). Paper chromatography of the extracts revealed that a number of amino-acids were present, and these included one which was presumed from its R_F value to be alanine.

The experiments described here confirm the observation[5] that the *B. subtilis* proteolytic enzyme subtilisin will germinate spores of some *Bacillus* species. The experiments also indicate, however, that germination by subtilisin is not induced directly by the action of the enzyme

on spores, but by L-alanine and perhaps by other amino-acids which are probably released by the proteolytic action of the enzyme during its incubation.

VIROLOGY

Marker Studies of Poliovirus

VARIATION in the chemical properties of the protein coat of different strains has been used as a marker test in investigations of the genetics of polioviruses. Bengtsson, Philipson, Persson and Laurent[1] recently showed that a group of these tests had a common basis. Small differences in the electrical charge of the protein of various strains of the same serotype resulted in different patterns of binding to charged adsorbents.

The *d* (ref. 2) and *m* (ref. 3) markers and the inhibition of plaque formation by dextran sulphate[4] measure depression of growth in the presence of polyanions, while the aluminium adsorption[5] and elution tests[6] and elution from DEAE cellulose[7] depend on the physical separation of infectious particles by differential adsorption.

For application on an epidemiological scale, a test of this property which is simple to perform and which conserves both materials and labour is desirable. The possibility that tube titration in the presence of a low concentration of dextran sulphate might meet these requirements was therefore investigated.

Primary rhesus monkey kidney cell cultures were used, with the control series maintained on medium 199 alone and the test series on medium 199 containing dextran sulphate 2000 (Pharmacia, molecular weight 2×10^6) in the concentrations shown in Tables 1 and 2. Virus dilutions were made at $\log_{10}$ intervals and two tissue culture tubes in each series were inoculated per dilution. The viruses tested are shown in Tables 1 and 2, and the results, calculated by the Kärber method, are based on readings for day 6.

Table 1 shows that the poliovirus type 1 vaccine strain (*LSc2ab*) can readily be differentiated from the type 1 Mahoney strain by titration in 0·05 per cent dextran sulphate. The poliovirus type 2 and type 3 prototype strains are not, however, clearly separated under any of the conditions tested by such a minimal technique. This is reminiscent of the findings of Wallis, Melnick and Wimberley[5], who showed large differences in the adsorption of poliovirus type 1 strains to aluminium salts but less satisfactory results for types 2 and 3.

Table 2 shows the results of tests on two groups of poliovirus type 1 strains: (*a*) strains isolated from patients with clinical poliomyelitis in the prevaccine years; (*b*) strains isolated from subjects given oral poliomyelitis vaccine.

The groups are clearly separated by the test, although the small range of values may limit its usefulness when applied to an individual strain. The titrations were carried out using minimum numbers of tubes. Greater accuracy would be obtained by increasing the number of tubes inoculated per dilution but this would mean corresponding increase in the labour and materials used.

*MK*1 = first passage in rhesus monkey kidney.
*MK*2 = second ,, ,, ,, ,, ,,

The test should be applicable to the epidemiological study of type 1 polioviruses. This is the type mainly associated in the past with paralytic poliomyelitis. It has also been the cause of the limited outbreaks of poliomyelitis which have occurred in Britain since vaccination became widespread.

Y. E. COSSART

Virus Reference Laboratory,
Central Public Health Laboratory,
Colindale Avenue,
London.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Tuesday, September 27

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1)—Symposium on "Ergonomics and Safety in Motor Car Design".

INSTITUTE OF PETROLEUM, EXPLORATION AND PRODUCTION GROUP (joint meeting with the Geological Society, at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Discussion Meeting on "The Origin of Oil".

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 6 p.m.—Informal meeting on "Control Valve Characteristics and Sizing".

Wednesday, September 28

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (in Lecture Theatre 2, Physics Department, Imperial College, London, S.W.7), at 5.30 p.m.—Dr. R. F. Churchhouse: "Using Computers to Discover New Results in the Theory of Numbers".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, TELEVISION GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. R. I. Kinross: "Television Wire Broadcasting Systems".

Wednesday, September 28—Thursday, September 29

EUGENICS SOCIETY (in the Botany Lecture Theatre, University College, Gower Street, London, W.C.1), at 10.30 a.m. on Wednesday and 10 15 a.m. on Thursday—Symposium on "Social and Genetic Influences on Life and Death".

Thursday, September 29

RESEARCH AND DEVELOPMENT SOCIETY (at Imperial College, London, S.W.7)—Symposium on "Communicating the Results of Research and Development".

SOCIETY FOR ANALYTICAL CHEMISTRY, ATOMIC-ABSORPTION SPECTROSCOPY GROUP (at Thornton Research Centre, Chester), at 10 a.m.—Mr. D. J. Jenkins and Mr. W. Slavin: "Flames for Analysis".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. R. Knight: "13 Types of Picture Quality from 13 Television Programme Contractors".

Thursday, September 29—Friday, September 30

INSTITUTE OF BIOLOGY (at the Royal Geographical Society, Kensington Gore, London, S.W.7), at 10 a.m. daily—Symposium on "Biology and the Manufacturing Industries".

Friday, September 30

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—FOOD ENGINEERING PANEL (at the National College of Food Technology, Weybridge, Surrey), at 6.15 p.m.—Symposium on "Continuous Food Processing".

Saturday, October 1

BRITISH RADIOLOGICAL PROTECTION ASSOCIATION (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 9.45 a.m.—Symposium on "Radiation and Genetics" (organized by The Faculty of Radiologists).

Monday, October 3

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Parameters Which Need to be Standardized to Specify a P.C.M. Interface" opened by Mr. R. O. Carter.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "The Mossbauer Spectrometer" opened by Mr. E. L. Bush and Mr. H. Grayson.

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 6 p.m.—Prof. E. Boyland: "A Chemist's View of Cancer Prevention" (The Michael Williams Lecture).

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at Shell Centre Theatre, Shell Centre, London, S.E.1), at 6.30 p.m.—Scientific Films.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SENIOR PHYSICIST (with at least five years' relevant postgraduate experience) to join a team of hospital physicists based at the Liverpool Clinic, and to undertake the duties of Radiological Protection Adviser to the hospitals of North Wales and also to take part in the development of radioisotope techniques at the Liverpool Centre—The Group Secretary, Central Wirral Hospital Management Committee, Clatterbridge Hospital, Bebington, Wirral, Cheshire (September 27).

ASSISTANT LIBRARIAN (graduate with appropriate academic and professional qualifications or experience)—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (September 30).

RESEARCH ASSISTANT (preferably with a degree or Diploma in Technology which includes mathematics or statistics, and an interest in the application of computers to applied mathematical problems) IN THE POSTGRADUATE SCHOOL OF MATHEMATICS, to assist in an investigation of queues in which arrivals are partly regular and partly random (which is the situation in most real problems as opposed wholly random or wholly regular arrivals as in most theoretical solutions)—The Registrar, Bradford Institute of Technology, Bradford, 7 (October 2).

SCIENTISTS (preferably with research experience) for permanent posts concerned with fundamental work on brewing materials and fermentation—The Director, Brewing Industry Research Foundation, Nutfield, Redhill, Surrey (October 3).

TEMPORARY LECTURER or ASSISTANT LECTURER IN GEOPHYSICS IN THE DEPARTMENT OF EARTH SCIENCES—The Registrar, The University, Leeds, 2 (October 3).

CHAIRMAN OF THE DEPARTMENT OF CHEMISTRY, Trent University, Peterborough, Ontario, Canada—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 10).

PLANT ECOLOGIST (preferably an algologist); and an EMBRYOLOGIST or an INVERTEBRATE ZOOLOGIST IN THE DEPARTMENT OF BIOLOGY, Trent University, Peterborough, Ontario, Canada—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 10).

READER IN ORAL SURGERY at University College Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 11).

LECTURER IN HAEMATOLOGY IN THE BLAND-SUTTON INSTITUTE OF PATHOLOGY—The Secretary, The Middlesex Hospital Medical School, London, W.1 (October 14).

ASSISTANT LIBRARIAN (CATALOGUER) (qualified librarian with a good honours degree)—The Registrar, Bradford Institute of Technology, Bradford, 7 (October 15).

CHAIR OF PURE MATHEMATICS IN THE SCHOOL OF MATHEMATICS AND PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, Norfolk, NOR 88C (October 15).

DIRECTOR OF THE INSTITUTE—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire (October 15).

LECTURER IN MECHANICAL ENGINEERING and an ASSISTANT IN MECHANICAL ENGINEERING—The Secretary of the University Court, The University, Glasgow (October 15).

SECOND CHAIR IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, The University, Newcastle upon Tyne (October 15).

SCIENTIFIC OFFICER (biologist, with at least a good honours degree, and preferably a qualification or experience in microbiology) for research on pathogens of insects of agricultural importance—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1051/77 (October 17).

LECTURER or ASSISTANT LECTURER IN AGRICULTURAL EXTENSION at the University of the West Indies, Trinidad—The Inter-University Council, 33 Bedford Place, London, W.C.1 (October 21).

SENIOR LECTURER or LECTURER IN VETERINARY HISTOLOGY IN THE DEPARTMENT OF VETERINARY ANATOMY, University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (October 22).

CHAIR AND HEADSHIP OF THE DEPARTMENT OF PHYSIOLOGY—The Registrar, The University, Leeds, 2 (October 24).

CHAIR OF PHILOSOPHY at Bedford College—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 24).

SENIOR LECTURER or LECTURER IN SOCIAL ANTHROPOLOGY IN THE FACULTY OF ECONOMIC AND SOCIAL STUDIES, University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (October 25).

CHAIR OF HUMAN MORPHOLOGY; CHAIR OF BIOCHEMISTRY; CHAIR OF COMMUNITY HEALTH; and CHAIR OF MEDICINE IN THE NEW MEDICAL SCHOOL—The Registrar, The University, Nottingham (October 31).

FARADAY CHAIR OF ELECTROCHEMISTRY—The Deputy Secretary, The University, Southampton (October 31).

POSTDOCTORAL RESEARCH WORKER (with a primary qualification in physiology, physics or psychology (with understanding of statistical methods), and preferably some knowledge of computer programming) in the control and function of the small eye-movement of fixation and associated problems (stabilized retinal images, etc.)—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire (October 31).

SENIOR LECTURER/LECTURER (specialist in any field of philosophy) IN PHILOSOPHY at Flinders University of South Australia—The Registrar, Flinders University of South Australia, Bedford Park, South Australia, or The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 31).

TECHNICAL OFFICER (with experience of modern vacuum technology and associated instrument making) IN THE DEPARTMENT OF PHYSICS, for duties which will include assisting research groups investigating ionization phenomena in gases and other projects, and the maintenance, development and operation of major instruments and associated vacuum equipment—The Registrar, University of New England, Armidale, New South Wales, Australia (October 31).

VETERINARY OFFICERS, GRADE II (members of the Royal College of Veterinary Surgeons with one year's appropriate post-graduate experience) with the Ministry of Agriculture, Fisheries and Food—The Civil Service Commission, 23 Savile Row, London, W.1, quoting 130/66/2 (November 4).

HEAD OF THE DEPARTMENT OF PSYCHOLOGY—Dr. P. D. McTaggart-Cowan, President, Simon Fraser University, Burnaby 2, British Columbia, Canada (November 15).

READER IN MEDICAL PARASITOLOGY at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 16).

ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER (with a degree, Dip.Tech., H.N.C. or equivalent; if under 22, at least two G.C.E. "A" levels in scientific subjects) IN THE CHEMICAL MICROBIOLOGY DEPARTMENT, to work on proteins and enzymes of milk and cheese—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 66/29.

ASSISTANT (graduate or non-graduate) IN THE MEDICAL PROFESSORIAL UNIT for biochemical research involving automated amino acid analysis—The Governors, St. Bartholomew's Hospital, London, E.C.1, quoting Project No. 611, reference No. A30/736.

BIOCHEMIST (basic grade, probationary or post-probationary) for duties concerned primarily with blood gas analysis and biochemical aspects of investigation into metabolic disturbances associated with respiratory failure—The Personnel Officer, Royal Infirmary, Edinburgh, 3, Scotland.

MICROBIOLOGIST (Lecturer—medical or non-medical) to assist in the study of cross-infection and in an expanding programme of microbiology—The Secretary-Administrator, Institute of Laryngology and Otology, 330/332 Gray's Inn Road, London, W.C.1.

POSTDOCTORAL ASSISTANT to work under Prof. J. S. Anderson, F.R.S., on high-temperature inorganic chemistry—The Secretary, Inorganic Chemistry Laboratory, The University, South Parks Road, Oxford.

PROFESSOR AND HEAD OF THE DEPARTMENT OF OPHTHALMIC OPTICS—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff.

PROFESSOR OF PHARMACEUTICS—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff.

QUALIFIED PHYSICAL CHEMISTS to undertake research in inorganic thermochemistry and thermodynamics, and on vapour phase reactions partly at

high temperature—The Director of Research, Fulmer Research Institute, Stoke Poges, Bucks.

RESEARCH ASSOCIATE (candidate qualified in genetics or agriculture) IN ANIMAL BREEDING IN THE SCHOOL OF AGRICULTURE for work concerned with studies of the application of genetic theory to animal improvement—The Registrar, The University, Newcastle upon Tyne.

RESEARCH OFFICERS (graduates in biological sciences, preferably with an interest in mammalian systems, associated with a broader physico-chemical knowledge) for participation in research work in the field of safety evaluation of drugs and other chemicals—The Personnel Officer, Huntingdon Research Centre, Huntingdon, quoting Ref. GHW/3/G.

SCIENTIFIC ASSISTANT (graduate in science, preferably in biochemistry or microbiology) for microbiological assays in connexion with serum B_{12} estimations—The Consultant Haematologist, Glasgow Royal Infirmary, 84 Castle Street, Glasgow, C.4.

SENIOR TECHNICIAN (preferably with experience in high temperature techniques) to join a research group studying high-temperature chemical and electrical transport properties of refractory oxide materials—Dr. B. C. H. Steele, Metallurgy Department, Imperial College, London, S.W.7.
